tahir99-VRG & vip.persianss.ir

Hemostasis and Thrombosis

Basic Principles and Clinical Practice

SIXTH EDITION

tahir99 - VRG & vip.persianss.ir

tahir99-VRG & vip.persianss.ir

Front Cover Note

The front cover symbolizes the basic (background) and clinical aspects (foreground) of hemostasis and thrombosis considered in this volume. The background is a surface representation of thrombin in standard orientation (see Figure 9.16B) indicating the location of the 60-loop (magenta) and the g-loop (green) that border the substrate-binding cleft. The foreground is a schematized artery (modified from Figure 112.3) containing a thrombus and a downstream (remote) bleeding site.

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

PREFACE

The preface to the first edition of *Hemostasis and Thrombosis: Basic Principles and Clinical Practice* discussed the "hemostatic system" as the product of a multimillion year evolutionary process that has resulted in a finely balanced mechanism that is poised for hemostasis yet constrained to ensure the continuous flow of blood. The complexity of the system was illustrated by the factor VIII: von Willebrand factor (vWF) complex, a protein complex that serves as a nexus for platelet adhesion, blood coagulation, and endothelial cell function and whose dysfunction is a common cause of bleeding and perhaps thrombosis as well.

As with the first edition, the sixth edition of *Hemostasis and Thrombosis: Basic Principles and Clinical Practice* "reviews the biochemistry and physiology of hemostasis, as well as the pathophysiology of thrombosis, and considers the diagnosis and treatment of both."

However, over the three decades since the publication of the first edition, an exponential growth in the breadth and scope of new information together with increasing demands of clinical practitioners has mandated substantive changes in the book's content and organization, an evolution in its own right. Hemostasis has been dissected down to the atomic level and the sequencing of the human genome is providing new opportunities to understand the molecular basis for thrombotic disorders that remain the major causes of morbidity and mortality in our current society. Thus, the sixth edition is a distinctly different product in comparison with the first edition. We have striven to assemble a textbook that is current and complete, giving both basic and clinical scientists access, in a single place, to current concepts about hemostasis and thrombosis. We humbly acknowledge that the current edition will be quickly outdated as the acquisition of knowledge continues at a rapid pace beyond its publication. Indeed, it is tantalizing to consider how subsequent editions over the next 30 years will reshape our views about hemostasis and thrombosis. We hope that thoughtful readers will discern the gaps in our present knowledge and devise ways to close them.

We have taken to heart the insightful comments of reviewers of prior editions and have added or altered whole sections of the textbook to make it more accessible, useful, and informative. To start, the sixth edition has an entirely new editorial group, with each member bringing outstanding talent and expertise to the book's composition. The new editors include (in alphabetical order) William C. Aird (Harvard Medical School), who has created entirely new sections on vascular biology and the endothelium and who has himself recently published a large volume on *Endothelial Biomedicine* (Cambridge University Press); Joel S. Bennett (University of Pennsylvania), who has made seminal contributions to our understanding of platelet biochemistry and who has reorganized the basic and clinical sections related to platelets; Sam Schulman (McMaster University), who has wide experience in all aspects of both thrombosis and bleeding disorders and who is at the forefront of clinical trial assessments of new anticoagulants; and Gilbert C. White, II (BloodCenter of Wisconsin), who is widely knowledgeable in coagulation and platelet physiology and the clinical aspects relating broadly to these fields. Victor J. Marder (David Geffen School of Medicine at UCLA) is the lone editor to have participated in all of the previous five editions and who is fortunate to have the broad and deep expertise of the new editors in conceiving and constructing the sixth edition. All of the editors contributed to all aspects of the volume, having both overlapping and complementary experience and expertise in coagulation, platelet physiology, vascular biology, and clinical aspects of venous, arterial, microvascular, and complex hematologic disorders that have become the routine in outpatient and inpatient medical management. The principles described in this book are now widely applied to virtually every discipline in medicine, notably but not at all limited to neurology, cardiology, pulmonology, orthopedic and vascular surgery, oncology, and radiology.

The sixth edition comprises 132 chapters (two pairs of chapters of closely related content are indicated as A and B). Entirely new sections of importance have been added, including those that consider fundamental science and methods related to every aspect of hemostasis and thrombosis, vascular biology and primary disorders of blood vessels, and bleeding or thrombotic manifestations in systemic conditions in which the hemostatic system is secondarily perturbed. While the book has been expanded and reorganized to more broadly cover the field, it is not meant to serve as a practical guide for all aspects of diagnosis and treatment. Rather, it is designed to provide a conceptual framework for approaching complex issues in hemostasis and thrombosis, for rationally considering the science, and for logically applying reasoned insights to clinical problems. Ideally, the information will be applied in a productive manner to translate science to important new clinical breakthroughs, as has already occurred in the 30 years since the publication of the first edition.

On a technical note, the sixth edition is being published as a single volume in four-color format throughout, which represents an improvement over previous editions. Purchasers of the book will be provided access to an electronic version that allows downloading of all graphics for academic purposes. For clarity and brevity, each chapter is limited to 20 references in the printed version. The full list of references may be accessed in the electronic version.

In conclusion, it is the editors' hope that readers will find that the sixth edition of this long-standing primary reference addresses the myriad of scientific and clinical questions emerging from this exciting and still growing field of inquiry.

Victor J. Marder
William C. Aird
Joel S. Bennett

Gilbert C. White, II

FROM THE PREFACE TO THE FIRST EDITION

The hemostatic system has evolved over millions of years from a much simpler system. In the limulus, a 400-million-year-old living fossil, the entire hemostatic system is contained in one cell (the amebocyte) that, in response to endotoxin elaborated by a vibrio, engulfs the organism and forms a coagulant from intracellular constituents. This single cell can be viewed as a progenitor of the platelet and the leukocyte, serving both hemostatic and inflammatory functions. The hemostatic system that evolved in humans features extracellular coagulation proteins, many of which are still present in platelets and endothelial cells, and has, therefore, conserved a function and structural interrelationship of plasma proteins and cellular elements.

Hemostasis and Thrombosis reviews the biochemistry and physiology of hemostasis, as well as the pathophysiology of thrombosis, and considers the diagnosis and treatment of both. The difficulty of separating one part of the system from another is illustrated by considering one of the best known hemostatic proteins, factor VIII, which is currently regarded as a complex of two molecules—von Willebrand protein and procoagulant factor VIII. Von Willebrand protein is synthesized in endothelial cells and megakaryocytes and is secreted into the plasma, while the coagulant factor VIII molecule is synthesized in other cells, possibly under the control of the von Willebrand protein. The latter influences platelet adhesion to exposed subendothelium and probably to other cells, while factor VIII increases the rate of factor X activation and thrombin formation, which, in turn, stimulates platelets to undergo the release reaction and to aggregate and convert fibrinogen to fibrin. An obvious requirement for hemostasis, being deficient in the coagulant portion in classic hemophilia and in both the coagulant and platelet cofactor portions in von Willebrand disease, the factor VIII complex is probably also intimately associated with pathologic thrombus formation. Thus, an understanding of the role of factor VIII requires a detailed knowledge of its interactions with platelets, vascular wall cells, and other plasma proteins, as well as the influence of rheologic factors on these reactions, as manifest in the opposing mechanisms of hemostasis and thrombosis.

This textbook is directed at all who wish to explore this fascinating area of biology in greater depth. We hope that it will prove to be a useful reference for the student, the physician, and the scientist who is interested in laboratory or clinical aspects of these disorders and who may wish to obtain a comprehensive discussion and complete reference source. Many authors have contributed to *Hemostasis and Thrombosis*, and some overlap of information was inevitable, but this was not actively avoided. Therefore, we hope that each chapter is complete in its own right, concentrating on either basic aspects or clinical applications of a disorder or relevant cellular or protein components.

tahir99-VRG & vip.persianss.ir

ACKNOWLEDGMENTS

The editors wish to express their appreciation to Dr. Robert W. (Bob) Colman for his foresight and efforts in the genesis of *Hemostasis and Thrombosis: Basic Principles and Clinical Practice*. It was his concept of a comprehensive text encompassing the breadth of basic and clinical science of this field that was responsible for the first five editions of *Hemostasis and Thrombosis* and that is the inspiration for the sixth. Bob has been an important contributor to many aspects of the field in studies that have spanned surface activation of coagulation; the role of lipids, membrane receptors, and phosphodiesterases in regulating platelet function; the structure and function of coagulation factor V; and the physiology of kinins, particularly with regard to inflammation and angiogenesis.

Since the first edition was published in 1982, *Hemostasis and Thrombosis: Basic Principles and Clinical Practice* has stood as the preeminent standard. Although much of its success can be attributed to wise choices of authors, the skill of the editors in choosing authors and in organizing their contributions into a coherent text is equally important. In addition to Bob Colman, six others have participated in editing the previous five editions of the text. Therefore, the present editors wish to acknowledge the vital efforts of Jack Hirsh and Edwin Salzman, who along with Victor Marder coedited the first three editions, and Alex Clowes, Jim George, and Sam Goldhaber, who participated in subsequent editions. Their expertise, energy, and creativity have provided the foundation upon which we have based the sixth edition.

We note with sadness the passing of Edwin Salzman in 2011 after a prolonged and difficult illness. Ed was a unique individual and a wonderful colleague whose contributions to understanding and treating thrombotic diseases and the nuances of platelet function will be long remembered.

Finally, GCW, SS, WCA, and JSB wish to express their great appreciation to Victor Marder for his leadership during the development of the 6th edition. His organizational skills, dedication to detail, and commitment to quality were inspiring and have made this edition what it is. We thank him for inviting us to be a part of this edition and making us part of the *Hemostasis and Thrombosis* tradition.

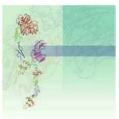
CONTENTS

Contributing Authors v
Preface xv
From the Preface to the First Edition xvii
Acknowledgments xix

PART I: INTRODUCTION TO THE FIELD OF HEMOSTASIS AND THROMBOSIS

1. The Field of Hemostasis and Thrombosis: Selected Translational Achievements 3
Victor J. Marder, William C. Aird, Joel S. Bennett, Sam Schulman, and Gilbert C. White, II
2. Molecular Evolution of the Vertebrate Blood Coagulation System 11
Marianne A. Grant and William C. Aird
3. Molecular and Clinical Genetics 26
Lesley Everett, Karl Desch, and David Ginsburg
4. Coagulation Enzymology 41
Sriram Krishnaswamy
5. Cell Biology, Protein Processing, and Cell Signaling 52
Randal J. Kaufman and Laura Popolo
6. Overview of the Immune System 66
Andrew H. Lichtman
7. Biostatistics and Epidemiology: The Basic Science of Clinical Research 87
Kerry L. Lee



PART II: BASIC PRINCIPLES OF HEMOSTASIS AND THROMBOSIS

SECTION A: COAGULATION AND FIBRINOLYSIS

8. Overview of Basic Coagulation and Fibrinolysis 103
Gilbert C. White, II, Victor J. Marder, Sam Schulman, William C. Aird, and Joel S. Bennett
9. The Blood Coagulation Factors and Inhibitors: Their Primary Structure, Complementary DNAs, Genes, and Expression 110
Dominic W. Chung, Wenfeng Xu, and Earl W. Davie
10. Genetics of Coagulation 146
Rodney M. Camire and Paris Margaritis
11. Tissue Factor and the Initiation and Regulation (TFPI) of Coagulation 163
James H. Morrissey and George J. Broze, Jr.
12. Factor V and Factor VIII 179
Randal J. Kaufman, Philip J. Fay, Laura Popolo, and Thomas L. Ortel
13. Structure and Function of von Willebrand Factor 197
Sandra L. Haberichter and Robert R. Montgomery
14. Structure and Function of Vitamin K–Dependent Coagulant and Anticoagulant Proteins 208
Kanagasabai Vadivel, Amy E. Schmidt, Victor J. Marder, Sriram Krishnaswamy, and S. Paul Bajaj

15A. Factor XI 233
Peter N. Walsh and David Gailani

15B. The Factor XII–Driven Plasma Contact System . . 242
Thomas Renné

16. Fibrinogen Structure and Function 254
John W. Weisel and Carl-Erik H. Dempfle
17. Factor XIII 272
Cédric Duval, Helen Philippou, and Robert A.S. Ariëns
18. Antithrombin and the Serpin Family 286
Susan C. Bock
19. Protein C, Protein S, Thrombomodulin, and the Endothelial Protein C Receptor Pathways . . 300
Laurent O. Mosnier and John H. Griffin
20. Plasminogen Activation and Regulation of Fibrinolysis 314
Nicola J. Mutch and Nuala A. Booth
21. Inhibitors of Fibrinolysis 334
Björn Wiman and Anna Ågren

SECTION B: PLATELET BIOLOGY

22. Overview of Megakaryocyte and Platelet Biology 341
Joel S. Bennett
23. Platelet Production: Cellular and Molecular Regulation 349
Elisabeth Cramer Bordé and William Vainchenker
24. Megakaryocyte Structure and Platelet Biogenesis 365
Joseph E. Italiano, Jr. and John H. Hartwig
25. Thrombopoietin 373
Kenneth Kaushansky and Ian Hitchcock

26A. Major Platelet Glycoproteins: Platelet Glycoprotein Ib-IX-V 382
Michael C. Berndt and Robert K. Andrews

26B. Major Platelet Glycoproteins: INTEGRIN $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) 386
Feng Ye and Mark H. Ginsberg

27. Platelet Glycoprotein Polymorphisms and Relationship to Function and Immunogenicity . . 393
Thomas J. Kunicki and Diane J. Nugent
28. The Basis for Platelet Adhesion 400
Brian Savage and Zaverio M. Ruggeri
29. Shear Effects on Platelets and the Vessel Wall in the Pathogenesis of Atherothrombosis 410
David L. Bark, Jr., Warwick S. Nesbitt, Angus K.T. Wong, and Shaun P. Jackson

32. Molecular Basis for Platelet Secretion 441
Shaojing Ye and Sidney W. Whiteheart

33. Platelet Signal Transduction 449
Charles S. Abrams and Lawrence F. Brass

34. Platelet Prostanoid Metabolism 462
Tilo Grosser and Garret A. Fitzgerald

35. The Role of Platelets in Blood Coagulation 468
Peter N. Walsh

36. Blood-Borne Microparticles 475
José A. López and Swaminathan Murugappan

SECTION C: VASCULAR BIOLOGY

37. Overview of Vascular Biology 493
William C. Aird

38. Development of the Vasculature, Angiogenesis, and Lymphangiogenesis 498
Aernout Luttun and Peter Carmeliet

39. Rheology and Vessel Wall Stress 516
Larry V. McIntire, Juan M. Jiménez, Suzanne G. Eskin, and Peter F. Davies

40. Nitric Oxide: The Vascular Biology of Nitric Oxide and Nitric Oxide Synthases 536
Bradley A. Maron and Thomas Michel

41. Blood Vessel Wall in Health and Disease 549
Keith R. Brunt, Sonya Hui, Jagdish Butany, and Mansoor Husain

42. Endothelial Cell Function 560
William C. Aird

43. Role of the Endothelium in Hemostasis 569
Michael J. Krisinger and Edward M. Conway

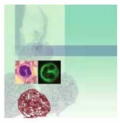
44. Coagulation-Independent Signaling of the Extrinsic Coagulation Pathway 579
Wolfram Ruf

45. Heparin and Vascular Proteoglycans 585
Douglas M. Tollefsen and Lijuan Zhang

46. Endothelial Cell–Blood Cell Interactions 598
Klaus Ley

47. Leukocyte Function and Contribution to Disease 614
Edith Van de Vijver and Taco W. Kuijpers

48. Laboratory Markers of Endothelial Cell Activation and Dysfunction 623
Eduard Shantsila, Gregory Y.H. Lip, and Robert P. Hebbel



PART III:
DISORDERS OF COAGULATION, PLATELETS, AND VESSEL WALL

SECTION A: BLEEDING DISORDERS OF COAGULATION AND FIBRINOLYSIS

49. Overview of Inherited Hemorrhagic Disorders 641
Gilbert C. White, II, Harold R. Roberts, and Victor J. Marder

50. Differential Diagnosis of the Bleeding Patient 648
Jill M. Johnsen and Barbara A. Konkle

51. Clinical Manifestations and Therapy of Inherited and Acquired Hemophilia 659
Edward G.D. Tuddenham, Peter W. Collins, and T.T. Yee

52. von Willebrand Disease: Diagnosis, Classification, and Treatment 670
J. Evan Sadler and David Lillicrap

53. Rare Inherited Coagulation Disorders Other than Hemophilia 684
Pier Mannuccio Mannucci, Flora Peyvandi, and Massimo Franchini

54. Afibrinogenemias and Dysfibrinogenemias 693
Dennis K. Galanakis

55. Familial Multiple Coagulation Factor Deficiencies 709
Bin Zhang and David Ginsburg

56. Clinical Disorders of Fibrinolysis 715
Daphne B. Stewart, Charles W. Francis, and Victor J. Marder

57. Acquired Disorders of Coagulation: The Immune Coagulopathies 723
Charles R.M. Hay

58. Laboratory Markers of Activated Coagulation and Its Regulation 738
Kenneth A. Bauer and Helen A. Ireland

SECTION B: ACQUIRED AND INHERITED PLATELET DISORDERS

59. Overview of Acquired and Inherited Clinical Platelet Disorders 751
Joel S. Bennett

60. Differential Diagnosis of Thrombocytopenia 757
Joel S. Bennett and Charles S. Abrams

61. Immune Thrombocytopenia and Posttransfusion Purpura 763
Howard A. Liebman, Douglas B. Cines, and James B. Bussel

62. Drug-Induced Thrombocytopenia 776
Richard H. Aster and James N. George

63. Inherited Thrombocytopenias 785
Paquita Nurden and Alan T. Nurden

64. Acquired Nonimmune Thrombocytopenia 796

Introduction to the Field of Hemostasis and Thrombosis

CHAPTER

1

The Field of Hemostasis and Thrombosis: Selected Translational Achievements

VICTOR J. MARDER, WILLIAM C. AIRD, JOEL S. BENNETT, SAM SCHULMAN, AND GILBERT C. WHITE, II

INTRODUCTION

As with any field of active scientific inquiry, the field of "Hemostasis and Thrombosis" has experienced its own evolution of thoughts and concepts, and the ever refining of the details of existing information. Given the enormous worldwide impact of hemostatic and thrombotic disorders, the intense focus of scientists on the field is justified, even essential. The modern era of coagulation could arguably be dated from 1905, when Morawitz proposed that four ingredients are involved in clot formation.[1] By this formula, fibrinogen (factor I) is converted to fibrin by thrombin, produced from prothrombin (factor II) by the action of "thrombokinase" (factor III) and calcium (factor IV). The designations factors I, II, III, and IV were preserved in the nomenclature consensus agreement of 1959,[2] which brought some semblance of order to the plethora of synonyms used for each real or implied clotting participant reported by that time. Observations regarding thrombotic disorders in the venous circulation were reported independently, and one could date the origin of this discipline to the late 19th century with the reports of Virchow (1856)[3] and Trousseau (1865).[4] Virchow's many and dramatic breakthrough observations include the now-obvious connection between venous thrombosis of the lower extremity with pulmonary embolism,[3] although the often-cited "Virchow's triad" of causes for venous thrombosis may actually not belong to his credit alone.[5] Trousseau brought to our attention the association of carpal spasm with tetany, but more memorably, the association of malignancy with venous thrombosis.[4,6]

RECOGNITION OF THROMBOSIS AND HEMOSTASIS AS A UNIFIED FIELD OF SCIENTIFIC INQUIRY

Despite the slow pace of discovery during the first half of the 20th century, there were a number of important and remarkable observations. Three separate discoveries of potential therapeutic agents are representative. First is the serendipitous purification of an anticoagulant from liver in 1916 by Jay McLean, a Johns Hopkins medical student,[7,8] named "heparin" by his faculty mentor William Howell.[9] Second is the serendipitous finding[10] by Tillett and Garner in 1933 to 1934 of a clot-lysing ingredient in Streptococcal broth, termed fibrinolysin.[11–12] Third is the detective work that solved the mystery of hemorrhagic disease in cattle caused by spoiled (moldy) sweet clover hay[13], leading ultimately to the purification of dicoumarol by Campbell and Link in 1941.[14,15] Translation of these observations to the clinic was likewise a slow process; it took 20 years until heparin was tested in a relevant animal model,[16] 14 years for a coumarin agent to be applied as a rodenticide,[17] and 12 years for fibrinolysin (Streptokinase) to be used in animals[18] and 16 in humans but for the lysis of pleural adhesions, not vascular thrombosis.[19, 20] Concurrent with these discoveries, inquiry into the components of blood coagulation began to reveal the complexity of this process. Historical reviews detail these events,[21–25] but suffice it to say that patients with distinct deficiencies were identified in a flurry of discovery in the 1940s and 1950s, following work on antihemophilic factor (factor VIII) in 1937 by Patek and Taylor.[26] The full cast of clotting factors was then identified, mostly through clinical comparisons and the differential correction of abnormal blood coagulation in the laboratory. In this way, patients were found who were deficient in "proaccelerin" (factor V) by Owren,[27] "serum prothrombin conversion accelerator" (factor VII) by Alexander,[28] "Christmas factor" (factor IX) by groups led by Aggeler,[29] Biggs,[30] and Schulmann,[31] "plasma thromboplastin antecedent" (factor XI) by Rosenthal et al.,[32] "Hageman factor" (factor XII) by Ratnoff,[33] "Stuart-Prower factor" (factor X) by Hougie et al.,[34] and "fibrin stabilizing factor" (factor XIII) by Duckert,[35] some 17 years after its biochemical identification by Robbins[36] and by Laki and Lorand.[37]

These observations were facilitated by the development of simple, yet incredibly important, bench technology for measuring blood coagulation, namely, the prothrombin time devised by Quick in 1935 (the "Quick time")[38] and the partial thromboplastin time by Langdell, Wagner, and Brinkhous in 1953.[39,40] With the development of platelet aggregometry by Born and by O'Brien in 1962,[41,42] the field of platelet physiology and pathology took a major leap forward[21] beyond the 19th century description of a role for platelets in clot and thrombus structure,[43–45] and the early 20th century descriptions of Glanzmann thrombasthenia,[46] von Willebrand disease,[47] and Bernard-Soulier syndrome.[48]

The expanding number of hereditary bleeding disorders and the vexing problem of competing terminology for the same clotting component contributed to a complexity that even to this day, frightens the medical student and humbles the young scientist upon entering the field. The nomenclature issue was resolved by the committee,[2] providing for simplified nomenclature for the bewildering array of blood clotting components, using Roman numerals for each factor. More importantly, clarity to the question of how the factors interact to initiate clotting was provided in 1964 via the brilliant syntheses of the science by Ratnoff and Davie[49] of the "waterfall" and by Macfarlane[50] of the

"cascade" of biochemical events. Admittedly, these explanations were not without need for modification.[22,23] For example, it was necessary to account for thrombin activation of factors V and VIII,[51] for their function as cofactors and not enzymes,[52] and for the activation of factor IX by the "extrinsic" system factor VII: tissue factor complex.[53] Still, the schemes devised by Ratoff and Davie and by Macfarlane had a profound impact on our concepts of blood coagulation and provided a framework for a remarkable, ever-accelerating application of new scientific technology to the "field."

One might assume that the "field" of hemostasis and thrombosis existed from the start. However, a formal designation of a discipline for the study of both bleeding and clotting disorders was glaringly absent until the mid-1900s, and many basic and clinical research groups focused uniquely on the diagnosis and treatment of patients with hereditary bleeding disorders caused by clotting factor or platelet disorder, or on the pathology, treatment, and prevention of thrombosis, mostly in the venous circulation. Arguably, the field of Hemostasis and Thrombosis began with three organizational events, the first being the founding of the journal Thrombosis et Diathesis Haemorrhagica (TDH) in 1957, formally inviting scientific submissions in both thrombosis and bleeding. Second, the International Committee on Clotting Factors, upon completing its nomenclature goals, changed its focus and name in 1964 to the International Committee on Thrombosis and Hemostasis (ICTH). Third, the International Society on Thrombosis and Haemostasis (ISTH) was established in 1969, incorporating the ICTH as the Scientific and Standardization Committee and collaborating with the journal TDH as a major outlet for publishing reports and scientific studies. Now, many former Hemophilia Centers are termed Hemophilia and Thrombosis Centers, reflecting a broader scope of interest and cementing the collaboration of basic scientists working in the areas of vascular and cell biology, biochemistry, genetics, physiology, immunology, and pathology with clinical scientists with expertise in diagnosis, pharmacology, biostatistics, epidemiology, and public health. A major goal of the field is to apply basic principles to clinical practice, and notable achievements have been accomplished in the field of Hemostasis and Thrombosis.

OVERVIEW OF HEMOSTASIS AND THROMBOSIS

In a healthy individual with an intact vascular system, blood flow is unimpeded and the soluble and cellular components of the blood are balanced to maintain blood fluidity yet are poised for a rapid and effective response to vascular trauma (FIGURE 1.1). This balance is complex and multilayered but can be affected by confounding influences such as hereditary polymorphisms, inflammatory processes, malignancy, vascular injury, superimposed medical illness or surgical intervention, or drug exposure yet be primed for effective protection against excessive bleeding after vascular trauma.

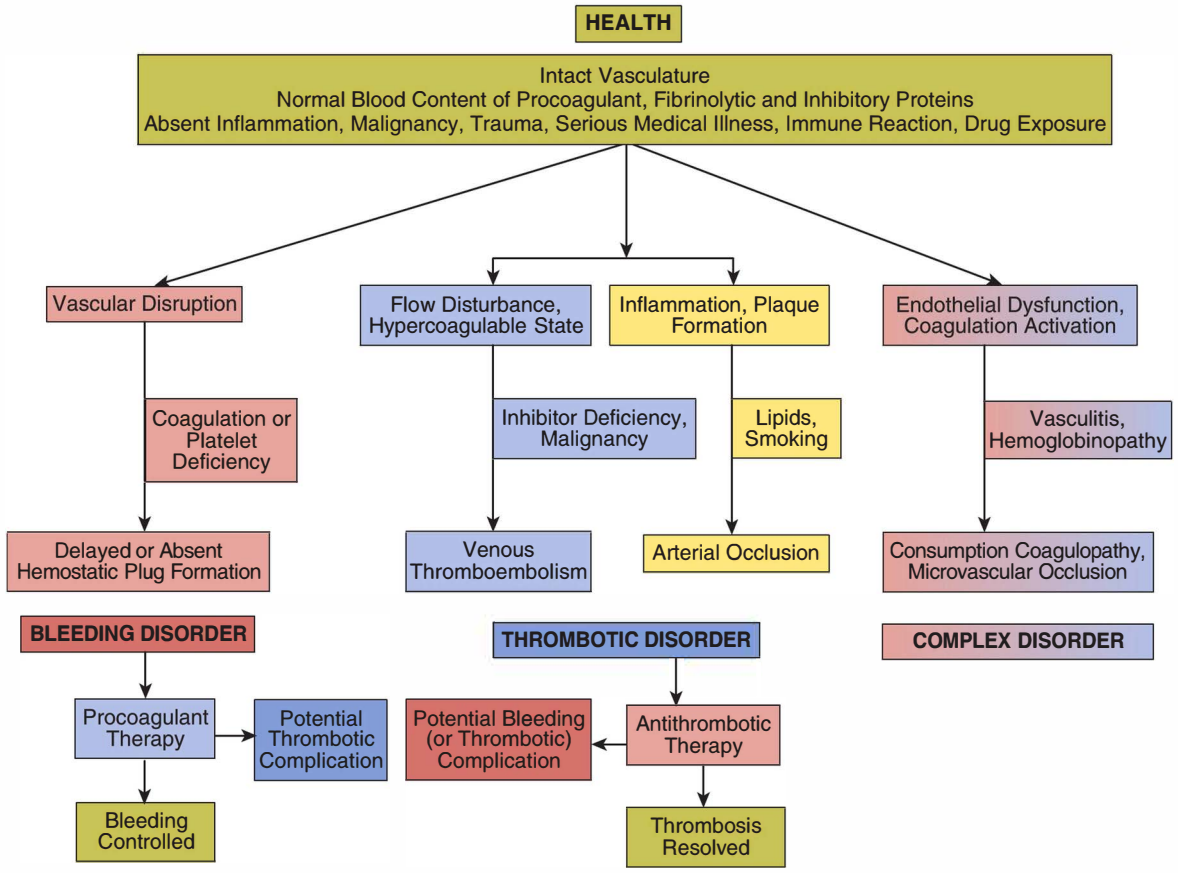

FIGURE 1.1 Schematic of bleeding and thrombotic disorders, contributing factors, and complications of therapy.

HEMOSTATIC DISORDERS

Hemostatic disorders may first become apparent after vascular injury such as during surgery or may seem to be "spontaneous" without evident injury, but following otherwise trivial activities such as walking or dental care (FIGURE 1.1, **left**). While the distinction between normality and a mild bleeding state is often problematic, as in the case of "simple" purpura, fully manifest bleeding disorders, regardless of the etiology, may be dramatic and life threatening. Based on the current state of knowledge and clinical experience, the diagnosis of a hereditary coagulation disorder is usually straightforward. Nonetheless, the relative contribution of coagulation factor deficiencies to bleeding varies, and in some individuals with abnormal *in vitro* coagulation tests, bleeding may be unusually absent (factor XII deficiency) and there may even be a risk of thrombosis (lupus anticoagulant). The hemorrhagic manifestations of thrombocytopenia and/or platelet dysfunction are distinctive, manifest as mucocutaneous bleeding due to small capillary leaks. Immune disorders such as acquired hemophilia due to autoantibodies against or thrombocytopenia due to the appearance of platelet autoantibodies can appear suddenly in a patient with no prior history of bleeding. Once a diagnosis is made, treatment is usually evident and effective, but the same cellular and protein components that are involved in hemostasis also promote thrombosis. Thus, in some instances, such as with the use of recombinant factor VIIa to arrest hemorrhage, treatment carries a potential complication of thrombosis.[51]

VENOUS THROMBOSIS

The predispositions for venous or arterial thrombotic disease differ markedly. A triad of conditions, generally attributed to Virchow,[5] consisting of the confluence of a systemic hypercoagulable state, disturbance of venous blood flow (stasis), and vascular injury makes for a perfect storm of venous thromboembolic (VTE) disease. For example, in 1959, Sevitt and Gallagher[52] highlighted the VTE risk that can complicate hip fracture in which hypercoagulability is induced by the release of bone marrow contents into the circulation, the fracture causes complete immobility, and there is associated venous damage due to the initial injury or surgical repair. However, not all three components of the triad are required to present an increased risk of VTE, as reflected by the 80% prevalence of VTE after total knee arthroplasty in the absence of DVT prophylaxis[53] or the smaller risk of VTE that accompanies ankle and even arthroscopic surgery.[54] In the latter instances, it would not be unreasonable to anticipate that additional factors, such as the absence of a natural anticoagulant inhibitor such as protein C (PC) or the presence of the factor V Leiden mutation, strongly impact on clinical outcome.[55–57,58] The balance of hemostasis and thrombosis is reflected in their respective hereditary predispositions of absent inhibitors of procoagulant proteins or coagulation inhibitors.

Options of the effective treatment of venous thromboembolism are expanding rapidly with the recent introduction of oral thrombin and factor Xa inhibitors to the standard regimen of coumarins and heparins.[59] Nonetheless, in converse to the treatment of bleeding disorders, (FIGURE 1.1, **bottom center**), treatment of VTE with anticoagulants carries a risk of a bleeding complication. Again, concomitant hereditary predispositions, in this case to bleeding, increase the risk of such a complication.

ARTERIAL THROMBOSIS

Arterial thrombosis is responsible for the most prevalent and lethal pathologic conditions in the world, myocardial infarction and ischemic stroke.[60] The pathogenesis of these arterial events is distinct from that in venous thrombosis and usually results from the rupture of an atherosclerotic plaque in epicardial coronary vessels and often, but not always, involves an upstream embolic event in ischemic stroke. Thrombi in the vicinity of a ruptured atherosclerotic plaque have a prominent platelet component, initiated by exposure of blood to tissue factor on the plaque surface and in plaque debris. This results in a "white thrombus," composed predominantly of platelets and fibrin, although a retrograde red thrombus composed of red cells and fibrin may form when arterial blood flow is blocked. The "white thrombus" is analogous to the primary hemostatic platelet plug that forms after vascular trauma, a clear example of the coalescence of cellular and coagulation responses in physiologic and pathologic conditions. Predispositions to arterial thrombosis are distinct from those that predispose to venous thrombosis, being primarily those influences that promote arthrosclerosis, and less commonly resulting from inflammation (vasculitis) or immune damage as in the antiphospholipid syndrome (APLS). Less often, arterial occlusion can result from the same pathophysiology as VTE, as after embolization of an atrial thrombus in a patient with atrial fibrillation or from paradoxical embolization in a patient with a patent foramen ovale.

Because platelets are the predominant component of arterial thrombi, antiplatelet drugs are the agents of choice in treating these disorders. As with treatment for VTE disease, there is a risk of antithrombotic treatment inducing a hemorrhagic complication, with the added burden that the hemorrhage may be intracranial in a patient with an ischemic stroke. Adding complexity to treatment, we now appreciate that treatment can result in thrombosis as well as hemorrhage. Thus, the heparin-induced thrombocytopenia (HIT) that results from immune complexes containing antibodies against platelet factor 4 (PF4) can produce arterial and venous thrombi, and vitamin K antagonists (coumarins) can induce cutaneous microvascular thrombosis producing skin necrosis in a patient with inherited PC deficiency.[62,63]

COMPLEX DISORDERS

These disorders manifest both bleeding and thrombosis and emphasize the disparate properties of some coagulation proteins. Thrombin, the central player in the coagulation cascade, mediates feedback amplification of the "intrinsic" system by activating factor XI; activates platelets to expose phosphatidylserine, thereby accelerating the formation of factor Xa; activates factors V, VIII, and XI; activates factor XIII and the thrombin-activated fibrinolysis inhibitor making clots more resistant to plasmin lysis; and cleaves fibrinopeptides A and B from fibrinogen to induce fibrin formation. Thrombin also binds to thrombomodulin (TM) on microvascular endothelial cells and changes its character to activate PC. When bound to the endothelial cell activated protein C (APC) receptor and in concert with cofactor protein S (PS), APC proteolytically inactivates factors Va and VIIIa, thus effectively turning off the coagulation cascade. Accordingly, thrombin is not only the quintessential procoagulant enzyme but also the quintessential anticoagulant molecule.

The prototypical example of a complex disorder (FIGURE 1.1, **right**) is disseminated intravascular coagulation (DIC), most

commonly associated with sepsis and endotoxemia, in which there is activation of both platelets and coagulation.[64] This results in loss of endothelial antithrombotic functions, microclot formation, consumption of platelets and coagulation factors, microvascular occlusion causing organ failure, and bleeding. The difficulty in recognizing and managing DIC derives in part from the variable multi-organ dysfunction that can be mimicked by other pathologic syndromes. For example, thrombotic thrombocytopenic purpura, initially described by Moschowitz in 1924, results from the failure to cleave ultra-large high molecular weight von Willebrand factor (vWF) multimers because of an inherited or acquired ADAMTS 13 deficiency. This results in platelet thrombi in the microcirculation of the brain, kidney and even heart, lungs and liver.[65] Thus, at one extreme are the abnormal or absent vWF proteins that cause the hemorrhagic syndrome of von Willebrand disease,[66] while at the other extreme is the persistence of ultra-large multimers on the endothelial surface[67] that are decorated with platelets and lead to microvascular occlusion.

Multiple small and medium-sized vessels can be occluded as part of specific disorders, such as sickle cell disease, polyarteritis, and the APLS. APLS in particular may present with complex features, including non-bacterial thrombotic endocarditis, systemic activation of coagulation, embolic phenomena, placental ischemia, as well as the lupus inhibitor that prolongs the PTT and prothrombin time (INR). While patients with APLS may also have a specific coagulation factor inhibitor that causes bleeding,[68] the inhibitor actually represents a risk for the thrombotic, not hemorrhagic, manifestations.[69] Thus, patients with APLS can present a dilemma for clinicians as patients could simultaneously manifest both bleeding and thrombosis. Additional examples could include patients with the Budd-Chiari syndrome (hepatic vein thrombosis) portal hypertension and bowel ischemia who also have active bleeding from esophageal varices or patients with postoperative hip or knee replacement patient and significant bleeding into joint prosthesis, but also having a proximal DVT and PE.

SELECTED TRANSLATIONAL ACHIEVEMENTS IN THE FIELD OF HEMOSTASIS AND THROMBOSIS

Translational advances made by the "clotters" have had an immense impact in medicine. A limited number of highly selected translational achievements are described below and reflect the broad application of their insights on medical practice beyond the field of hemostasis and thrombosis.

NEW ORAL ANTICOAGULANTS

Heparin and coumarin-based vitamin K antagonists have been the mainstays of thrombosis treatment and prevention for more than half a century, and efforts to improve on their safety, efficacy, and especially their pharmacologic limitations, have led to development of some very inventive agents. Examples of new directions in anti-coagulant therapy include the strict anti-thrombin leech salivary gland extract, hirudin,[70] and its recombinant or synthetic derivatives,[71] and short peptide inhibitors of thrombin such as argatroban,[72] which remain in clinical use as intravenous antithrombotic agents for patients with HIT. In 1992, Bode et al.[73] at the Max-Planck Institute for Biochemistry reported the crystallographic solution of the 3-dimensional configuration of thrombin with a resolution of 1.9 Å and revealed the active site pocket in complex with D-Phe-Pro-Arg CH_2Cl and other non-peptidic molecules. This observation paved the way for the design of highly-specific thrombin inhibitors with perfect fit into the serine protease pocket. Drug development at the Swedish company Hässle (subsequently Astra and then Astra-Zeneca) led to the first orally available thrombin inhibitor melagatran (and its prodrug ximelagatran).[74] The concept applied to the design of these synthetic agents was to mimic the structure of fibrinopeptide A and, as opposed the slow-tight binding of another prototype (efegatran), melagatran demonstrated a high association rate constant indicating that it would rapidly inhibit thrombin.[75] Gustafsson et al. pioneered the preclinical development and clinical trials with melagatran,[76,77] showing that the drug had similar efficacy and bleeding risk as low molecular weight heparins and warfarin for prophylaxis against VTE,[78,79] prophylaxis against stroke in atrial fibrillation,[80,81] and treatment of VTE.[82,83] Notwithstanding the liver toxicity that appeared during the phase III clinical trials and led to the withdrawal of the drug in 2006, the concept of an oral anticoagulant that avoided the multiple drug interactions and which did not require the careful laboratory monitoring used for coumarin agents, was correct. Direct-acting thrombin inhibition, not requiring activation of the serpin antithrombin (AT), is effective and with a bleeding risk similar or less than with conventional anticoagulants. A favorable risk/benefit-ratio was confirmed with the successor to melagatran, dabigatran, in a large trial in patients with atrial fibrillation, showing that reduction of ischemic stroke can be achieved simultaneously with reduction of intracranial bleeding.[84] Currently, more than 500,000 patients are receiving long-term dabigatran for stroke prophylaxis. New small molecule anticoagulants that bind in the factor Xa serine protease pocket have also been developed, including rivaroxaban, apixaban and edoxaban and advanced clinical trials show impressive efficacy and safety results in stroke prevention in atrial fibrillation,[84,85,86] in DVT prophylaxis and treatment,[87–89,90,91] and in acute coronary syndromes.[92] It now appears that we have entered a new age of anticoagulant pharmacotherapeutics that will decrease our reliance on parenteral heparins or the oral coumarins.

ABCIXIMAB, THE FIRST THERAPEUTIC MONOCLONAL ANTIBODY

The saga of the development of a chimeric human/mouse anti-$\alpha_{IIb}\beta_3$ monoclonal Fab fragment into the anti-thrombotic agent abciximab over a period of nearly 40 years is a superb example of the elegant translation of basic studies of hemostatic mechanisms into a successful and widely used medication. In the late 1950s and early 1960s, platelets were found to aggregate when exposed to stimuli such as the adenine nucleotide ADP, a phenomenon that was missing from the platelets of patients with the bleeding disorder Glanzmann thrombasthenia.[93] Further, platelet aggregation was noted to require the additional presence of the plasma protein fibrinogen, an observation that would prove to be the key to understanding the mechanism of platelet aggregation.[94]

With the development of the methodology to separate proteins by molecular weight, Phillips et al.[95] found that platelets

from patients with thrombasthenia lacked glycoproteins, that were subsequently designated glycoproteins IIb and IIIa. Shortly thereafter, Bennett and Vilaire[96] and Marguerie, Plow, and Edgington[97] demonstrated that platelets contain specific receptors for fibrinogen that bound fibrinogen only following platelet stimulation by agonists such as ADP. Moreover, these receptors were missing from thrombasthenic platelets.[96] Taken together, these observations provided an explanation for the functional defect in thrombasthenia and suggested that the proteins missing from thrombasthenic platelets, a heterodimer composed of GPIIb and GPIIIa, represented the fibrinogen receptor. More importantly, the data provided a testable hypothesis[96] for the mechanism of platelet aggregation: binding of dimeric fibrinogen molecules to the 50,000 to 80,000 GPIIb/IIIa molecules on one activated platelet to the same number of GPIIb/IIIa molecules on adjacent activated platelets crosslinked the platelets into macroscopic hemostatic aggregates.

A variety of techniques were applied to confirm this hypothesis, including the production of monoclonal antibodies in mice directed against the human GPIIb/IIIa heterodimer. A number of these antibodies prevented fibrinogen binding to activated platelets, reproducing the thrombasthenic phenotype using normal platelets.[98,99] The implication of these results did not escape the notice of Coller and collaborators at Centocor who posited that such an antibody could be engineered into a drug that might be useful in preventing the platelet thrombi responsible for acute coronary syndromes and stroke. To avoid antibody binding to the platelet FcγRIIa receptor, they converted the monoclonal antibody (designated 7E3) to Fab fragments.[100,101] Then, to minimize the antigenicity of the murine molecule, they replaced the framework of the mouse Fab with that of human IgG. The resulting chimeric molecule, abciximab (c7E3, ReoPro), inhibits agonist-stimulated fibrinogen binding and platelet aggregation *in vitro*, binds tightly to GPIIb/IIIa with a dissociation constant of ≈ 5 nM, and binds to the vitronectin receptor $\alpha_v\beta_3$ and the leukocyte integrin $\alpha_M\beta_2$ as well.[102]

An elegant series of experiments in animals confirmed the hypothesis that abciximab could inhibit platelet-mediated thrombosis *in vivo*[103,104] and the clinical efficacy of abciximab as an antiplatelet agent in humans was confirmed in four pivotal clinical trials in patients undergoing percutaneous coronary intervention (PCI) for acute coronary syndromes.[105] In 1994, abciximab was approved by the FDA for the prevention of ischemic complications of angioplasty and subsequently, for PCI with stents and as medical therapy for unstable angina.

THE CLONING OF FACTOR VIII AND THE DEVELOPMENT OF RECOMBINANT PRODUCTS

The cloning of the F8 gene and the development of safe factor VIII concentrates for the treatment of hemophilia A was a major translational advance in the field of blood coagulation in the past 40 years. The urgency for the development of recombinant products was driven by the discovery that HIV-1 was transmitted by blood products and was especially concentrated during the manufacture of pooled plasma derived clotting protein concentrates.[106,107] The gene for factor VIII was cloned in 1984 by two groups—scientists at Genetics Institute working with scientists at the Imperial College of London and other institutions and with support from Baxter Healthcare, and scientists at Genentech working with colleagues at UCSF, Mayo Clinic and other institutions with support from Bayer Pharmaceuticals. This illustrates the considerable strength that an academic-industry collaboration can bring to a task. The publication of the F8 gene and structure by these two groups appeared in back-to-back articles in *Nature*.[108,109,110,111] At the time, F8 was by far the largest gene cloned and it remains one of the largest. Following the cloning of the F8 gene, the race was on to develop recombinant forms of factor VIII. Just 3 years later, in March 1987, the first infusion of recombinant factor VIII was administered.[112] Recombinant factor VIII preparations were co-licensed by Baxter Healthcare and by Bayer Pharmaceuticals and these products quickly gained market-share against plasma-derived products. The production of recombinant factor IX followed,[113] as did recombinant factor VIIa,[114] a product that has proven safe and effective in the treatment of patients with factor VIII and IX inhibitors, as well as other bleeding disorders. Additional products now include recombinant vWF,[115] recombinant factor XIII,[116] and recombinant ADAMTS13.[117] The process of improving the properties of factor concentrates continues; for example, the elimination of all traces of human protein in an effort to minimize contamination of blood-borne infections[118] and the production of molecular variants to prolong the half-life of infused factor and reduce the number of injections needed for prophylaxis (see Chapter 79). Recombinant products are not without side effects, the most important of which is the occurrence of thrombotic complications after infusing an activated enzyme such as factor VIIa,[119] but this potential is well within the risk to benefit equation considering its broad application in serious hemorrhagic situations, including battlefield wounds. A question also remains as to whether recombinant factor VIII products are more prone to induce inhibitors than plasma-derived products,[120] but this appears less likely with recent information that implicates the potential role of factor VIII haplotypes.[121]

To date, it is estimated that more than 50 billion units of recombinant clotting factor products have been produced since their introduction; current annual sales of recombinant factor VIII exceed $1.5 billion per year, while sales of recombinant factor VIIa and recombinant factor IX are $750 million and just under $500 million, respectively. Most importantly, no new cases of human immunodeficiency or hepatitis virus transmission have been reported since the introduction of recombinant products.

The significance of the development of recombinant clotting factors cannot be underestimated. Not only did it provide a safe and effective method of treatment for hemophilia and other bleeding disorders, but it helped spawn and validate the field of biotechnology. It showed that recombinant therapeutics could be generated in large enough amounts to supply the whole disease population, that good manufacturing processes and reproducibility could be developed, and that the products could be successful pharmaceutics. Recombinant factor VIII was one of the early recombinant proteins, along with insulin, interferon α and γ, granulocyte colony stimulating factor (G-CSF), and erythropoietin. In many ways, these first recombinant products paved the way for biologics, in general. These were among the first proteins to go through FDA approval and they therefore set the standard for expectations regarding analysis. But it did more than this. By providing large amounts of purified factor VIII, it fostered previously unapproachable research on the structure

and function of factor VIII. It led to better understanding of the role of factor VIII in the coagulation process. It facilitated studies aimed at gene therapy for hemophilia. It also enabled current work aimed at generating imuteins (mutant proteins) with improved clotting factor properties—for example, ones that have a prolonged time in circulation or enhanced activity or reduced antigenicity.

DISCOVERY OF VASCULAR ENDOTHELIAL GROWTH FACTOR

It has long been recognized that tumors are associated with increased blood vessel growth. In 1971, Judah Folkman, a pediatric surgeon-scientist at Children's Hospital in Boston, published a seminal paper in which he suggested that the identification of key molecules mediating tumor angiogenesis might lead to new anti-angiogenic therapies that would starve a tumor.[122] Folkman's hypothesis was followed by decades of intense research that has culminated in the introduction of a number of anti-angiogenic medications in clinical practice.

In 1979, Harold Dvorak at Harvard Medical School demonstrated that tumors become enveloped in fibrin-gel within hours of implantation,[123] that a hepatocarcinoma tumor cell line secretes a vascular permeability factor (VPF), and that fibrin gels implanted into guinea pigs induce an angiogenic response. Thus, Dvorak established a pathophysiologic link between increased vascular permeability, neoangiogenesis, and stromagenesis in tumor growth. In 1983, the Dvorak team purified VPF from the hepatocarcinoma cells, and showed that the 34 to 42 kDa protein was distinct from other known permeability factors such as prostaglandins, kallikrein, leukokinins or histamine. When injected into guinea pig skin, VPF caused a rapid, transient increase in microvascular permeability without causing endothelial cell damage or mast cell degranulation, antihistamines did not block its action, and antibody against purified VPF neutralized virtually all of the permeability-increasing activity.[124] Dvorak went on to show that a broad spectrum of tumor cells from several species, including humans, secrete the same VPF.[125] He proposed that the permeability activity might be important for tumor growth. In collaboration with the Monsanto Company, Dvorak sequenced the NH2-terminal amino acid sequence of tumor-secreted VPF that had been purified to homogeneity.[126]

In 1989, Napoleone Ferrara, working at Genentech Inc. in San Francisco, purified a heparin-binding factor from pituitary follicular cells which was a potent mitogen for vascular endothelial cells, naming the protein vascular endothelial growth factor (VEGF).[127] That same year, he reported the cDNA sequence for bovine and human VEGF.[128] In back-to-back articles in *Science*, Daniel Connolly from Monsanto Company, who had shown that VPF was also a potent endothelial cell mitogen, reported the cloning of the gene.[129] VEGF and VPF proved to be identical. In collaboration with others at Genentech, Ferrara developed a murine anti-human VEGF monoclonal antibody with potent anti-tumor effect in xenograft models,[130] followed by development of the antibody bevacizumab (Avastin) that binds and neutralizes all human VEGF-A isoforms. Based on positive phase III trials, Avastin received FDA approval for colorectal cancer treatment in 2004, and another Genentech anti-VEGF antibody (ranibizumab, Lucentis) was FDA approved in 2006 for the treatment of wet age-related macular degeneration.

Dvorak went on to show that VEGF/VPF is widely overexpressed not only by many malignant animal tumors and human cancers, but also by epithelial and inflammatory cells in healing wounds and chronic inflammatory diseases. This process is highly adaptive in the case of wounds, and is shut off once healing has occurred, as VEGF/VPF levels return to normal. In contrast, tumors continue to produce large amounts of VEGF/VPF, promoting further blood vessel and tumor growth, prompting the comment that tumors behave as "wounds that fail to heal."[131] The discovery of VEGF/VFP stands as a seminal contribution in the field of vascular biology, with >37,000 articles related to this protein having been published, dealing not only with its permeability-enhancing and pro-angiogenic functions, but also with its critical role in embryonic development, inflammation, pulmonary pressure homeostasis, neural and vascular patterning, and general endothelial physiology.

THE PROTEIN C ANTICOAGULANT SYSTEM AND THROMBOPHILIA

Natural coagulation inhibitors protect against inappropriate activation of coagulation in the circulation.[132] The first example of an inherited deficiency was described by Egeberg in 1965[133] for AT; patients with partial deficiency (65% to 80%) manifesting a 5- to 10-fold increased risk of VTE disease,[134] and patients with complete deficiency presenting a significant risk of fetal demise.[135] While hereditary AT deficiency occurs in 0.02% of the general population,[134] other risk factors for VTE disease are in aggregate >100-fold more prevalent. Identification of the PC anticoagulant system, we resulted predominantly from the efforts and insights of Stenflo, Lollar, Owen, the Esmons (Chuck and Naomi), Dahlbäck, and Bertina. Esmon and Dahlbäck have recorded their personal recollections in the discovery of TM[136] and the FV Leiden mutation,[137] as well as general reviews of the PC pathway and thrombophilia.[138–140]

The sequence of discoveries that led to identification of the PC anticoagulant system started with the description of a new vitamin K-dependent protein by Stenflo in 1976.[141] "PC" was the third peak eluted from an absorption column, over which Stenflo had passed a barium sulfate extract of bovine plasma; the protein resembled other vitamin K-dependent proteins in its content of γ-carboxyglutamic acid residues, but its function was unknown. Esmon et al.,[142] working with Stenflo, Suttie and Jackson, showed that PC is a precursor of a serine esterase that bound to phospholipid, but that "thrombin and factor Xa could not activate PC," and that it did "not seem to be necessary for blood coagulation." In 1976, Kisiel, Ericsson and Davie[143] demonstrated that PC could be activated by Russell's viper venom or trypsin, and in 1977, Kisiel et al.[144] showed that PC was activated by thrombin and that APC acted upon factor V, observations that were confirmed and extended in 1979 by Walker, Sexton and Esmon.[145]

As described by Esmon and Owen,[136] interest turned to the endothelium as a participant in thrombin regulation, following the *in vitro* demonstration of thrombin binding to cultured endothelial cells.[146–148] Lollar and Owen[149] performed *in vivo* rabbit studies and *ex vivo* isolated rabbit heart perfusion studies.[150] Radio-labelled DIP-thrombin was cleared in remarkably rapid fashion, 90% at 1 minute, in the vascular bed of multiple organs after aortic injection and in the lungs after intravenous injection. They concluded that thrombin clearance was achieved by

saturable, high affinity binding sites in a reversible manner and that active thrombin was released from these sites after rapid neutralization by AT. Studies in the isolated heart using plasma-free buffer (no plasma inhibitors) produced the same clearance results as in the whole rabbit model, allowing them to propose the presence of thrombin binding sites on the "endothelial cell surface."[149]

In seminal experiments performed by the Owen:Esmon team, they infused both thrombin and PC into the isolated rabbit heart and recovered "potent anticoagulant activity," 20,000-times that achieved in solution. This suggested the presence of a cofactor on the vascular endothelium that catalyzed the reaction.[151] The cofactor, later called TM, was isolated from rabbit lung by Naomi Esmon, Whyte Owen and Chuck Esmon[152] and was shown to increase PC activation by 1,000-fold over thrombin alone. The Esmons went on to show that TM binding of thrombin changed the character of the enzyme, eliminating its procoagulant activation of platelets[153] and its ability to clot fibrinogen.[154] Coupled with the effect of activated APC to prolong a clotting time, it was then understood that the TM interaction converted thrombin to an anticoagulant protein.

The anticoagulant effect of APC occurs when it inactivates factor Va,[154,155] an activity promoted by the cofactor, PS.[156] Further, PS along with unactivated factor V work in concert with APC to degrade factor VIIIa.[157,158] Only free PS acts as the cofactor, as it is regulated by interaction with C4b-binding protein.[159] Thus, similar to thrombin, factor V has both procoagulant and anticoagulant effects (Janus-faced), as it is a procoagulant cofactor for factor Xa in the prothrombinase complex and an anticoagulant cofactor with PS and APC to inactivate factor VIIIa.[160] The complexity of the system is further illustrated by the potentiation of PC activation by the endothelial cell PC receptor.[161,162]

The key clinical aspect of the PC anticoagulant pathway[139] as it relates to hereditary thrombophilic states, is illustrated by patients with deficiencies of PC and PS, but it even more notable in mutation of the target protein, factor Va. As described by Dahlbäck,[137,163] detailed studies linking families with a thrombotic tendency to the curious phenomenon of "APC resistance"[57,164,165] were eventually traced to a mutation in factor V in which Arg506 is replaced by glutamine (G to A in nucleotide 1691).[55,56,58] The mutation at this site and at a second APC cleavage site (amino acid 306)[155] render the factor Va substrate resistant to APC action, thus precluding a physiologic limit to coagulation, and explaining the thrombophilic tendency of patients carrying these mutations.[164] Whereas PC and PS deficiencies account for 0.2% and 0.03% to 0.13% of thrombophilias in the general population, the factor V "Leiden" mutation is by far the commonest hereditary predisposition, present as carriers in 3% to 7% of the white population.[134]

The progression of events, from discoveries of new vitamin K-dependent proteins that were not procoagulants, to indirect evidence of endothelial-mediated activation of PC by thrombin, very rapid clearance of thrombin by the microcirculation, purification of TM, study of APC action on factor Va for its anticoagulant function, cofactor roles for PS and intact factor V, and the mutational analysis of a factor V protein that is resistant to APC, have allowed the field of thrombosis management to reach a new level of understanding and practice.

CHAPTER

2

Molecular Evolution of the Vertebrate Blood Coagulation System

MARIANNE A. GRANT AND WILLIAM C. AIRD

Most multicellular organisms have evolved hemostatic mechanisms to prevent the loss of fluid and promote blood vessel repair following injury. In invertebrates, hemostasis is mediated by blood cell (hemocyte) aggregation and/or gelatinization of hemolymph. In vertebrates, blood clotting involves both cells (thrombocytes in nonmammalian vertebrates and platelets in mammals) and a highly conserved network of protease reactions that ultimately lead to thrombin-catalyzed conversion of a soluble plasma protein, fibrinogen, into an insoluble, polymeric fibrin clot. Hemostasis in vertebrates is balanced by a number of important natural anticoagulant pathways.

An interesting question is *when* did the clotting cascade evolve? Previous studies have demonstrated that thrombin-catalyzed conversion of fibrinogen to fibrin occurs in all extant vertebrates, from jawless fish to mammals, but is conspicuously absent in invertebrates. These findings indicate that the clotting cascade evolved during an extremely narrow window of time (a mere 50 to 100 million years) in the ancestral vertebrate following the divergence of the protochordates (urochordates and cephalochordates) some 500 to 600 million years ago. A related question is *how* did the clotting system evolve? The answer, of course, is through natural selection of heritable traits that conferred a survival advantage. However, any such explanation must take into account not only the short time period during which the vertebrate clotting mechanism appeared, but also the fact that virtually every component of the clotting cascade is important and that some factors depend on others for their activity. As we will discuss in this chapter, the explanation appears to involve a combination of gene duplications, exon shuffling, and functional diversification. Finally, we must ask *why* did the clotting cascade evolve in the first place? At first glance, the response seems straightforward enough: to stem the loss of blood at sites of injury in animals with a highly pressurized closed circulation (i.e., vertebrates). However, there is now increasing evidence that coagulation may have played a critical early role in innate immunity.

The goal of this chapter is to review various evolutionary questions related to the clotting cascade. We begin by introducing basic principles of evolutionary biology. Next, we briefly review the mammalian clotting cascade and reframe the various components in terms of their protein domains or modules, which serve as a substrate for natural selection. After a brief discussion of comparative hemostasis, we provide a summary of what is known about the clotting cascade in extant vertebrates and invertebrates. Finally, we draw on these data to propose a scheme that explains the evolutionary origins of the clotting system.

PRINCIPLES IN EVOLUTIONARY BIOLOGY

Terminology

An important challenge in uncovering evolutionary histories is to reconstruct the past based on evidence from the present. Unfortunately, there is little in the fossil record that sheds light on the origins of hemostasis. Rather, we are left with comparative analyses of morphology, function, and molecular sequences. A central assumption in comparative anatomy and physiology is that two structures that look or act alike are closely related. However, that is not always the case. Structures may look similar simply because they have evolved similar adaptations. This is termed *convergent evolution*. An example is seen in the case of the horseshoe crab (*Tachypleus tridentatus*), which contains a clotting system comprised of a protease cascade of three serine protease (SP) zymogens and a clottable protein (coagulogen). However, these components arose independently of the vertebrate clotting proteins. Among other things, they lack γ-carboxylated glutamic acid (GLA) domains, epidermal growth factor (EGF)-like domains, and kringle domains, which promote essential interactions of vertebrate clotting factors. Conversely, *divergent evolution* describes dissimilar phenotypes that share a common ancestor. The interpretation of molecular phylogenies for gene sequence divergence is similarly wrought with limitations. It is widely believed that the vertebrate genome has undergone two whole-genome duplication (WGD) events in addition to many local duplications, translocations, gene conversions, and gene loss. Thus, it is important to distinguish between *orthologous genes* (orthologs) and *paralogous genes* (paralogs). Orthologous genes in different species have evolved directly from a common ancestral gene, whereas paralogs have evolved from a common ancestral gene through duplication and have diverged in sequence and function from the parent gene through mutations and selection or drift. Stated another way, orthology is the relationship where sequence divergence follows speciation, whereas paralogy is defined as that condition where sequence divergence follows gene duplication.

Methods

To establish the evolutionary history of the coagulation cascade, we must turn to modern-day animals (especially early diverging vertebrates) and examine how their blood clots and/or determine whether their genome contains sequences for the various clotting factors. Functional studies of nonmammalian vertebrates have routinely employed the same clotting time assays that are used in humans, including whole-blood clotting time, prothrombin (PT) time, and activated partial thromboplastin

time (aPTT). However, the absence of factor-deficient plasma from many of these species has precluded the use of mixing studies to measure individual clotting factor levels. Functional studies of blood clotting in early vertebrates are further hampered by inter- and intraspecies variations in clotting times, small volumes of available blood (e.g., in small fish such as the zebrafish), and the nonuniform plasma composition and body temperatures of poikilotherms.

Protein purification has been used to isolate fibrinogen in different species. However, such a strategy is not feasible for many of the SPs, which circulate at trace levels. With the advent of polymerase chain reaction (PCR), it has been possible to use degenerate primers (based on multiple sequence alignment of available gene sequences) against specific domains of clotting factors to clone the cDNA for SP clotting factors. More recently, searching for DNA sequences (orthologs) has been facilitated by the availability of the whole-genome sequence of the sea squirt (*Ciona intestinalis*), amphioxus (*Branchiostoma floridae*), puffer fish (*Fugu rubripes*), and other higher vertebrates. Complete genome sequence is not available for lamprey or hagfish. However there is a lamprey trace database maintained by the NCBI and EBO. Once DNA sequences are available from multiple species, it is possible to align sequences and construct phylogenic trees, which are diagrams that depict the lines of evolutionary descent of different species, organisms, or genes from a common ancestor. Sequence similarities and phylogenic trees based on aligned sequences provide important information about when clotting factors arose during evolution. In addition to analyzing DNA sequences, it is valuable to examine gene organization. For example, the occurrence and arrangement of catalytic and peripheral domains yields clues about gene duplication and exon shuffling. Similarities in intron–exon structures are characteristic of orthologous genes. The presence of two similar genes (paralogs) on the same chromosome is a clue that they originated from local duplication, rather than genome-wide duplication.

Taxonomy

Studies on the evolution of the clotting cascade have focused on the vertebrate–invertebrate divide, namely the chordates. Chordates form a phylum of animals that includes vertebrates and closely related invertebrates. There are three subphyla: urochordates or tunicata (composed of more than 3,000 species and represented by the sea squirt), cephalochordates or lancelets (composed of ~29 species and represented by amphioxus), and the extant vertebrates including jawless fish or cyclostomes (hagfishes and lampreys) and jawed vertebrates or gnathostomes (composed of ~53,000 species) (FIGURE 2.1). Urochordates and cephalochordates are referred to as basal chordates, or protochordates. Among other features, they have a notochord that persists throughout life but do not have backbones. Traditionally, cephalochordates were considered to represent the closest living relatives of vertebrates, with tunicates representing the earliest chordate lineage. However, recent evidence indicates that urochordates are more closely related to vertebrates than are cephalochordates.[1,2] Jawless fish are the earliest appearing vertebrates. The two extant genera are hagfish and lamprey. Although morphologic and molecular phylogenic studies have yielded conflicting results, it is believed that hagfish and lamprey are not monophyletic, but rather represent separate divergences, with hagfish being more primitive.[3] The jawed vertebrates include cartilaginous fish (also termed elasmobranchs), the bony fishes (also termed teleosts), amphibians, reptiles, birds, and mammals.

Mechanisms

It is widely accepted that the vertebrate genome has undergone multiple rounds of WGD (reviewed in Ref.[4]) (FIGURE 2.1). Although the timing and the genomic scale of such duplications remain poorly understood, the favored hypothesis is that the first round occurred in a common ancestor of jawed and jawless vertebrates (~630 to 565 million years ago), with the second round occurring in a common ancestor of the jawed vertebrates (~565 to 525 million years ago). An additional WGD may have occurred in an ancestor of the majority of ray-finned fish some 350 to 320 million years ago. The idea of genome duplication has been strengthened by the observations that model vertebrates often have multiple duplicate genes (paralogs) corresponding to a set of invertebrate orthologs.[5,6] When a gene is duplicated, one of the copies is redundant and escapes purifying selection. Natural selection cannot operate on idle proteins, but only on those that are being used. Thus, most gene duplications from WGDs are rapidly lost (this accounts for why the genome of sea squirt is smaller [330 Mb] than that of amphioxus [540 Mb]). Rarely, the mutations may provide the gene with a new function. Indeed, duplicate functional modules arising from WGDs are likely to have played a critical role in enhancing morphologic and functional complexity during vertebrate evolution.[4,7,8]

Although it is widely accepted that large regional or WGD events contributed to the structure of vertebrate genomes,[9–11] local duplication and translocation have certainly contributed to the evolution of multigene families on separate chromosomal regions. Domain shuffling (insertion) is another important mechanism for the evolution of novel genetic material. Since the domains are often correlated with exon boundaries, exon shuffling is considered to be the driving force behind domain shuffling.[12] In this way, different domains of modular proteins may have evolved in unrelated protein families, and then been subsequently fused to previously existing domains.[13] Other mechanisms of domain shuffling include simple fusion of genes and recruitment of mobile elements.

OVERVIEW OF MAMMALIAN BLOOD COAGULATION

Mammalian blood coagulation is a complex, balanced process initiated and regulated by a networked series of protein reactions and interactions that form positive and negative feedback loops. In humans, blood coagulation involves more than two dozen extracellular proteins, almost half of which are members of the SP family. Blood coagulation in mammals (FIGURE 2.2) is initiated by the exposure and binding of factor VII (FVII) to membrane-bound (cell surfaces in the subendothelial matrix) tissue factor (TF). Bound TF activates FVII to the protease FVIIa generating a TF–FVIIa protease complex that can proteolytically activate FIX and FX, producing proteases FIXa and FXa, respectively. In the absence of its activated cofactor FVa, FXa generates trace amounts of thrombin by the proteolytic processing of PT. This thrombin cleaves FXI to FXIa.

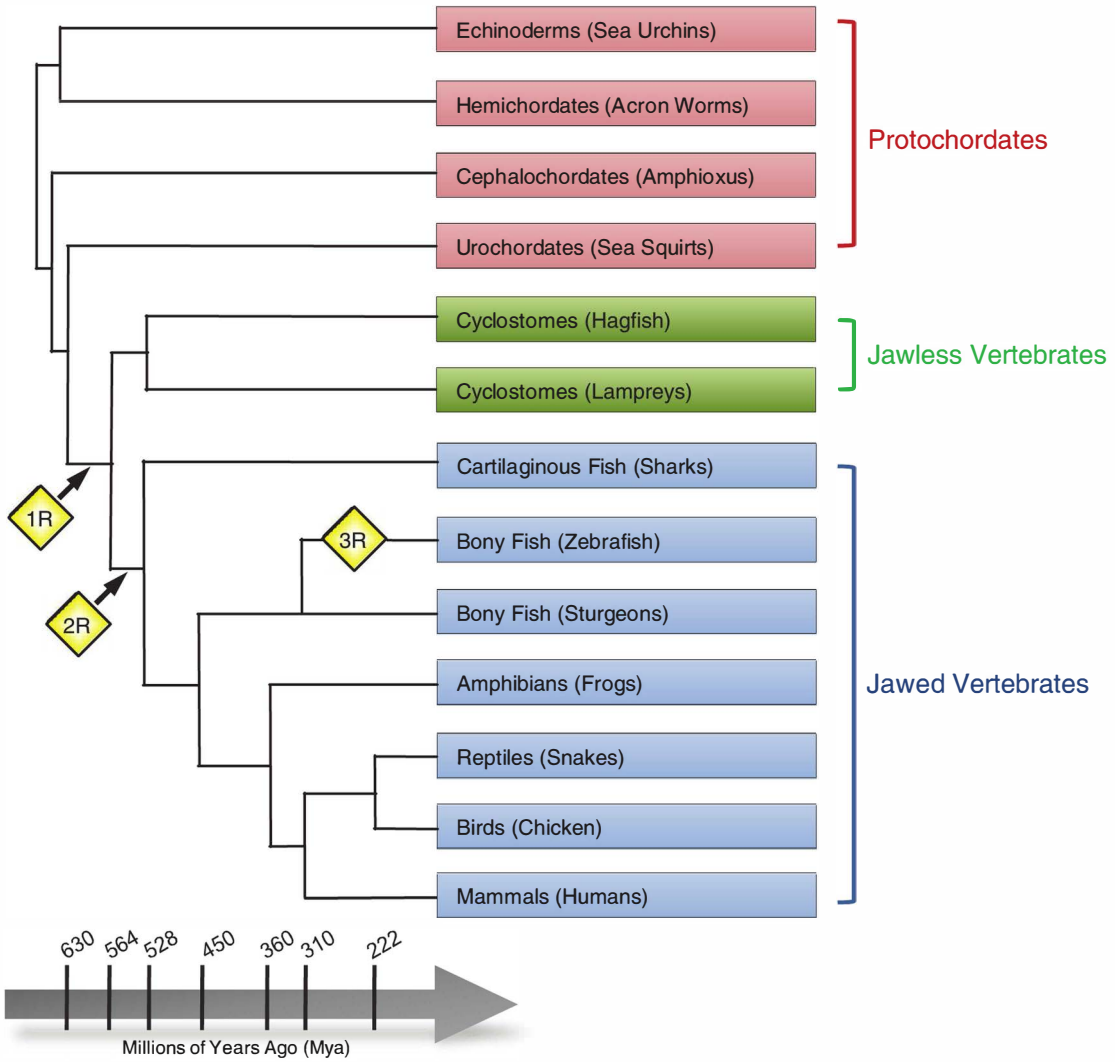

FIGURE 2.1 A phylogenetic tree representation of WGD during evolution. The points in evolutionary time where WGD events have been hypothesized to occur are indicated by *yellow diamonds*. The first round of WGD (*1R*) is thought to have occurred at the stage of divergence between urochordates and cyclostomes. The second WGD round (*2R*) is estimated to have occurred after the divergence of jawless fish (cyclostomes) and jawed vertebrates. A third round of WGD (*3R*) that is hypothesized to be a lineage-specific or fish-specific genome duplication is shown during divergence in the bony fish lineages.

FXIa then cleaves FIX to FIXa, which along with FVIIIa cleaves larger amounts of FX to FXa. Although insufficient to initiate significant fibrin polymerization, trace amounts of thrombin formed in the "initiation" stage of coagulation are sufficient to proteolytically activate FV and FVIII in a positive feedback loop. Greater amounts of activated FVa and FVIIIa function as cofactors for FXa and FIXa, respectively, forming complexes that amplify the generation of thrombin during the "propagation" stage, which leads to the generation of the large amounts of thrombin required to convert fibrinogen to fibrin. These reactions occur on the surface of platelets that are anchored to the subendothelial matrix *via* collagen and von Willebrand factor, which themselves activate platelets along with the newly generated thrombin.

Thrombin also proteolytically activates the anticoagulant pathway (see FIGURE 2.2). Thrombin forms a complex with the endothelial thrombomodulin (TM) receptor, and by an allosteric mechanism its substrate specificity is altered. The procoagulant substrates of thrombin, including FV, FVIII, and fibrinogen, are no longer efficiently proteolyzed. Instead, the thrombin–TM complex activates protein C (PC), generating activated PC (APC), which then associates with its protein S (PS) cofactor to rapidly inactivate procoagulant cofactors FVa and FVIIIa. Thrombin-TM-mediated activation of PC is further augmented 10- to 20-fold if PC is bound to another receptor, termed endothelial protein C receptor (EPCR).[14] The procoagulant process of "propagation" described above occurs independently of the TF–VIIa complex, which is rapidly inactivated

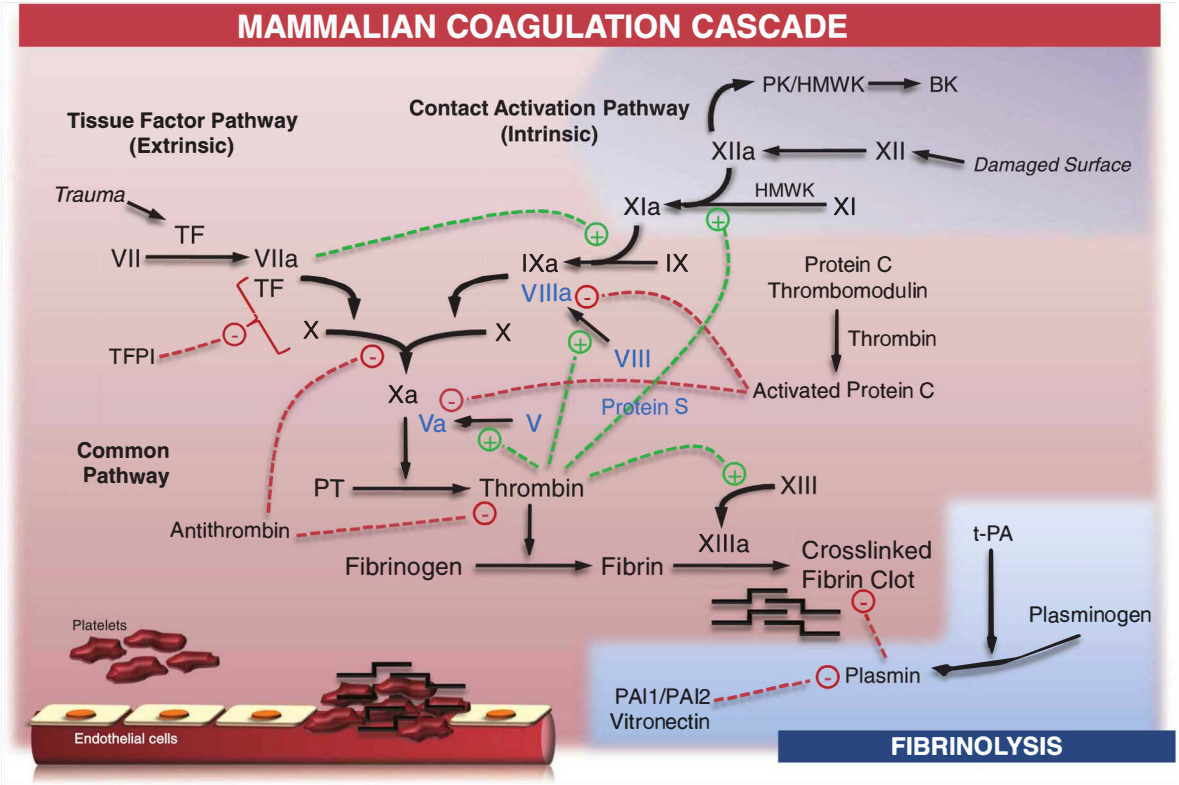

FIGURE 2.2 Schematic representation of coagulation in mammals. *Solid black arrows* represent the cascade of reactions of zymogen activation to active enzyme (suffix a) and the active complex formations driven by protein–protein interactions of factors in the system. Stimulatory actions are indicated with *green dashed lines* (+). Inhibitory actions are indicated with *red dashed lines* (–). PT, prothrombin; TF, tissue factor; TFPI, tissue factor pathway inhibitor; PAI 1 and PAI 2, plasminogen activator inhibitors 1 and 2 ; t-PA, tissue-type plasminogen activator; PK, prekallikrein; HMWK, high molecular weight kininogen; BK, bradykinin.

by the tissue factor pathway inhibitor (TFPI). Thrombin, FIXa, and FXa are specifically inhibited by antithrombin (AT), heparin cofactor II (HC II), and Z-dependent protein inhibitor/protein Z (PZ) complex. The fibrin clot is lysed in fibrinolysis (see FIGURE 2.2) by plasmin, which is generated from plasminogen by cleavage with tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA). This reaction is subsequently inhibited by two plasminogen activator inhibitors, namely plasminogen activator inhibitor (PAI)-1 and PAI-2.

The contact system is composed of three proteins: FXII, prekallikrein (PK), and high molecular weight kininogen (HMWK) (reviewed in Ref.[15]). The intrinsic or contact pathway is initiated when FXII is autoactivated upon exposure to negatively charged surfaces (including kaolin, silicone rubber, polyethylene, celite, and glass), forming FXIIa. FXIIa converts FXI to FXIa, which in turn converts FIX to FIXa. FXII also activates PK, forming plasma kallikrein that can reciprocally activate more FXII and liberate kinins (e.g., bradykinin) from HMWK.[15] Kinins are small peptides that bind to receptors on many cell types, leading to an inflammatory response, including vasodilatation and vascular permeability. Although FXII promotes surface-activated clotting *in vitro*, deficiencies of the contact system proteins (if one excludes FXI) are not associated with clinical bleeding. Under *in vivo* conditions, FXI is activated by thrombin and not by FXIIa.

CLOTTING FACTORS, CELL SIGNALING, AND INFLAMMATION

In addition to their role in coagulation, several components of the clotting cascade mediate cell signaling. For example, the structural protein fibrinogen has been shown to activate inflammatory cells *via* distinct ligand–receptor interactions (reviewed in Ref.[16]). SPs bind to protease-activated receptors (PARs). PARs belong to the family of 7-transmembrane G-protein–coupled receptors. There are four known members (PAR-1, -2, -3, and -4), each of which is activated by proteolytic cleavage of its *N*-terminal domain. Thrombin binds and activates PAR-1 (and to a lesser extent PAR-3 and PAR-4). FVIIa-TF and FXa signal through PAR-2. In this way, initiation of coagulation is mechanistically coupled with cell-signaling events, which typically contribute to a proinflammatory phenotype (reviewed in Ref.[17]). In contrast, APC activates PAR-1 and when bound to EPCR is cytoprotective. APC exerts pleiotropic effects not only on endothelial cells, but also on neuronal cells and innate immune cell populations. Other natural anticoagulants, including AT and TFPI, also inhibit inflammation *via* cell-signaling–dependent mechanisms.[18,19]

GENE ORGANIZATION AND PROTEIN DOMAIN STRUCTURE

The clotting proteins contain genetically autonomous units (domains or modules), which are linked together to form unique domain architectures.[13] In many cases, the domains are encoded by separate exons. Among these domains are SP catalytic domains and subsidiary (noncatalytic, regulatory) domains that mediate biologic specificity of the enzymes through protein–protein interactions and localization of the clot to sites of injury. For example, GLA domains and discoidin domains serve to anchor proteins to platelets at the sites of wounds. Kringle, EGF, and plasminogen-apple-nematode (PAN) domains mediate protein–protein interactions necessary for the ordered assembly of proteins in the clotting cascade. It has been proposed that these various nonregulatory domains represent genetically autonomous units (miniproteins) that have undergone shuffling (e.g., fusion to proteases) during evolution.[13] The relationship between SP paralogs can be inferred by the kinds and arrangements of secondary domains associated with the catalytic protease domains. Indeed, the similarities in gene organization and protein domain structure among the major mammalian blood procoagulant, anticoagulant, and clotting cofactors suggest that that they evolved through the duplication and functional diversification of different gene families (FIGURE 2.3).[13] Three of these families are discussed in turn.

The GLA-EGF1-EGF2-Serine Protease Family

Vitamin K–dependent SPs are comprised of a GLA-EGF1-EGF2-SP domain structure common to FVII, FIX, FX, PC, and PZ. In contrast to these latter proteases, PT has two kringle (K) domains in place of the EGF domains. The EGF-like domain is a short sequence containing six cysteine residues, which have been shown to be involved in disulfide bonds. The main structure is a two-stranded beta-sheet followed by a loop to a *C*-terminal short two-stranded sheet. Similarly, the kringle domain has a unique characteristic triple-loop fold structure, whose conformation is defined by three pairs of cysteine disulfide bonds, a number of hydrogen bonds, and small pieces of antiparallel beta-sheet. (Kringle domains are also found in hepatocyte growth factor, apolipoprotein a, u-PA, t-PA, and plasminogen.) Analysis of amino acid sequence and codon usage at highly conserved residues associated with the active site function in the SP domain distinguishes PT from FVII, FIX, FX, and PC and suggests that thrombin was the ancestral blood coagulation enzyme.[20,21,22] With the exception of PT, the genes encoding vitamin K–dependent factors of coagulation have virtually identical exon/intron distributions.

The A1-A2-B-A3-C1-C2 Cofactor Family

A1-A2-B-A3-C1-C2 domain structure is common to cofactors FV and FVIII, which are members of the ferroxidase family of proteins. FV and FVIII share sequence identity with the copper-binding plasma protein ceruloplasmin (CP) and the enterocyte transmembrane protein hephastin (HP), which have a common A1-A2-A3 domain structure. FV and FVIII differ from CP and HP in having two discoidin domains (C1 and C2) at their *C*-terminal ends. The discoidin domains of FV and FVIII bind to thrombocyte surfaces to orient the cofactors normal to the surface where they serve as binding cofactors for FX or FIX, respectively, and allow for optimal conversion of PT to thrombin. In FV and FVIII, there is an additional domain between domains A2 and A3, designated the B domain, which is released following thrombin activation. The B domain has no known structural homologs and is dispensable for procoagulant activity. The primary sequences of human FV and FVIII are 40% identical except in the B domain where there is no homology.

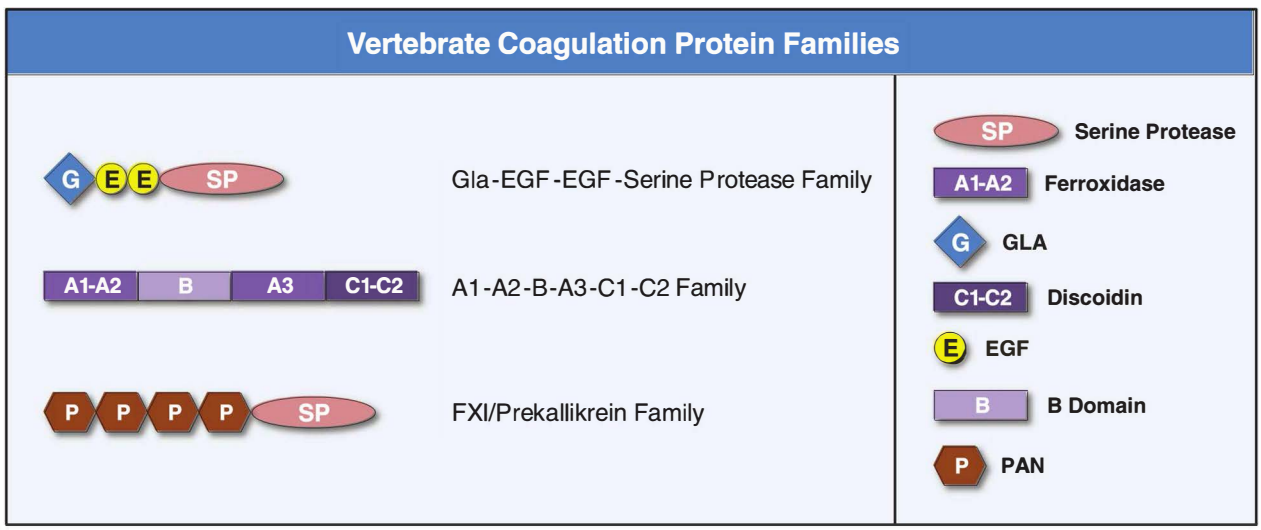

FIGURE 2.3 Schematic representation of the three major vertebrate coagulation protein families. The GLA-EGF-EGF-SP family comprises FVII, FX, FIX, PC, and PZ. The A1-A2-B-A3-C1-C2 protein family includes cofactors FV and FVIII. The PAN-SP family consists of FXI and PK. Domain representations are illustrated on the *right*. Epidermal growth factor (EGF)-like, discoidin (C), ferroxidase (A), γ-carboxy glutamic acid (GLA), plasminogen-apple-nematode (PAN), serine protease (SP), and B (B) domains.

The FXI/Prekallikrein Family

FXI and PK are closely related SP proteins. The most notable feature of FXI and PK is a series of four disulfide-constrained approximately 90-amino acid repeats initially called apple domains. More recently, these domains have been assigned to the larger domain superfamily known as the PAN module superfamily.[23] FXI is a disulfide-linked dimer that circulates in blood as a complex with HMWK.[24] PK, the zymogen of the protease α-kallikrein, is a monomeric homolog of FXI with the same domain structure that also circulates in complex with HMWK.

COMPARATIVE FUNCTIONAL STUDIES OF BLOOD COAGULATION

The horseshoe crab has a hemolymph coagulation system. However, it uses different enzymes and structural proteins to form a clot compared with vertebrates. In other words, arthropod hemolymph clotting factors are not orthologs of vertebrate blood clotting factors. Indeed, fibrin clots have not been observed in any protochordate (the closest relatives of the vertebrates). In the sea quirt, hemostasis is mediated by circulating cells called hemocytes, which become clumped at sites of injury.[3,25] Amphioxus does not have circulating blood cells and appears to lack clotting.[3,25]

The earliest animals to exhibit fibrin clots are the fishes. The first systematic study of fish coagulation was published in 1962 by Russell Doolittle.[26] Blood and plasma were collected from lamprey, dogfish shark (an elasmobranch), blackfish (a teleost), and human. Whole-blood clotting time (blood collected directly into glass tubes without anticoagulant) was fast in blackfish (less than a minute), very slow in dogfish, and weak/poorly organized in lamprey even after 24-hour incubation at room temperature. Addition of lamprey tissue extract to the sample resulted in rapid clot formation within 1 minute. These findings led to the conclusion that lamprey lack an efficient intrinsic pathway. Addition of high concentrations of calcium resulted in accelerated clotting in dogfish and blackfish, but reduced clotting efficiency in human plasma. Plasma clotting in all fish was greatly accelerated by addition of aqueous extracts of homologous tissue (TF source). Although the effect demonstrated relative species specificity, even lamprey skin extract accelerated the clotting of human plasma and bovine brain extracts accelerated the clotting of lamprey plasma. Taken together, this early study suggested that blood coagulation in fish is fundamentally similar to clotting in mammals, with the major difference lying in the intrinsic pathway.

A subsequent report confirmed poor whole-blood clotting of lamprey blood.[27] Consistent with an absence of an intrinsic pathway, the aPTT was >120 seconds. Surprisingly, the PT time with bovine thromboplastin (tissue extract) was shorter than it was with lamprey skin extracts. Elasmobranch blood also revealed long whole-blood clotting times, although these were highly variable between specimens. As with lamprey, the aPTT was more than 120 seconds. Comprehensive analyses of multiple species of bony fish revealed highly variable clotting times. Most of the fish clotted in times close to the human range. Homologous tissue extracts had variable thromboplastic effects.

A previous study of blood from multiple elasmobranch species showed very long clotting times in glass tubes (in some cases exceeding 48 hours).[28] These data were used to conclude that cartilaginous fish lack an intrinsic clotting mechanism. Additional calcium (up to a certain concentration) resulted in a marked shortening of the clotting time. Beyond that concentration, the clotting time became prolonged again. The clots that formed lysed rapidly. Clot lysis was prevented by the addition of epsilon-amino caproic acid. In assays of the extrinsic pathway, tissue extract from skate accelerated skate clotting time (but not that of human plasma). Human brain extract accelerated human but not skate clotting times.

More recently, hemostatic parameters have been measured in zebrafish.[29] Zebrafish thromboplastin was found to clot zebrafish but not human plasma, and rabbit thromboplastin resulted in only partial clotting of zebrafish plasma. Thus, these findings confirmed the species-specific nature of the TF–VII interaction. In addition, the aPTT was measurable (using a rabbit partial thromboplastin reagent), indicating the presence of an intrinsic cascade. This latter result is surprising based on the clear absence of contact factors in zebrafish. Warfarin dissolved directly into the tank water resulted in dose-dependent prolongation of PT time and aPTT. Addition of unfractionated heparin to zebrafish plasma resulted in dose-dependent prolonged aPTT.

Blood clotting in fish is highly dependent on environmental variables. For example, when fish that live in estuarine waters were exposed to normal fluctuations in temperatures and salinity, their whole-blood clotting varied widely.[30] Similarly, in reptiles, which also lack an intrinsic system, clotting times are influenced by changes in temperature and pH that reflect variations associated with normal life activities.[31]

In summary, these and other studies suggest that all groups of fish (cyclostomes, elasmobranchs, and teleosts) generate thrombin through pathways involving vitamin K–dependent factors, exhibit FXIII-dependent fibrin crosslinking, and mediate fibrinolysis that is inhibited by the same factors that inhibit fibrinolysis in mammals.[26,32,33]

COMPARATIVE MOLECULAR STUDIES OF BLOOD COAGULATION

The evolutionary appearance of various genes associated with the process of blood clotting can be inferred by examining the genomes of various classes of extant vertebrates. The availability of whole-genome sequence databases from a variety of vertebrates has provided an opportunity to answer the question of whether all vertebrates employ the full repertoire of factors involved in mammalian clotting. Below we review the biochemical evidence and evidence from molecular cloning and DNA sequence analysis (of genomic and expressed sequence tag (EST) databases) for the major blood coagulation proteins in vertebrates. In the first part, we review these data from the standpoint of different animal groups (FIGURE 2.4). In the second part, we reframe the findings according to the individual clotting factors (FIGURE 2.5). Thus, some overlap between the two sections is unavoidable. However, we find both approaches to be complementary. Together, they provide a strong foundation for formulating plausible evolutionary scenarios to account for the evolution of blood coagulation network by a gradual step-by-step Darwinian process.

From the Perspective of Animal Groups

Basal Chordates (Sea Squirt and Amphioxus)

Two protochordate genomes have been fully sequenced to date, the urochordate or ascidian called the sea squirt (*C. intestinalis*) and the cephalochordate called amphioxus or lancelet

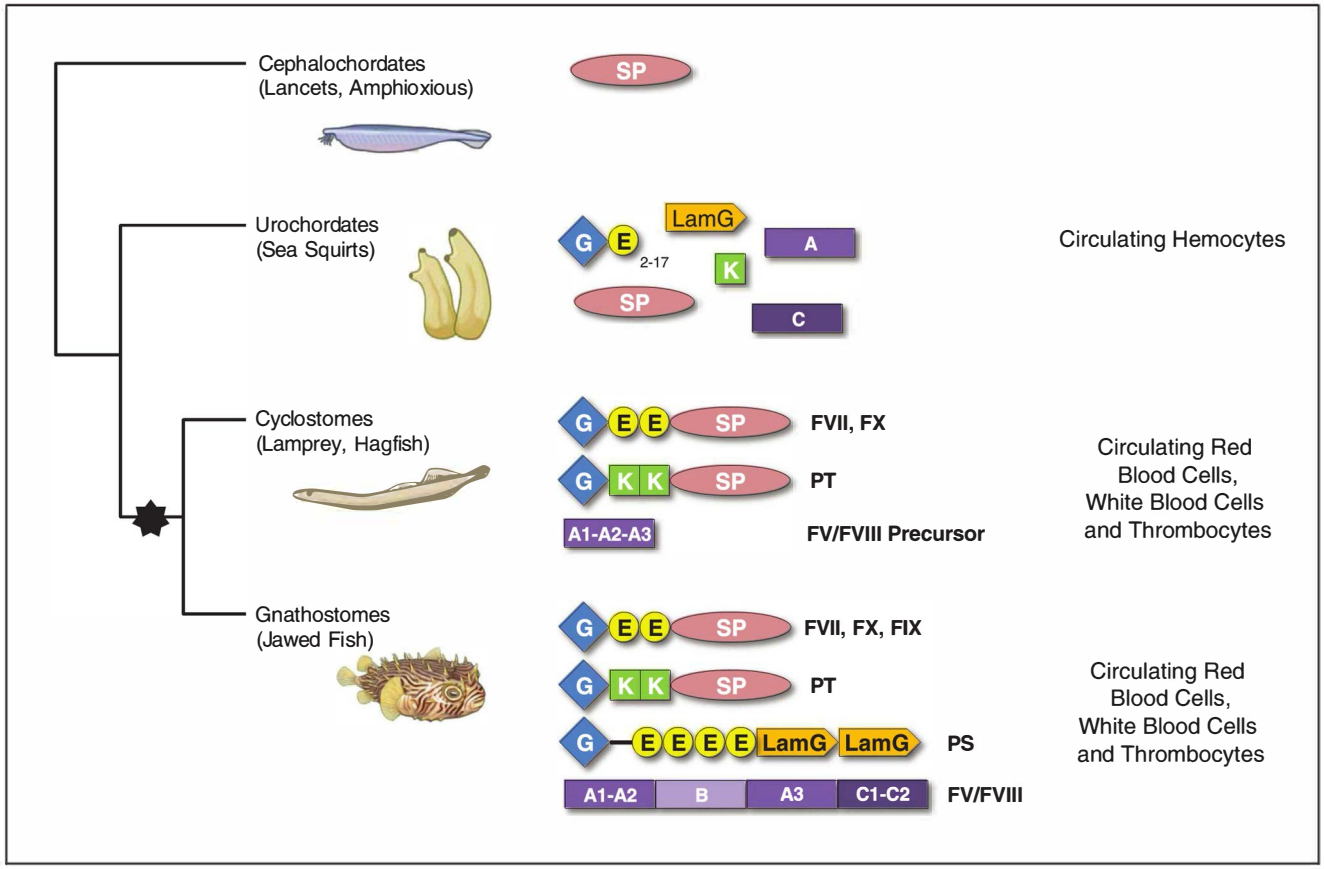

FIGURE 2.4 A phylogenetic tree representation of coagulation factor domain precursors and coagulation factor gene families in early chordates. Shown are the coagulation gene families with characteristic domain structure found in bony fish (gnathostomes) and lamprey (cyclostomes), as well as coagulation factor precursor domains found in sea squirt (urochordates) and amphioxus (cephalochordates) genome sequences. The type of circulating cells identified in each vertebrate class and the coagulation factors that have been identified in each vertebrate class are described on the *right*. The (*) symbol represents the evolutionary time point where members of the GLA-EGF-EGF-SP, GLA-K-K-SP, and triplicated A domain–containing protein families emerged from ancestral SP precursors. GLA (G), kringle (K), EGF-like (E), laminin G (LamG), serine protease (SP), ferroxidase (A), discoidin (C), and B (B) domains.

(*B. floridae*). Recent whole-genome sequence analysis of the sea squirt has revealed the presence of proteins containing many of the same domains that occur in vertebrate clotting factors, including GLA, EGF, kringle, and V/VIII A and C domains. However, none of these modules is physically linked to an SP domain, arguing against the existence of any genuine orthologs for the coagulation factor genes.[25] In contrast, they almost always occur in association with multiple EGF domains (in the case of the tunicate, *Halocynthia roretzi*, one GLA domain-containing protein was found to be associated with a receptor kinase[34]). Interestingly, one of these proteins is followed by two laminin G domains.[25] This sequence of GLA-EGF-laminin is similar to that found in PS. A recent search of the *C. intestinalis* genome also revealed a candidate predecessor of FV/FVIII.[25] It has three ferroxidase A domains similar to those found in CP/HP as well as two discoidin domains, as observed in vertebrate FV and FVIII. There are several genes for fibrinogen-related domains (FREDs) in the genomes of both the sea squirt and amphioxus.[3] In addition, a putative fibrinogen ancestral gene was found. Although this gene shares many of the same domains and structure as vertebrate fibrinogen, its sequence shows that it cannot possibly be a substrate for thrombin or FXIII.[25] In summary, protochordates, and for that matter all invertebrates studied to date, lack orthologs for any of the vertebrate clotting factors. However, the *C. intestinalis* genome contains the catalytic and accessory domains that ultimately comprise vertebrate clotting factors.

Jawless Fish (Hagfish and Lamprey)

The genome of jawless fish has unique features. For example, most lamprey species have more than 150 chromosomes, and genomic sequences reveal an extraordinarily high GC content in protein-coding regions, which probably reflects highly biased codon usage in these animals.[35] The study of clotting factors in jawless fish is mostly limited to lamprey.[36,37] A combination of protein purification, degenerate PCR-based cloning, DNA sequencing, and searches of genomic databases has revealed the presence of a clotting cascade that is decidedly simpler than in mammals. Early studies identified the PT and fibrinogen genes and proteins,[38,39] indicating that the final step of blood clotting has been conserved throughout vertebrate evolution. The fact that homologous

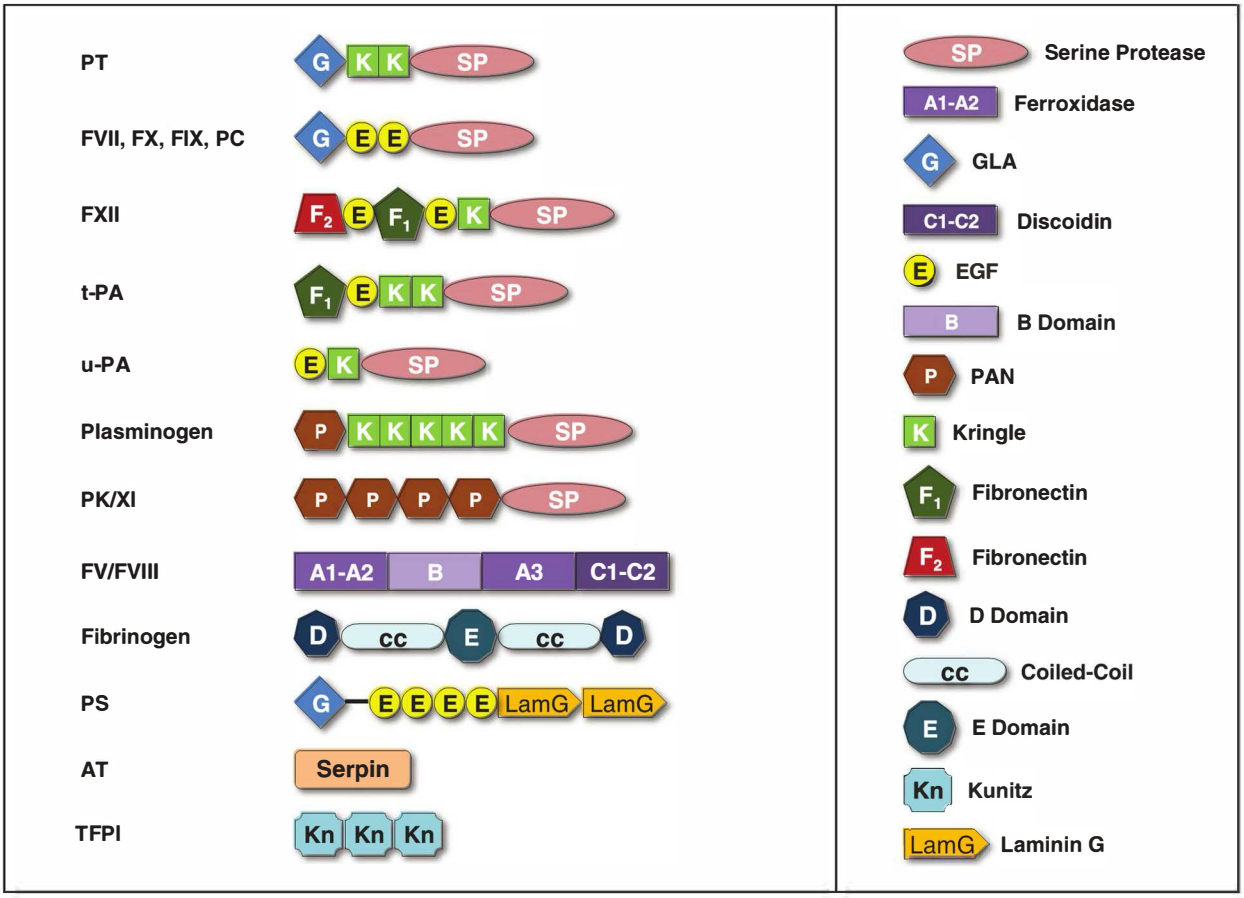

FIGURE 2.5 Schematic representation of the domain content of coagulation factors. Identification of the individual domain representations is shown on the *right*.

tissue extract promotes clotting of lamprey blood in a PT assay indicates the presence of TF. Lamprey has three factors VII (the sequence of one of these predicts that it is inactive) and two factors X (one appears to be inactive).[37,40,41] Sequence analysis indicates that the duplication of FX occurred well after the divergence of the lamprey. Thus, lampreys have an intact extrinsic pathway. In contrast, efforts to clone FIX have failed. While searches of the two B domains from FV and FVIII against lamprey trace database did not yield significant hits, there were a large number of hits with the A domain. The majority of these were similar to CP/HP. However, one was closer to V/VIII than to CP/HP and may represent an ancestral V/VIII gene. Lampreys have a simple HMWK, but lack other components of the contact system, including FXI, FXII, and PK.[37] On the fibrinolytic and anticoagulant side, lamprey liver EST analyses have also suggested the presence of PC, TFPI, TM, t-PA, and plasminogen.[37] There is no evidence for AT. However, a possible gene for HC II is present.[37]

It should be emphasized that in most cases, the presence of a procoagulant or anticoagulant is based on EST analyses. With few exceptions, the full-length clones are not available, and a functional role for many of these putative clotting factors remains to be established. As discussed earlier, hagfish are now considered to be more primitive than lamprey. Thus, it would be useful to know whether the same complement of clotting factors is present in hagfish or whether they have an abbreviated repertoire. Recent work in our own laboratory has revealed the presence of genes for PT, FVII, FX, plasminogen, and TFPI in *Myxine glutinosa*. Despite extensive studies using degenerate PCR primers against multiple domains, we have not identified FIX or FXI. In summary, lamprey and hagfish possess a similarly abbreviated clotting cascade that is limited to the extrinsic pathway alone. They have a plasmin-based fibrinolytic system, and natural anticoagulants against the extrinsic pathway (TFPI), cofactors (TM-PC), and SPs (HC II).

Bony Fish

The most complete information about the coagulation cascade in bony fish is from puffer fish (*F. rubripes*). Two major studies have examined the genome of the puffer fish for the presence of putative clotting factors. One such study revealed the presence of a single gene for PT, three for FVII (only one of which is predicted to be functional), two for each of FIX (both of which may be functional) and PC (one of which is predicted to be inactive), and one for FX, FV, and FVIII.[42] In another study, orthologs were identified for each of the five vitamin K–dependent SPs (one PT, four FVII, two FIX, one FX, and PC).[41] Similarities in the sequences of the two FIX genes suggest the occurrence of a gene duplication, leading to two homologs after fish diverged from the lineage leading to tetrapods. As in humans, FX and FVII are adjacent on the same chromosome, consistent with a previous

local gene duplication. Also identified were genes for TF (only 34% identity with human TF, but identical intron–exon structure), fibrinogen, the A chain of FXIII, FV, FVIII, plasminogen, t-PA, u-PA, AT, TFPI, TM, and PS. There was no evidence for FXI, PK, FXII, or PAI-1.

HMWK is present and is more complex than that of lamprey. However, as with jawless fish, the contact system (FXI, FXII, and PK) is missing in puffer fish. Since they lack FXI, it is likely that FIX in fish is activated by FVIIa. Consistent with the lamprey data, puffer fish have the fibrinolytic components (u-PA, t-PA, and plasminogen); TM and PC; and TFPI. However, they also have evidence for PS and AT. In summary, teleosts have evolved FIX and a more complete set of cofactors (FV, FVIII, and PS). AT also makes its first appearance in bony fish. Since they lack PK, another activating protease likely serves to generate kinins.

Amphibians and Birds

Contact series proteases made their first appearance in tetrapods; FXII first appears in amphibians. Interestingly, the predecessor of mammalian FXI and PK also appears first in amphibians. Birds lack both FXI and FXII.

From the Perspective of Individual Clotting Factors

Tissue Factor

TF is a transmembrane glycoprotein composed of two fibronectin type III domains, which are very common in vertebrate proteins, a membrane-spanning domain for cell surface attachment, and a short cytoplasmic tail. Protein sequence comparisons show that TF belongs to a large group of proteins called cytokine receptors. Cytokine receptors can be divided into families on the basis of their sequences and overall domain structures. TF belongs to the class 2 group of cytokine receptors and shares a similar arrangement of fibronectin and membrane-spanning domains with various cytokine receptors in the same class (e.g., the interferon receptor, IFN-γR). Similarity in domain structure and sequence identity among these varied proteins is highly suggestive of common ancestry. Searches of the sea squirt genome have identified two potential class 2 cytokine receptors.[41] Sequence comparisons suggest that these genes expanded into a very large number of paralogs during early vertebrate evolution. Many of these receptors play roles in the innate immune response against bacteria and viruses.

Evidence for TF-initiated coagulation in fish was established in 1962 from biochemical studies in which aqueous extracts of homologous tissue greatly reduced plasma clotting times.[26] These and subsequent studies demonstrated TF activity in jawless fish (lamprey and hagfish), cartilaginous fish, bony fish, amphibians, reptiles, birds, and mammals. TF has proven difficult to clone or identity in genome databases, because it is a rapidly changing gene (mammalian proteins are only 60% to 70% identical to one another). A single gene was found for TF in sequence database searches of the puffer fish (*F. rubripes*) genome.[41] The putative protein is only 34% identical with human TF, but the five introns are situated at the same positions in the puffer fish and human genes. The molecular cloning of TF has also been reported from the rainbow trout (*Oncorhynchus mykiss*).[43] Comparisons of mammalian and teleost TF amino acid sequences show high conservation of residues identified as critical for function in human TF.

Prothrombin

Initial evidence for PT in jawless fish was demonstrated by functional studies in lamprey in 1962.[33] Thereafter, amplification and sequence analyses of PT-encoding cDNAs from numerous vertebrate species were reported, and full-length gene sequences from mammals, birds, bony fish, lamprey, and hagfish have been characterized.[38] The PT amino acid sequence is highly conserved between hagfish and humans (hagfish 50% sequence identity; 69% sequence similarity with human). The presence of the PT and fibrinogen genes and proteins in cyclostomes (lamprey and hagfish) indicates that the final step of blood clotting has been conserved throughout vertebrate evolution.

It is widely believed that the SPs evolved from an ancestral trypsin-like protease containing a signal peptide and a zymogen peptide domain. Sequence and species comparisons indicate that PT was the ancestral blood clotting protein. It is unique among the vitamin K–dependent proteases in that it has two kringle domains following the GLA domain, while in the other proteases there are two EGF domains. The origin of PT has been debated.

Phylogenetic analyses of the vitamin K-dependent clotting factors suggest that the ancestral trypsin-like SP had a signal and a zymogen peptide domain.[13] Before the divergence of vitamin K–dependent SPs and the fibrinolytic enzymes, an EGF domain was likely inserted into the ancestral protease. Subsequent insertion of another EGF domain and the GLA domain occurred in the ancestral blood coagulation enzyme. PT diverged from the ancestral EGF-SP in a subgroup that included PT, PC, FIX, FX (and FVII), and the EGF domains were replaced by kringle domains from another subgroup that included u-PA, t-PA, and plasminogen.[13] Elsewhere, it was proposed that PT was derived from a K-K-K-K-SP domain-containing ancestor.[3] According to this scenario, duplications of the kringle domain-containing PT gene would have led to the appearance of an ancestral gene for FVII, FX, and eventually FIX. In this case, there would have been considerable domain shuffling in the early stages that resulted in the replacement of kringle domains (characteristic of PT) with EGF domain-containing factors (characteristic of FVII, FX, and FIX). Still another group posited that PT arose independently from other vitamin K–dependent factors by way of a GLA-EGF-laminin G (LamG)-type domain-containing predecessor (that also gave rise to PS).

Fibrinogen

Mammalian fibrinogen is a disulfide-linked hexamer ($\alpha_2\beta_2\gamma_2$), containing three pairs of three chains, encoded by separate genes, alpha, beta, and gamma. Fibrinogen-related proteins have been found in mollusks, echinoderms, and insects, where they participate in the immune response. These findings suggest that FREDs evolved before the divergence of the protostomes and deuterostomes.[21] Initial demonstration that jawless fish (lamprey and hagfish) have fibrinogen came from functional studies by Doolittle et al.[44,45] Fibrinogen was purified from the plasma of lamprey and shown to have the same subunit structure as that found in mammals. Orthologs of the fibrinogen genes, alpha (denoted alpha-1), beta, and gamma, have been reported from lamprey, *Petromyzon marinus*,[39] and lamprey, *Lethenteron japonicum*,[37] as well as a separate gene encoding a minor form of the α-chain, denoted alpha-2.[39] In puffer fish, the β- and γ-chains of fibrinogen are 58% and 52% identical

to their human counterparts. The α-chain in puffer fish is less conserved. The fibrinogen gamma (γ)-chain gene produces two gene products from alternative (or non) splicing, γ and γ′ respectively. The γ′-chain of human fibrinogen serves regulatory roles in the binding of FXIII by fibrinogen[46,47] and in the binding of thrombin by fibrin.[48,49] Sequence analysis of fibrinogen γ sequences from lamprey to human indicates that the γ′ sequence is directly descended from a primitive unspliced version of the γ gene. The intron involved in this particular γ-chain splicing did not appear until the evolution of reptiles and birds.[3,50] The results suggest that the regulation of clotting in the manner of FXIII binding to fibrinogen and by thrombin binding to fibrin is a phenomenon that appeared relatively late in the evolution of the vertebrate coagulation process.

Factor VII, IX, X, and Protein C

Separate liver lamprey EST analyses identified one FVII gene sequence and two putative FX sequences in *P. marinus* and *L. japonicum*, respectively.[36–38] In the case of both *P. marinus* and *L. japonicum*, one of the FX gene products lacks key residues in the activation sequence and ought not to be active as proteases. To date, despite searching with FIX sequences from a wide variety of species, no evidence for a FIX sequence in lamprey has been found. Additionally, another cDNA clone from lamprey EST analysis encoded an SP domain similar to that of human PC; however efforts to clone portions of the gene beyond the SP domain failed, and thus the entire domain content of the gene sequence remains unclear.[37] Four genes were found for FVII (42% to 44% identity) in puffer fish at sites adjacent to each other and to a gene for FX; however, one of the homologs has an active site mutation in the catalytic SP region. The single FX gene identified in puffer fish is 41% identical to human FX. FIX first appears in teleosts. Indeed, as described earlier, there are two FIX genes in puffer fish, both of which may be functional. The proteins are 51% identical with each other and share greater similarity with one another than to mammalian FIX sequences, suggesting that gene duplication giving rise to the two homologs occurred after teleost fish diverged from the lineage leading to tetrapods.

The origins of FVII, FIX or FX, and PC, relative to PT, are debated. It is not clear whether they arose from a common ancestral protease. In any case, it has been proposed that the ancestral vitamin K–dependent (Gla-EGF-EGF-SP)—whether or not it arose independently of PT—initially duplicated (a WGD) (FIGURE 2.6), giving rise to PC and the ancestral FVII/FIX/FX gene.[42] The next gene duplication gave rise to FVII and the

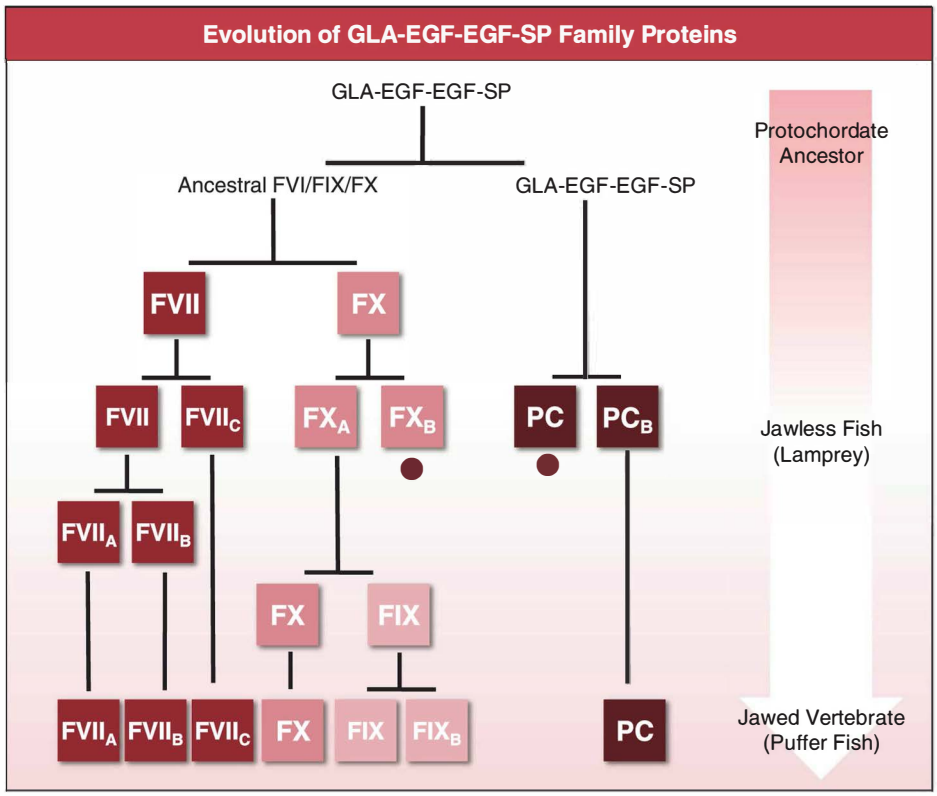

FIGURE 2.6 A scheme for the evolution of the blood coagulation GLA-EGF-EGF-SP family in early vertebrates based on sequence phylogenetic analyses. Initial gene duplication of an ancestral GLA-EGF-EGF-SP gave rise to two lineages, one giving rise to FVII and FX *via* an ancestral FX/FVII, the other giving rise to PC. The FVII/FX lineage is thought to have undergone additional rounds of local and genome-wide duplications to give rise to the two FXs and three FVII genes identified in the lamprey (jawless fish). Gene loss (X) of one of the FX genes and further gene duplication is thought to have given rise to the three FVII genes, one FX gene, and two FIX genes identified in the puffer fish (bony fish). The PC lineage is thought to have undergone genome-wide duplication and subsequent gene loss (X).

ancestral FIX/FX gene (see FIGURE 2.6). It is interesting to note that the FX and FVII genes are chromosomally adjacent to each other in puffer fish and humans (in contrast, the genes encoding for FIX, PC, FV, and FVIII are located on separate chromosomes in humans). This finding suggests an evolutionary origin of FX and FVII genes from a gene-duplication event on a single chromosome, which generated FVII and FIX/X only a short time before the last common vertebrate ancestor emerged. A third gene duplication (a WGD) gave rise to FIX and FX (see FIGURE 2.6). There would, of course, have to be some gene loss to account for the present repertoire of SPs.

Factor V and Factor VIII

As discussed earlier, FV and FVIII consist of three A domains and two *C*-terminal discoidin domains. There is a long, extended region between the second and third A domains, called the B domain.[51] Searches against the B domain in lamprey failed to yield significant hits, whereas a search against the A domain revealed a possible single precursor/predecessor of FV/FVIII (this finding is consistent with the presence of FX, but absence of FIX in lamprey). In contrast, in puffer fish, genes for FV and FVIII were readily identified, which encode for large proteins composed of three A domains and two *C*-terminal discoidin domains (41% and 42% identity with human orthologs, respectively).[42] The B domain between the second and third A domains varies greatly between puffer fish and human proteins (FV B domain, 16% sequence identity; FVIII B domain, 6% identity), consistent with large variations observed between the B domains of FV and FVIII from any species. These findings suggest that there has been very little selective pressure to conserve amino acid sequences in the B domains. The B domain in human FV and FVIII is encoded by a single large exon. It has been postulated that these exons arose through gene insertion and that the exons encoding the B domains of both FV and FVIII are derived from a single primordial cofactor gene (in which case the lack of current sequence homology between the two cofactors would be due to divergent evolution). FV and FVII are closely related to CP and HP (which share an A1-A2-A3 domain structure) (FIGURE 2.7). All four triplicated A domain–containing proteins appear to have evolved from a common ancestral gene through two serial gene-duplication events. It has been proposed that two first rounds of WGD generated ancestral FV/FVIII and CP/HP genes from an ancestral gene with an A1-A2-A3 structure.[42] Since both FV and FVIII have the domain structure A1-A2-B-A3-C1-C2, gain of B and C domains likely occurred before a second gene-duplication event, which gave rise to all four genes (FV, FVIII, CP, and HP)[42] (see FIGURE 2.7).

Factor XIII

FXIII is a transglutaminase that circulates in the plasma as a heterotetramer of two catalytic A subunits and two carrier B subunits (2A and 2B). Upon activation by thrombin, FXIIIa catalyzes the formation of γ-glutamyl-ε-lysyl amide crosslinks between adjacent fibrin molecules to form a mechanically stable, insoluble clot. The A chain of FXIII was identified in sequence analysis of the puffer fish whole genome, but a gene for the FXIII accessory B chain was not found.[41] In mammals, the B chain is composed of 10 "sushi" domains, also known as complement-control modules or β_2-glycoprotein domains. These domains are quite common in mammalian proteins where they occur in various components of the complement system. Sushi domains are also common in the puffer fish genome. However, no gene encoding for a sushi domain arrangement corresponding to that found in the FXIII accessory B chain was identified.

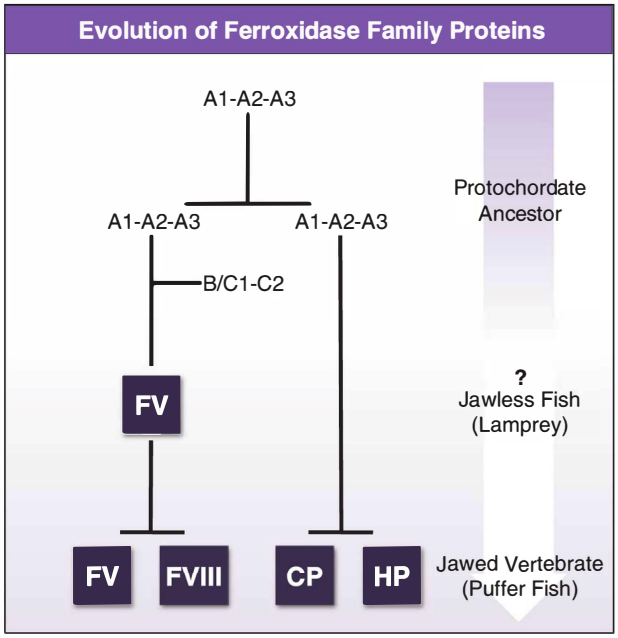

FIGURE 2.7 A scheme for the evolution of the blood coagulation ferroxidase domain family in early vertebrates based on sequence phylogenetic analyses. Initial gene duplication of an ancestral triplicated A domain-containing (A1-A2-A3) gene gave rise to two lineages, one lineage giving rise to coagulation cofactors FV and FVIII identified in jawed vertebrates and the other lineage giving rise to ceruloplasmin (CP) and hephastin (HP) proteins.

The Contact System

HMWK is present in all vertebrates. HMWK in the lamprey is highly simplified. The complexity of its structure has increased during evolution (e.g., compared with fish, HMWK in birds and mammals is composed of additional domains).[25] A functional role for a kinin–kininogen system in jawless fish is supported by a study in hagfish in which bradykinin promoted vasorelaxation of precontracted mesenteric arteries.[52] In contrast to HMWK, the SPs of the contact system (FXII, FXI, and PK) evolved only later with the tetrapods. FXII has a similar domain structure as hepatocyte growth factor activator (HGFA), and these two genes are thought to represent paralogs. Genes for HGFA, but not FXII, are present in lamprey and puffer fish.[53] FXII has been found in the genome of a reptile (Carolina green lizard) and is present in frog, platypus, and opossum genomes.[3] FXII is absent in birds, suggesting that birds have lost the gene for FXII over the 300 million years since the divergence of birds from mammals.[54] Interestingly, some marine mammals (whales, dolphins, and porpoises) have also lost the gene for FXII.[55] These animals diverged from other mammals 60 million years ago. The loss of FXII in these animals has left as its trace a corresponding pseudogene.

FXI and PK have similar DNA sequences and domain arrangement and are thus considered to be recently derived paralogs. The most notable structure of these proteins is the presence of a series

of four disulfide-constrained 90- to 91-amino acid repeats originally called apple domains, but now referred to as PAN domains. The apple/PAN domains of FXI and PK are believed to have derived from the *N*-terminal domain of plasminogen and hepatocyte growth factor.[53] A single paralog of FXI and PK occurs in frog, chicken, and platypus (a monotreme, which diverged from other mammals 160 million years ago), suggesting that it first appeared in early tetrapods.[53] FXI first makes its appearance in the opossum, which has two distinct genes for FXI and PK.[53] (The aPTT is much faster in opossum compared to human.) Thus, the FXI/PK precursor underwent gene duplication early in mammalian evolution, following the divergence of the monotremes from other mammals. Evidence suggests that PK was the ancestral gene for FXI/PK. In fact, no gene for FXI has been found in a nonmammalian species. Jawed fish lack the three contact factor proteases PK, FXII, and FXI. However, in contrast to jawless fish, they have FIX. In summary, the contact phase of clotting is a relatively late invention. It appears that the inflammatory response initiated by kinins evolved independently of the pathways leading to fibrin formation. The two systems became linked after the appearance of tetrapods.[25]

The Fibrinolytic System

t-PA has two kringle domains, while plasminogen contains five such domains. t-PA and plasminogen occur as early as the jawless fish. It is believed that fibrinolytic and blood coagulation enzymes originated from the same ancestral SP.[13] Following the divergence of these two families, a kringle domain was inserted into the common ancestor for plasminogen and plasminogen activators. The kringle domain underwent internal quintuplication (these were transferred to PT). After the divergence of u-PA and t-PA, a finger module (F) (related to fibronectin fingers) was inserted into t-PA and the kringle domain was duplicated.

Thrombomodulin

TM is an intronless gene. From an evolutionary standpoint, evidence suggests that intronless genes in mammals are more rapidly evolving. TM belongs to the family of C-type lectin-like domains, which bind to protein ligands rather than to carbohydrates, and are involved primarily in immune surveillance. C-type lectin-like domains are found in *Drosophila* and *Caenorhabditis elegans* proteins. TM shares similar domain composition and organization with C1qRp, a molecule involved in leukocyte adhesion and complement activation. In humans, TM and C1qRp colocalize to the same region of chromosome 2. Recent analysis of the NCBI Trace sequence database for lamprey (*P. marinus*) identified a potential sequence for TM, which contains a homologous *N*-terminal lectin domain and five EGF domains. This lamprey TM sequence is only 30% identical to human TM; however, as in other vertebrates (humans and puffer fish) the sequence is intronless.[36] Two intronless genes for TM were found in the puffer fish genome (29% and 37% sequence identity to human TM).[41] These two genes were found adjacent to each other. A similar arrangement is seen in the human genome where the intronless TM lies next to a related intronless gene (an accessory protein for complement factor C1Q).[56]

Antithrombin

AT belongs to the superfamily of SP inhibitors (serpins), which also includes α_1-antitrypsin and plasminogen activator inhibitors 1 and 2. Serpins have been identified in prokaryotes, plants, animals, and viruses. However, they have undergone extensive gene duplication and structural/functional divergence. Vertebrate serpins, including AT, appear to have arisen from a common invertebrate serpin that was intracellular rather than extracellular. AT has been cloned and sequenced from a wide variety of nonmammalian vertebrates. A gene for AT was found in puffer fish and zebrafish.[40,41] In both cases, the putative protein is 55% identical with the human protein. A search of the lamprey (*P. marinus*) genome draft assembly identified a sequence for an ortholog of HC II but no AT sequence.[36] The cDNA for HC II with one serpin (SP inhibitor) domain was identified in cyclostomes by liver EST analysis in lamprey (*L. japonicum*).[37] However, because of the simple domain organization and the presence of other coagulation genes or noncoagulation genes sharing the same domain, the identification is tentative. HC II has been cloned in multiple teleosts (Ref.[57] and references therein). In summary, it appears that HC II arose in a common ancestral vertebrate, whereas AT arose following the divergence of the jawless fish. Interestingly, AT-activatable heparan sulfate emerged some 250 million years earlier, suggesting this heparan sulfate proteoglycan initially served a nonanticoagulant function.

Protein S

PS has a Gla domain followed by four EGF-like domains and the sex hormone–binding globulin-like region consisting of two laminin G (LamG)-type domains. Sequence analysis of a liver EST from lamprey (*L. japonicum*) failed to reveal evidence for PS.[37] However, a putative PS gene was identified in the puffer fish genome with a similar intron–exon structure that encodes a protein with 48% sequence identity and 70% similarity with human PS. The putative PS gene, like its human counterpart, is situated near a similar homolog (a growth arrest–specific gene). Interestingly, a GLA domain–containing protein has been identified and cloned from the urochordate sea squirt, *C. intestinalis*, which resembles an elongated version of the PS prototype.[58] The GLA domain of this sea squirt protein, Ci-Gla4, is separated from the first EGF domain by a short putative disulfide loop—a situation analogous to PS where the GLA domain is separated from the first EGF domain by a thrombin-sensitive, disulfide-linked loop, noted as the thrombin-sensitive region (TSR). The potential common evolutionary origin of Ci-Gla4 and PS is further suggested by the finding that both disulfide loops are encoded by single exons. The central region of Ci-Gla4 has 17 EGF domains in tandem followed by two laminin G-like domains analogous to the domains at the *C*-terminus of PS.

Tissue Factor Pathway Inhibitor

TFPI is a Kunitz-type multivalent SP inhibitor. The Kunitz/bovine pancreatic trypsin inhibitor (BPTI) protease inhibitor family is found in a wide variety of animals, including in the venom of snakes. The prototypical Kunitz-type inhibitor is BPTI. TFPI has three Kunitz domains. Based on phylogenetic trees, the ancestral Kunitz-type inhibitor was predicted to have arisen about 500 million years ago. Recent analysis of the NCBI Trace sequence database for lamprey (*P. marinus*) identified a sequence for TFPI.[36] The lamprey sequence is 45% identical to human TFPI. The EST analysis of lamprey, *L. japonicum*, also identified a potential cDNA for TFPI containing a three-Kunitz domain organization.[37] TFPI has been cloned from carp and zebrafish,[59] with amino acid sequences of 30% and 28% identity

to human TFPI, respectively. Two genes for TFPI were identified in the puffer fish genome, just as is the case in humans. The amino acid sequence comparison best-match among these was 44% identical to the human TFPI sequence. Although functional data are presently lacking, these findings suggest that TPFI arose in the ancestral vertebrate.

Protease-Activated Receptors

PARs are G-protein–coupled receptors that play key roles in hemostasis, thrombosis, vascular development, and the inflammatory response. Four PARs (1 to 4) have been identified in mammals. Homologs of mammalian PARs 1 to 3 have been discovered in zebrafish.[60] The human and mouse PARs 1 to 3 genes are clustered in a small region (200 kb) of a single chromosome, PAR-1 and PAR-3 being separated by the IQGAP2 gene. PAR-2 is flanked by corticotropin-releasing hormone binding protein (CRHBP). Orthologs for PAR-1 and PAR-3 in zebrafish are also separated by IQGAP2 on the same chromosome. However, in the zebrafish, PAR-2 (in conjunction with CRHBP-2) is located on a different chromosome. These findings suggest that the zebrafish PAR-2 underwent tandem duplication and was translocated, along with CRHBP, away from PAR-1 and PAR-3 to a different chromosome.

PUTTING IT ALL TOGETHER

Comparative physiology, biochemistry, and DNA sequences allow for several predictions related to the evolution of the vertebrate clotting system. First, the absence of clotting factors in cephalochordates and tunicates and their presence in jawless fish suggest that the system evolved in an ancestral vertebrate some 500 to 600 million years ago. Second, although the basic clotting system (thrombin-mediated cleavage of fibrinogen) appeared over an extraordinarily short period of time (some 50 to 100 million years), the complex mammalian version did not arise in one fell swoop, but rather evolved over time. The extrinsic system appeared first, followed by FIX and then the contact system. Not surprisingly, the fibrinolytic system evolved with fibrinogen from the outset. The importance of anticoagulant mechanisms from the dawn of vertebrate lineage is evidenced by the presence of TFPI, HC II, and TM/PC (and possibly PS) in jawless fish. It seems that AT arose somewhat later. Finally, there is unlikely to be an extant vertebrate species with a more rudimentary clotting system than lamprey or hagfish. This leaves us to speculate on how the system might have arisen in the ancestral vertebrate (FIGURES 2.8 and 2.9).

The central feature of vertebrate clotting is the thrombin-catalyzed conversion of fibrinogen to fibrin. Based on molecular phylogenetic studies, thrombin was the first clotting SP to appear. It is unlikely that thrombin and fibrinogen appeared at the same time. Rather, they each evolved separately. Thrombin probably evolved first as a mediator of PAR-dependent cell signaling. Indeed, a critical role for PT in cell signaling during development is supported by knockdown studies in mice and zebrafish embryos.[61,62] It has been proposed that TF in the ancestral vertebrate directly activated thrombin, which then promoted PAR-mediated cell clumping.[3] A GLA domain could have helped to keep the evolving thrombin protease (or thrombin-like protease) localized on the surface of thrombocytes.

The subsequent appearance of fibrinogen would have allowed thrombin to broaden its attack, generating a more durable clot composed of fibrin.[3] Fibrinogen may have had an original, yet separate role apart from the coagulation system in cell–cell interactions, a property of many proteins with FREDs. Perhaps an early FXIII-like transglutaminase crosslinked fibrinogen to form a polymeric clot in a manner independent of

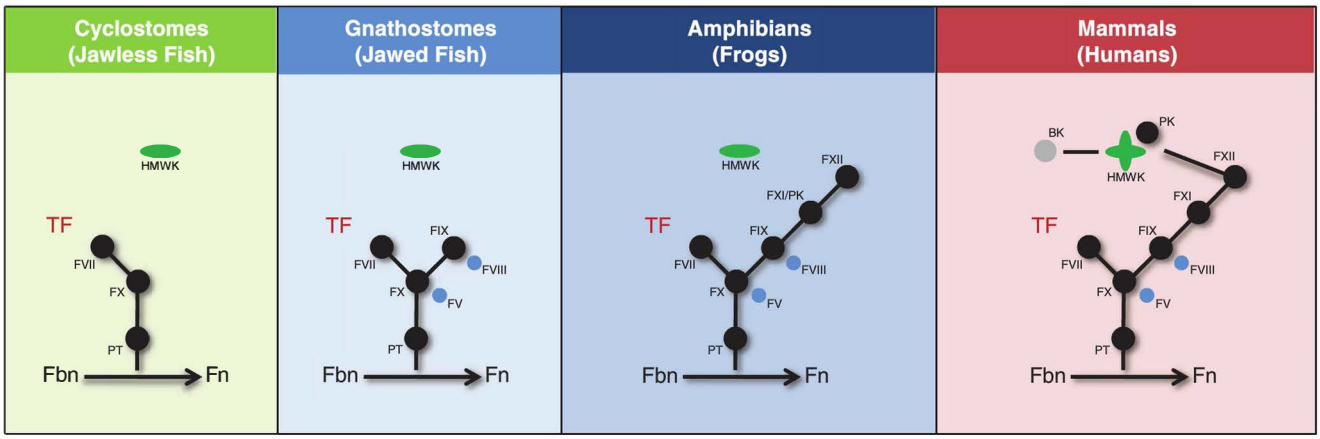

FIGURE 2.8 Increasing complexity of the coagulation system during vertebrate evolution. HMWK (*green oval*) is present in all vertebrates, though the complexity of its structure is increased in birds and mammals (indicated by a change in shape). The blood coagulation system in jawless fish generates fibrin (Fn) from fibrinogen (Fbn) through a simplified set of factors: TF and the SPs FVII, FX, and PT (*black circles*). Cyclostomes lack FIX and FVIII, and the presence of an ancestral FV/FVIII cofactor is not yet conclusive. In jawed fish, the cascade expands to include FIX (*additional black circle*). Both cofactors FV and FVIII (*blue circles*) are both present. In amphibians, factors of the contact system emerge, namely a single FXI/PK type factor and FXII (*additional black circles*). In mammals, duplication of the FXI/PK precursor gene results in separate genes for FXI and PK following divergence of the monotremes from other mammals. FXII cleaves PK to kallikrein; kallikrein hydrolyzes HMWK to bradykinin (BK, *grey circle*), thus connecting the clotting cascade with the kallikrein–kinin system.

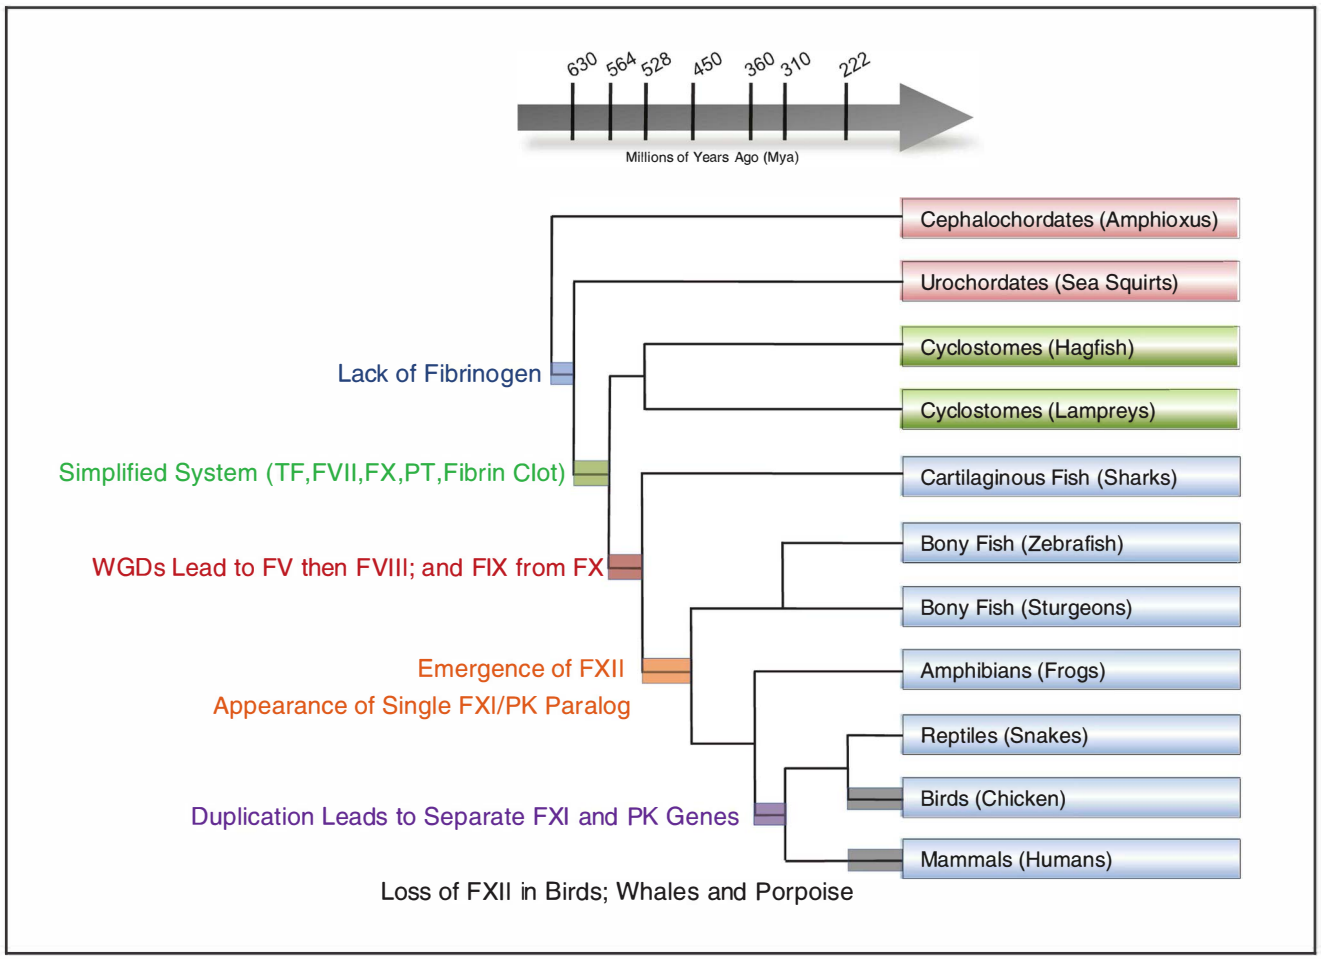

FIGURE 2.9 A phylogenetic tree representation of key evolutionary steps in the emergence of blood coagulation. Time periods of gene gain and gene loss are shown by *shaded boxes* on the evolutionary timeline.

thrombin-like activation. This scenario has similarities to the system that evolved independently in crustaceans like horseshoe crabs and lobsters, in which crosslinking enzyme leaks from damaged cells and causes a hemolymph protein to polymerize into a gel.

PT then underwent a gene duplication. The new gene (ancestral FX) would have undergone amino acid substitutions (e.g., to the substrate recognition pocket), resulting in a change in its substrate from fibrinogen to PT itself. There is some evidence that a precursor for FV/FVIII also arose around the same time, serving as a cofactor for FX. The ability of FX to activate PT released the dependence of PT on TF for its activation. A local gene duplication of FX resulted in the appearance of FVII only a short time before the last common vertebrate ancestor emerged (again, this duplicated gene underwent functional diversification with alteration of its substrate specificity, in this case from PT to FX). Thus, at the dawn of the vertebrates, blood coagulation was represented by the extrinsic cascade (TF-FVII-FX-PT-fibrinogen) alone. The next major change was the addition of FIX in the teleost lineage. This was accompanied by the appearance of distinct FV and FVIII genes. The contact system SPs (XII, XI, PK) appeared only with the tetrapods. The increasing complexity of the clotting cascade likely reflected the increasing demands of hemostasis in a wider spectrum of environments.[3] By enhancing the amplification property of the coagulation response, the addition of new proteases may have provided the necessary protection for animals with higher pressured cardiovascular systems and higher metabolic rates.

CHAPTER

3 Molecular and Clinical Genetics

LESLEY EVERETT, KARL DESCH, AND DAVID GINSBURG

Keeping up to date with the remarkable progress in human genetics and the rapidly changing genomic laboratory toolbox poses a significant challenge for hemostasis physicians and scientists. This chapter provides a review of fundamental concepts in molecular genetics and an overview of key genetic technologies.

GENOME STRUCTURE AND DNA SEQUENCE VARIATION

The first draft of the human genome was published in 2004, resulting from a publicly funded, international effort (The Human Genome Project) utilizing Sanger sequencing.[1] The human genome is packaged into 23 pairs of chromosomes, including 22 pairs of autosomes and 1 pair of sex chromosomes (XX or XY), with each chromosome containing a single double-stranded DNA molecule. Human chromosomes range in length from 51 to 249 megabases (Mb), with an average length of about 135 Mb.[2] The complete haploid human genome is approximately 3 billion base pairs (bp), with 6 billion base pairs for the full diploid genome. In addition to the 23 pairs of nuclear chromosomes in any human cell, there also exists a small mitochondrial chromosome (mtDNA molecule) that is present in each mitochondria and thus in multiple copies in the cytoplasm of each cell. The mtDNA molecule is only 16.6 kilobases (kb), a tiny fraction of the total human genome size.[2] Nevertheless, mutations of mtDNA cause a variety of human diseases and are also implicated in aging and age-associated disease.[3]

Only approximately 1.5% of the human genome corresponds to protein-coding sequence (~21,000 genes), while the remaining intergenic DNA is composed of repetitive sequences, control regions, and large sections of the genome with unknown function. Human protein-coding genes show enormous variation in size and organization. The average length of a gene is 53.5 kb, but genes can range in length from several hundred bp up to 2,400 kb (dystrophin).[2] Gene length in nucleotides typically correlates with the size of the encoded protein, but this in part depends on the number and size of *introns* and *exons* in each gene. An intron is a portion of a gene that is transcribed into RNA, but does not code for amino acids and is removed by splicing to generate the mature messenger RNA (mRNA) that is translated into protein. All but a very small number of human protein-coding genes contain introns. In contrast, exons are the portions of a gene that are retained in the mature mRNA. Though all the DNA sequences that encode amino acids are contained in exons, noncoding exons also exist, and these contain the 5′ and 3′ untranslated regions (UTRs) of each mRNA.

The average number of exons per gene is 9.8 (range 1 to 363), and the average exon size is 288 bp (range <10 bp to 18.2 kb). The distribution of genes along and between chromosomes is not uniform. Some chromosomal regions are densely populated with genes, while other regions (often referred to as "gene deserts") are gene poor. At the chromosomal level, some chromosomes have substantial regions of tightly packed (heterochromatic), transcriptionally silent DNA; these regions generally contain many repetitive DNA sequences and very few genes.

In addition to the coding exons, another 3% to 5% of the genome is composed of highly conserved noncoding sequences. These regions are thought to contain important regulatory sequences that may play critical roles in vertebrate development, regulation of transcription, DNA replication, and chromosome pairing and condensation.[4,5]

DNA Sequence Variants

Despite vast phenotypic variation in the population, human beings are genetically very similar. One individual human genome differs from another by approximately 1 nucleotide in every 1,000 bp (0.1%). Thus, each haploid human genome of 3×10^9 bp harbors approximately 3,000,000 DNA variants, most of which are rare and predominantly found in noncoding DNA such as introns and intergenic regions.

DNA sequence variants are classified by their frequencies in the population (common or rare) and by their nucleotide composition (single-nucleotide variants [SNVs] or more complex structural variants).[6] Some sequence variants are associated with human disease, while other sequence variants are "silent" or nonpathogenic.

All DNA Sequence Polymorphisms are Due to Mutations, but not All Mutations Result in Polymorphisms

A *mutation* is any change of an ancestral base-pair sequence to a different nucleotide. Rare DNA sequence variants may be unique to an individual or a family. In contrast, *polymorphisms* are common differences in DNA sequence, strictly defined as having a frequency ≥1% for the less common allele(s). Thus, all polymorphisms are due to mutations, but not all mutations result in polymorphisms.

A mutation may be (a) a single base-pair substitution, (b) a deletion or insertion of 1 or more base pairs (*indel*), or (c) a larger deletion, insertion, or other rearrangement of genetic material. Mutations may be neutral (i.e., cause no observable change in phenotype or functional disruption) or deleterious (disease causing). In humans, new mutations occur approximately every 1×10^{-8} bp/generation, which corresponds to approximately 60 new genetic mutations per individual.

However, >98.5% of mutations occur in introns or intergenic regions (noncoding regions), so it is difficult to assess the consequence and implication of these mutations for human health and disease susceptibility.

Most well-characterized disease-causing mutations occur in exons or in exon/intron junctions. DNA mutations may disrupt normal gene expression or function in several ways (See FIGURE 3.1 and Chapter 4). *Point mutations* are the replacement of a single-base nucleotide with another nucleotide. Some point mutations within the coding sequence do not alter the encoded amino acid (*synonymous substitution*) and have no effect on the function or expression of the gene. However, a subset of synonymous mutations may alter the structure, function, and expression level of proteins via other mechanisms.[7] *Missense mutations* (*nonsynonymous substitutions*) are changes in the DNA sequence that cause one encoded amino acid to be changed to a different amino acid, thus changing the overall peptide sequence of the gene product. Some missense mutations are deleterious to protein function, while others may be neutral.

Nonsense mutations are another type of nonsynonymous substitution, changing a specific amino acid codon to a stop codon and thereby producing a shortened protein product. *Frameshift mutations* result from the insertion or deletion of a number of nucleotides (not divisible by 3) that alters the normal protein-coding *reading frame*. The reading frame of a DNA or RNA molecule refers to the sequence of three-letter codons that can be translated into amino acids. A frameshift mutation changes the amino acid sequence downstream of the mutation, often resulting in a premature stop codon. Of note, small insertions/deletions (*indels*) of a multiple of three nucleotides will insert or delete one or more amino acids, but are not frameshift mutations because they do not alter the reading frame.

Finally, *splice-site mutations* result in an altered RNA sequence by changing the specific site at which splicing of an intron takes place during mRNA processing. Splice-site mutations may lead to the production of aberrant proteins. However, mutations far from a splice site may also affect splicing via alternate mechanisms[8] or may be implicated in abnormal polyadenylation of mRNAs, RNA stability, or transcript processing.[2] An important cellular mRNA surveillance mechanism known as *nonsense-mediated decay* (NMD) results in the instability of mRNA-containing nonsense mutations, thereby reducing the expression of truncated, potentially harmful proteins.[9]

Mutations that functionally disrupt protein-coding genes, known as *loss-of-function (LOF) mutations*, are surprisingly common in the human genome. LOF variants have historically been assumed to cause disease, as is the case for many Mendelian diseases. However, recent large-scale sequencing projects have revealed that apparently healthy individuals harbor at least 100 LOF variants in their genomes, including approximately 30 in the homozygous or compound heterozygous state.[10]

Some LOF variants that are common in healthy individuals have been known and well characterized for years, such as the O allele of the blood group ABO antigen locus, and other variants that contribute to variable drug-metabolizing capacity between individuals. Nevertheless, the finding that healthy individuals carry dozens to hundreds of seemingly benign LOF variants came as a great surprise to the scientific community. Even more startling is the mounting evidence that gene disruption may actually be beneficial in some cases.[10]

It is possible for one disease to result from many different types of mutations in a given gene. For example, over 1,000 unique mutations causing hemophilia A are reported in the worldwide hemophilia database (HAMSTeRS).[11] As a result of its X-linked inheritance, hemophilia A is observed with a high frequency in the human population (1:5,000 male newborns worldwide) (Chapter 51). As Haldane predicted in 1935, one-third of males with a lethal X-linked disorder should represent *de novo* somatic genetic mutations in eggs or sperm,[12] based on the assumption that one-third of lethal X-linked mutations are carried in males and will be lost in each generation. Thus, most hemophilia A mutations are expected to be on average only a few generations

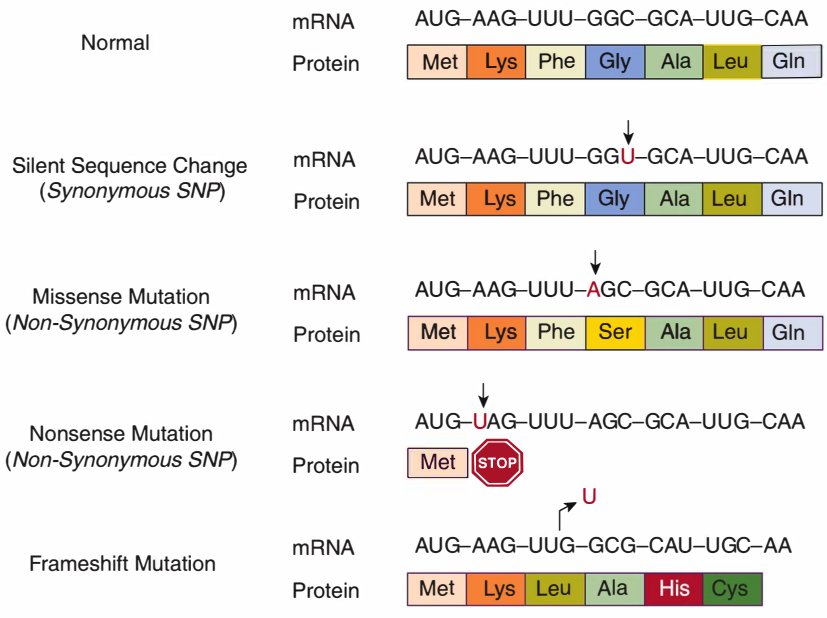

FIGURE 3.1 Examples of different classes of mutation.

old. Many of these mutations occur at CpG dinucleotides, which are known hotspots for mutation in mammalian genes.[13,14]

Mutations occurring outside of coding regions, such as in regulatory regions or in splice-site consensus sequences, may alter gene transcription or lead to alternative mRNA transcripts, respectively. Of historic interest, by analyzing DNA recovered from skeletal bone specimens of the Romanov family, a mutation in the *F9* gene predicted to alter RNA splicing was identified as the cause of the "Royal Disease" transmitted from Queen Victoria to the Royal families of Europe, thereby determining that this disease was hemophilia B, not the more common hemophilia A.[15]

Finally, in addition to smaller coding and noncoding mutations, structural rearrangements comprise another important class of genetic mutations, including deletions, insertions, inversions, and chromosomal translocations. Such larger genomic disruptions have been observed to cause hemophilia A, including Line 1 retrotransposon insertion.[11,16] Of particular note, the recurrent intron-22 inversion in the *FVIII* gene accounts for approximately 35% to 45% of all severe hemophilia A cases.[17] Duplications or deletions of large segments of DNA termed *copy number variations* (CNVs) are surprisingly common in the human genome. CNVs ranging in size from thousands to millions of base pairs may be present in anywhere from 0 to 2 or more copies when comparing one individual to the next.[18] CNVs can encompass entire genes or groups of genes, leading to gene dosage imbalance. Healthy individuals harbor multiple CNVs, which likely contribute to normal trait variation, though a subset of CNVs are associated with disease or disease susceptibility. Until recently, structural variants were technologically difficult to detect and characterize, as compared to single-nucleotide substitutions. Common structural variants are now estimated to involve between 9 to 25 Mb (0.5% to 1%) of the genome.[6]

Genetic Polymorphisms

As defined above, the formal definition of a polymorphism is any sequence or trait for which the less common or minor form(s) exhibit a population frequency of ≥1% (Table 3.1). These variants are considered to be *common* in the population. Common variants are not generally deleterious or associated with disease, which is consistent with the expectation that deleterious mutations would not typically be expected to reach a frequency of ≥1% in the population. *Single-nucleotide polymorphisms* (SNPs) represent positions in the genome where two or occasionally three alternative nucleotides are common in the population. Though the term "SNP" is typically used to refer to all single-nucleotide DNA variants, even those with minor allele frequencies ≤1%, the latter should more correctly be identified as SNVs. Unlike common polymorphisms with relatively high population frequencies, variants occurring at a frequency <0.01 in the population are considered to be rare. These variants are also known as "private" polymorphisms because they are often restricted to specific pedigrees in a population.

Of note, the terms *polymorphism* and *neutral variant* are often erroneously used synonymously. However, rare variants can be neutral and common polymorphisms can be deleterious (Table 3.1). In clinical practice, rare sequence changes in a disease gene in a patient can often only be described as "unclassified variants" or "variants of unknown significance." The relative frequency of neutral, near-neutral, and nonneutral genetic variants remains to be precisely determined (Table 3.2).[19]

Balanced polymorphisms represent a special class of genetic variant observed under balancing selection. In this case, an individual who is heterozygous at a particular genetic locus has a greater fitness or survival advantage compared to either type of homozygous individual, a phenomenon known as *heterozygote advantage*. For example, individuals with sickle cell trait (heterozygote carriers of the HbS mutation) are asymptomatic with normal life expectancy, though they are resistant to *Plasmodium falciparum* malaria,[20] which is endemic in West Africa. A balance exists between selection against individuals who suffer from sickle cell anemia (homozygous for HbS) and selection for heterozygous HbS carriers who are resistant to malaria.

Table 3.1

Classification of DNA sequence variants

Variant Frequency	<1%	≥1%
"Normal"	Rare variant or "private polymorphism"	Polymorphism
"Disease"	Disease-causing sequence variant	Common disease-causing variant For example, FV Leiden (2.5% allele frequency) and the common Δ508 cystic fibrosis mutation (2% allele frequency)

Databases Catalog Common Genetic Variation

The International HapMap Project is a publicly available catalog of common genetic variation in the human population. By collecting SNP data from hundreds of individuals, investigators can predict the likelihood of neighboring SNPs being inherited together. This analysis takes advantage of the fact that discrete blocks of genetic sequences tend to be inherited together more often (or less often) than expected by chance, given their individual allele frequencies in the population. This type of statistical association between genetic alleles is known as *linkage disequilibrium (LD)*, and it typically results from the maintenance of ancestral *haplotypes* in the population. Haplotypes are a series of specific adjacent SNP alleles that are inherited together because they have not yet been broken up by meiotic recombination. Such patterns of SNPs that are strongly correlated with each other across individuals form a limited number of relatively small haplotype blocks (10 to 50 kb).[21] Haplotype blocks thus provide important clues for understanding the evolutionary and demographic history of human populations.[22,23]

Several known genetic mutations, including the FV Leiden mutation and the prothrombin G20210A mutation, arose from a single mutational event on a distinct founder haplotype.[24,25] Haplotype blocks allow for the construction of genomic maps in populations sharing a geographic or ethnic background.[26] The original 270 HapMap samples were derived from

Table 3.2

Glossary of terms

Allele	One of two or more versions of a gene.
Allelic heterogeneity	A single disorder, trait, or pattern of traits caused by different mutations within the same gene.
Alternative splicing	More than one mRNA may be generated from the same gene by use of different exons, resulting in the generation of related proteins from one gene, often in a tissue- or developmental stage–specific manner.
Codominance	The phenotype of the heterozygote individual includes elements of both homozygous phenotypes (the discrete contributions of both parental alleles are visible in the phenotype).
Complex genetic traits	Result from the combined effects of many genetic loci and environmental factors (multifactorial).
Copy Number Variant (CNV)	A DNA sequence (ranging from thousands to millions of base pairs) that is present at variable copy number among individuals within a population, as compared to a diploid reference genome.
Epigenomic modifications	Chemical marks, such as DNA methylation and histone acetylation, that mediate the dynamic regulation of gene expression by influencing which genes are expressed and which are repressed.
Exome	The complete sequence of all exons in the human genome, comprising about 1.5% of the entire genome.
Exon	The portions of a gene that are retained in the mature mRNA. Though all the DNA sequences that encode amino acids are contained in exons, noncoding exons also exist, and these contain the 5′ and 3′ UTRs of each mRNA.
Frameshift mutation	Results from the insertion or deletion of a number of nucleotides (not divisible by 3) that alters the normal protein-coding reading frame.
Gene	The fundamental physical and functional unit of heredity. A gene is an ordered sequence of nucleotides located in a particular position on a particular chromosome that encodes a specific functional product (i.e., a protein or RNA molecule).
Genome-wide association studies (GWAS)	Utilize large samples of unrelated individuals to identify population-wide statistical associations between disease phenotypes and tested genotypes.
Genetic heterogeneity	Different genetic variants underlying the same phenotype or trait in different individuals or families (includes locus and allelic heterogeneity).
Genome browser	A database of genome information with graphical user interfaces.
Haplotype	A series of specific adjacent SNP alleles that are inherited together because they have not yet been shuffled by meiotic recombination.
Incomplete penetrance	A subset of individuals inheriting a disease-causing mutation exhibit no symptoms of the disease.
Indel	Insertion or deletion of a few nucleotides.
Intron	A portion of the gene that is transcribed into RNA but is removed by splicing to generate the mature mRNA that is translated into protein.
LD	A statistical association between genetic alleles such that discrete blocks of genetic sequences tend to be inherited together more often (or less often) than expected by chance.
Locus	The chromosomal location of a gene or a specific genetic sequence.
Locus heterogeneity	The same genetic disorder, trait, or pattern of traits that can be caused by mutations in one of a set of two or more genes.
Mendelian	A monogenic trait or disease whose pattern of inheritance suggests it is caused by variation at a single genetic locus—a monogenic character.

Table 3.2

Glossary of terms *(Continued)*

miRNA	Small RNA molecules that are processed from small hairpin RNA (shRNA) precursors that are produced from miRNA genes. miRNAs are 21–23 nucleotides in length, and through the RNA-induced silencing complex, they target and silence mRNAs in a sequence-specific manner.
Missense mutation	Change in the genetic sequence that causes one encoded amino acid to be changed to a different amino acid.
Modifier gene	Genes acting together with environmental and stochastic effects to modulate the effect of a major Mendelian gene.
Mutation	Any alteration in a gene from its ancestral state—may be disease-causing or a benign variant.
Next-generation sequencing (NGS)	New DNA sequencing methods based on massively parallel sequencing of thousands of DNA sequences simultaneously.
Nonsense-mediated decay (NMD)	A cellular mRNA surveillance mechanism used to detect nonsense mutations and to prevent the expression of truncated or potentially harmful proteins.
Nonsense mutation	A change from an amino acid codon to a stop codon.
Nonsynonymous mutation	A mutation that changes the encoded amino acid sequence to another amino acid or a stop codon.
Phenocopy	An individual with a phenotype (often environmentally induced) mimicking one usually produced by a specific genotype.
Point mutation	The replacement of a single-base nucleotide with another nucleotide.
Polymorphism	Any sequence or trait for which the less common or minor form(s) exhibit a population frequency of ≥1%.
Positional cloning	Using knowledge of chromosomal location to identify a disease gene.
Proteome	The set of proteins expressed by the genetic material of an organism under a given set of environmental conditions.
Quantitative trait	Many complex traits and diseases are quantitative, meaning that the observable human trait or disease varies over a continuous (and measurable) range of phenotypes.
RNA-seq	Transcriptome profiling technique that uses deep-sequencing technologies to provide a precise measurement of levels of transcripts and their isoforms.
Semidominance	Also known as incomplete dominance, this occurs when the phenotype of the heterozygote is an intermediate of the phenotypes of the two homozygous genotypes.
SNP	A position in the genome where two or occasionally three alternative nucleotides are common in the population, with the less common or minor form(s) exhibiting a population frequency of ≥1%. In common usage, often referred to as SNVs.
SNV	Similar to an SNP, but includes those with minor allele frequency <1%.
Synonymous mutation	A genetic mutation that does not alter the encoded amino acid sequence.
Transcriptome	The total mRNA content of a cell at a given time.
Variable expressivity	A wide range in disease severity or other features of the phenotype among individuals inheriting the same disease-causing mutation.

Caucasians of European ancestry, Yoruba people from Nigeria, and Asian individuals of Japanese and Han Chinese origin and included data for over 3.1 million SNPs. Currently in Phase III of the study, HapMap now includes data from 1,301 samples taken from 11 different global populations, enabling detailed study of common and rare genetic variation in diverse human populations.[27]

Another useful source of sequence variation data is the single nucleotide polymorphism database (dbSNP), a free public archive cataloging genetic variation within and across different species. In contrast to the HapMap Project, dbSNP contains information about SNPs as well as several other types of sequence variants from multiple species. The most recent dbSNP release (Build 135, November 2011) includes a total of 436,271,275 SNPs from 102 different organisms.[27] Finally, the database of genotypes and phenotypes (dbGAP) reports the results of studies investigating the interaction of genotype and phenotype, including data from genome-wide association studies (GWASs), medical sequencing, and other molecular diagnostic assays (Table 3.3).

Many methods are now available to detect DNA sequence variants, though most are now being supplanted by direct DNA sequencing. As explained later in the chapter, recent advances in sequencing technologies now enable the sequencing of entire exomes (the total complement of expressed exons in a genome) and whole genomes.

IDENTIFYING HUMAN DISEASE GENES

Human genetic diseases fall into two broad categories: (a) monogenic disorders, which are typically characterized by Mendelian inheritance patterns (e.g., hemophilia, von Willebrand disease [vWD]) or (b) multigenic, complex diseases in which multiple risk—conferring alleles in many genes cumulatively contribute to the disease (e.g., diabetes, heart disease). Human Mendelian traits give characteristic pedigree patterns that are often easily recognizable, including autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked inheritance patterns. Rapid progress has been made in identifying the genes responsible for monogenic diseases, with about 3,000 now catalogued in the Online Mendelian Inheritance in Man (OMIM) database.[28] The identification of causative genes for complex diseases has proved difficult, but new methods and technologies are facilitating rapid progress in this area.

Mendelian Genetics

Mendelian traits and diseases can be dominant, recessive, or codominant. Almost all Mendelian diseases can be inherited maternally or paternally, except for sex-linked disorders, imprinting disorders, and mitochondrial genetic disorders (mitochondria are exclusively maternally inherited).[29] The terms *dominant* and *recessive* are properties of the traits, not the genes themselves. A trait is *dominant* if it is evident in an individual who is heterozygous for the causal mutation at the causative locus, and it is *recessive* if mutation in both maternal and paternal alleles at the locus is required to elicit a phenotype. Glanzmann thrombasthenia and Bernard-Soulier syndrome are both autosomal recessive conditions and are two of the most clearly defined platelet functional disorders at the molecular level.[30,31] Only individuals who are homozygous for the deleterious mutations are affected by disease, with heterozygous "carriers" of each mutation unaffected.

In complete dominance, the phenotype of the heterozygote is indistinguishable from that of the homozygote. Such disorders are quite rare and typically result from gain-of-function or dominant-negative mutations. Though a homozygote has never been reported, the rare disorder α_1-antitrypsin Pittsburgh (α_1-AT-P) might be expected to exhibit complete dominance. This mutation (conversion of methionine to arginine at residue 358 [Met358Arg]) converts α_1-AT into a potent thrombin inhibitor resembling antithrombin III.[32]

Incomplete dominance, also known as *semidominance*, occurs when the phenotype of the heterozygote is an intermediate of the phenotypes of the two homozygous genotypes. For example, homozygous hereditary protein C deficiency results in neonatal purpura fulminans (Chapters 81 and 98), whereas heterozygous individuals may exhibit venous thrombosis with typical onset in the third to fourth decade of life.

Finally, in *codominance*, the phenotype of the heterozygote is the same as both homozygous phenotypes (the discrete contributions of both parental alleles are visible in the phenotype). ABO blood type is an instructive example; the I^A and I^B alleles are codominant in producing the AB blood group phenotype because both the A-type and B-type antigens are produced.

A genetic mutation may lead to different genetic disease phenotypes in different individuals. If a subset of individuals inheriting a disease-causing mutation exhibit no symptoms of the disease, this is referred to as *incomplete penetrance* (vWD and FV Leiden are well-known examples in hemostasis). Similarly, a wide range in disease severity or other features of the phenotype among individuals inheriting the same disease-causing mutation is referred to as *variable expressivity*. For example, the same platelet disorder might manifest with variable tendencies toward mucosal bleeding, menstrual bleeding, or epistaxis in different individuals. Although Mendelian disorders are typically due to mutations at a single genetic locus, incomplete penetrance and variable expressivity may result from the action of other genes, termed *modifier genes*,[33] acting together with environmental and stochastic effects. It is also possible for a member of an affected pedigree to exhibit manifestations of disease, yet lack the disease genotype segregating through the pedigree. For example, consider a family with one or more individuals exhibiting easy bruising and frequent nosebleeds, without inheriting the familial vWD mutation. These individuals are known as *phenocopies*, and their bleeding phenotypes may result from any number of causes unrelated to the familial VWD mutation.

Linkage Analysis for Genetic Mapping of Mendelian Traits

The genetic loci underlying most Mendelian disorders were historically identified by careful genetic and phenotypic analysis of affected family pedigrees. Through a process known as *linkage analysis*, the gene responsible for an observable phenotype or disease of interest is "mapped" to a specific chromosomal segment.[2] Mapping a disease locus requires the genotyping of hundreds to thousands of markers spanning the genome in both affected and unaffected family members. Pedigrees are then checked to identify specific genetic markers that are coinherited with the disease. An informative genetic marker in close physical proximity to a disease-causing allele is "linked" to that allele, serving as a proxy for the "presumed" nearby deleterious sequence variant. Following initial linkage studies, a process known as *positional cloning* (locating the precise position of a the disease-causing gene) has enabled the identification of many genes encoding important proteins in the coagulation system, as well as thousands of other known pathologic and nonpathologic Mendelian traits.[28]

There are several barriers to successful positional cloning. Large pedigrees are generally required to achieve statistical significance and to identify a gene's chromosomal location with high resolution. Other factors, including *incomplete penetrance, phenocopies, locus heterogeneity*, and genotyping errors can also limit the power of linkage analysis. Locus heterogeneity occurs when a single disorder or trait is caused by mutations in genes at two or more different chromosomal loci. For example, mutations in the *LMAN1* or *MCFD2* genes cause the same rare autosomal recessive bleeding disorder, combined deficiency of coagulation Factor V and Factor VIII (F5F8D).[34] In contrast, *allelic heterogeneity* refers to the existence of many different mutations within the same gene in unrelated people with the same phenotype, as described above for *FVIII* mutations in hemophilia A.

Complex Genetic Traits

Most common human genetic diseases are not monogenic and do not exhibit Mendelian inheritance patterns. Rather, they result from the combined effects of many genetic loci and environmental factors. Hence, these phenotypes are termed *complex* or *multifactorial*. Complex diseases include thrombophilia, hypertension, coronary artery disease, diabetes, obesity, cancer, and many others.

Many complex traits and diseases are quantitative, meaning that the observable human trait or disease varies over a continuous (and measurable) range of phenotypes. Genetic factors known as *quantitative trait loci* (QTLs) are thought to influence or contribute to this interindividual variation in observable quantitative traits.[35] Blood pressure and von Willebrand factor (vWF) levels represent quantitative, continuous traits. vWD may be a Mendelian disease, but plasma vWF levels represent a widely varying quantitative trait in the population.

Genome-Wide Association Studies

Although linkage studies are well suited to detect variants with large effects and high penetrance, they often fail to detect variants of small effect. Most complex traits are determined by environmental factors combined with small effects of multiple genes. To overcome the limitations of linkage analysis, GWAS and candidate gene association studies have served as the primary analytic methods for investigating complex disorders.

GWAS[36] utilize large samples of unrelated individuals to identify population-wide statistical associations between disease phenotypes and tested genotypes. GWAS is based upon the assumption that unrelated individuals with similar phenotypes also share the same common genetic risk variants, which they inherited from a distant common ancestor. GWAS involve genotyping a large number of SNPs to identify loci that are more or less common in people with the disease as compared to those without the disease. It is presumed that the SNPs found more commonly in diseased individuals are in linkage disequilibrium with the actual risk variants. Just as in linkage analysis, an SNP found to be associated with disease in a GWAS is merely a physical marker for the presumed disease-susceptibility variant. The specific SNP itself does not necessarily directly contribute any risk of disease, but rather serves as a proxy for a nearby causative variant.

The power of GWAS to detect a low-effect locus depends upon the number of individuals studied, the allele frequency of the tagging SNP, and the allele frequency of the actual causative genetic variant. Hundreds to thousands of individuals with and without a trait or disease of interest are typically recruited, and each participant is genotyped for up to a million or more SNPs and structural variants.

Allele frequencies at each of the genetic markers are then correlated with trait variation (disease or no disease, or level of the quantitative trait) in the population-based sample. Since the disease-causing genetic variant is assumed to be within a conserved haplotype, genetic markers on this haplotype will be closely associated with the disease-causing variant (i.e., the marker and variant are in LD) and will be more commonly observed in disease subjects than in healthy controls.[36,37] The results of this type of analysis are typically presented as a *Manhattan plot*, a visual scatter plot with genomic coordinates displayed along the x-axis and a measure of statistical significance for each SNP displayed on the y-axis. An example of a GWAS to identify common susceptibility risk variants for venous thrombosis is shown in FIGURE 3.2. Since heterozygosity for FV Leiden is associated with a sevenfold increased risk of venous thromboembolic (VTE) disease[38] and non-O blood group carriers are also more predisposed to VTE than are O carriers,[39] the large GWAS signals at these loci are not surprising.

GWAS have now been completed for most common human diseases and many related traits, including cardiovascular disease, inflammatory bowel disease, asthma, neuropsychiatric disorders, rheumatologic disorders, cancers, and common traits including obesity, height, and hair color. As of mid-2011, the National Human Genome Research Institute has cataloged 1,449 published GWAS reporting statistically significant genetic associations (P values $\leq 5 \times 10^{-8}$) for 237 traits, and this list is updated weekly with new reports (FIGURE 3.3).

Several notable GWAS have identified variants that confer a substantial risk of disease, including a common variant in the complement factor H (CFH) gene, which is associated with a two- to fourfold increased risk of age-related macular degeneration (AMD), accounting for 20% to 50% of AMD risk.[40] Prior to this surprising report, CFH and other members of the complement pathway had no known association to AMD. Similarly, GWAS identified several loci associated with high levels of HbF,[41] including variants near the *BCL11A* gene leading to reduced *BCL11A* expression. Subsequent studies demonstrated that *BCL11A* is a key determinant of the fetal to adult hemoglobin switch, a major modifier of disease severity in sickle cell disease and severe β-thalassemia, and a novel therapeutic target for the treatment of these diseases.

More commonly, however, GWAS have identified many susceptibility factors of small biologic effect and limited heritability, meaning that a significant proportion of the genetic determinants of most complex diseases remain to be discovered. For example, GWAS have successfully identified >50 risk loci for type 2 diabetes, though these common genetic variants have only explained a portion of heritability and add little predictive value to existing conventional clinical risk factors.[42] Similarly, genetic factors are responsible for approximately 80% of variation in platelet count, a highly heritable trait.[43] Despite this large heritable contribution, a recent meta-analysis of data from over

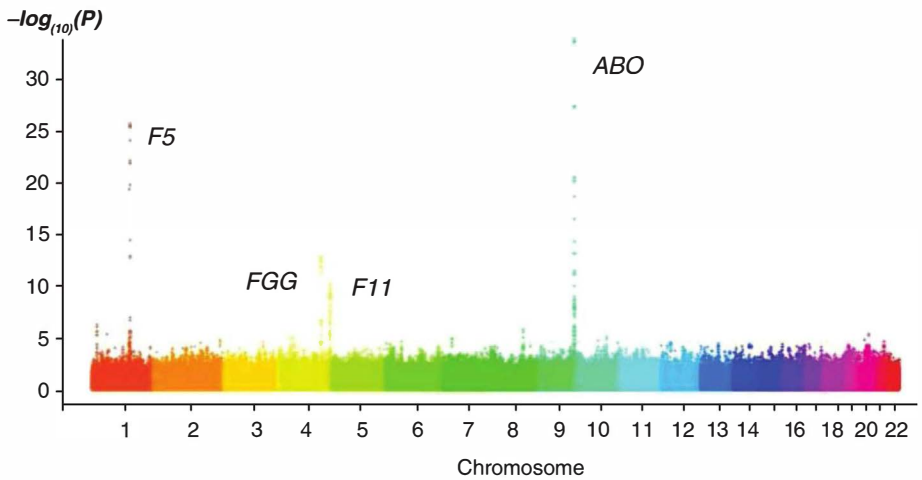

FIGURE 3.2 Thrombosis GWAS Manhattan plot of the association results from the combined analysis of two imputed GWAS data sets for 2,475,305 SNPs. No novel loci associated with venous thrombosis were identified. Through imputation analysis, only 99 SNPs reached genome-wide significance, and all of these SNPs were located within the *ABO, F5, FGG, or F11* loci. (Adapted from Germain M, Saut N, Greliche N, et al. Genetics of venous thrombosis: insights from a new genome wide association study. *PLoS One* 2011;6(9):e25581, with permission.)

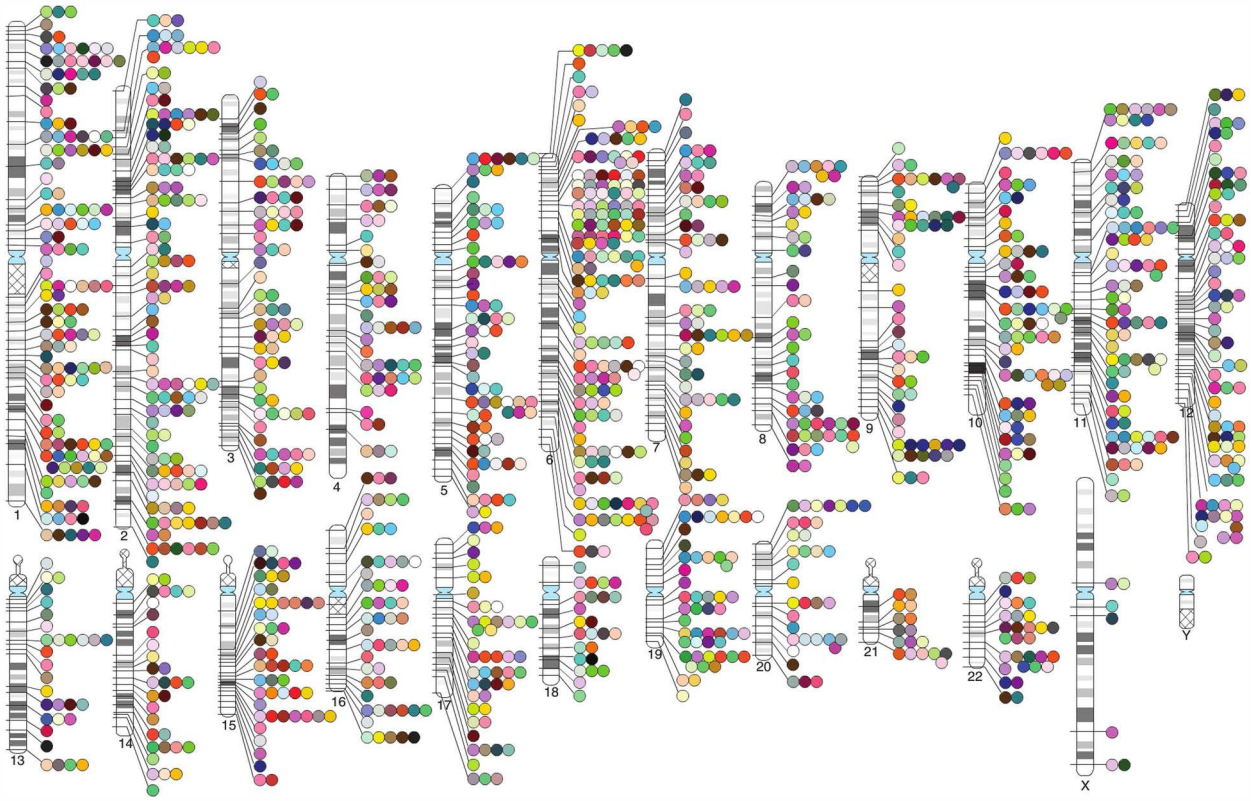

FIGURE 3.3 Published genome-wide associations through June, 2011. As of June, 2011, the National Human Genome Research Institute had cataloged 1,449 published genome-wide association studies demonstrating statistically significant genetic associations ($p \leq 5x10\text{-}8$) for 237 traits on all 22 autosomal chromosomes and on the X-chromosome. Each circle represents a unique reported association, and different colors correspond to different diseases.

66,000 individuals identified 68 genomic loci that cumulatively only account for 4.8% of the phenotypic variance in platelet count and 9.9% in mean platelet volume.[44] The remaining so-called missing heritability of these complex disorders could be due to the cumulative effect of multiple variants not detectable by current GWAS methods.[45,46] Of particular note, the contributions of most of these common variants of small effect size are not generally clinically useful for diagnosis, prognosis, or choice of therapy.[47] Advances in human genetics/genomics may eventually explain much of this missing heritability, with important implications for medical management.

Most Previously Reported Single-Gene Association Studies are Wrong

Single-gene association studies are based upon the expectation that an informative genetic marker located nearby a candidate gene should be more common in patients than in healthy controls. This approach has several inherent biases and shortcomings, including false-positive associations from multiple observations, as well as variable effects of population substructure.[47,48]

Very few of these previous reports have been confirmed by GWAS, indicating that they likely represent false-positive statistical errors. Instructive examples in hemostasis and thrombosis include the hundreds of candidate gene association studies performed to analyze the common plasminogen activator inhibitor 1 4G/5G and *MTHFR* gene polymorphisms for their roles in thrombosis, hypertension, coronary artery disease, and many other diseases. Despite the large number of reports, neither of these variants has been detected in any of the multiple well-powered GWASs for these same conditions.

Distinguishing Between Disease-Causing Mutations and Neutral Sequence Variants is Often Difficult

In addition to individual human genes, it is now possible to sequence entire exomes or genomes to identify genetic mutations. This raises the important questions of which mutations are disease causing and which are not? Distinguishing between disease-causing mutations, incidental gene-altering mutations, and neutral sequence variations is a critical clinical problem. The presence of widespread genetic diversity as well as LOF alleles in healthy individuals poses a major challenge for analysis of human genomes, particularly for clinical genome-sequencing studies.[49] For example, simply identifying a novel variant in a suspected gene in a patient does not establish causality. A rare variant in the *FVIII* gene of a hemophilia A patient that is absent from a set of healthy controls could be a neutral "private polymorphism" or a disease-causing mutation. While some changes in genetic sequence lead to obvious gene disruption (e.g., large deletions, rearrangements, frameshifts, or nonsense mutations), the impact of missense mutations is often unclear. Classifying the latter mutations often requires functional analysis of the encoded gene product. Though computational programs can estimate the functional consequence of genetic mutations,[49,50] these predictions are of limited clinical utility. In the absence of detailed functional

Table 3.4

Commercially available NGS platforms

Sequencing Platform	Read Length	Throughput	Sequence by Synthesis Method
Roche/454	400–600 bp	500 Mb/run	Pyrosequencing
Illumina HiSeq/Solexa	100 bp	200 Gb/run	Reversible terminators
ABI/SOLiD	50–100 bp	>100 Gb/run	Sequencing by ligation
Danaher/Dover/Azco Polonator	26 bp	8–10 Gb/run	Sequencing by ligation
Helicos Biosciences	25–55 bp	21–37 Gb/run	True single-molecule sequencing
Ion Torrent	>400 bp	>1 Gb/run	Sequence by synthesis on a semiconductor chip
Pacific Biosciences (PacBio RS)	>1,000 bp	~10 Mb/run	Single-molecule sequencing by "strobe sequencing"
Complete Genomics	Current: Short reads (70 bp) 2012: Long-fragment reads (LFR) (up to 10,000 bp)	>70 Gb/run	Current: Ligation-based chemistry LFR: will provide the ability to determine strand-specific sequences and enable whole-genome haplotyping.

analysis, missense mutations discovered in clinical testing must often be classified as "variants of unknown significance."

NEXT-GENERATION SEQUENCING

New DNA sequencing methods known as "*next-generation sequencing*" (NGS), or massively parallel DNA sequencing, were developed in the early to mid-2000s as a major advance over traditional Sanger sequencing.[51,52] High-throughput NGS generally involves a process of DNA template preparation, sequence generation, genome alignment, and assembly. Similar to Sanger sequencing, many NGS methods employ a "sequence-by-synthesis" approach, recording DNA sequences as each new nucleotide is incorporated into a growing DNA strand. These methods have dramatically improved sequencing speeds and high-throughput capacity, and they have lowered the cost of sequencing on a per base-pair basis. A number of NGS platforms are available commercially, each with slightly different profiles for base read length, error rate, throughput capacity, and method (Table 3.4). NGS technologies continue to improve rapidly, though significant limitations remain, including a relatively high (1%) error rate, requiring a high level of redundancy (often in the range of 50 to 100×) to distinguish true sequence variants from sequencing errors.

NGS technologies are already widely used for rapid genome sequencing[53,54] and for detailed analysis of transcribed mRNAs extracted from different cells and tissues. Massively parallel sequencing also plays a central role in new methods for the study of DNA–protein interactions (ChIP-seq, methyl-seq, and DNase-seq), defining genome-wide-binding patterns for transcription factors and other important regulatory molecules.[55,56]

Rapid advancements in DNA sequencing technologies have made the long-awaited "$1,000 genome" an imminent reality.[57] Improvements in NGS technology throughput have dramatically outpaced the rates of growth in computing and data processing capacity (FIGURE 3.4). Despite major advances in the

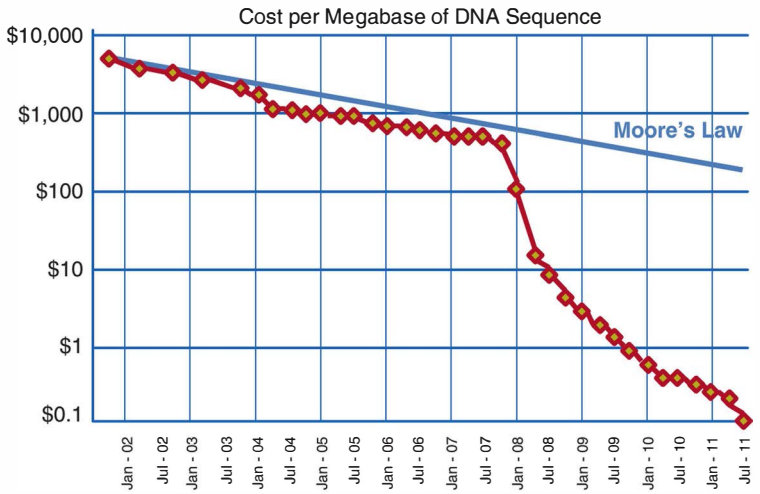

FIGURE 3.4 Massively parallel sequencing costs relative to Moore's law. As modeled by Moore's Law, historical trends in computing hardware, data processing, and memory capacity show that the capabilities of many digital electronic devices improve at roughly exponential rates. NGS sequencing technologies have outpaced advances in computing and data processing power.

computational analysis of large sequencing datasets, future developments in DNA sequencing technology are likely to increase the need for even more powerful computational platforms.[58]

NGS Technologies and Monogenic Diseases

The availability of NGS has enabled new approaches to the search for novel disease-causing mutations in diseases for which the responsible gene is unknown. Exome sequencing specifically targets the approximately 1.5% of the genome containing approximately 80% of the disease-causing mutations for Mendelian diseases.[59,60] The remaining approximately 20% of Mendelian disease mutations not detected by exome sequencing likely lie in introns or intergenic regulatory sequences, or are simply missed because only approximately 90% of the exome is efficiently captured and sequenced by currently available exome-sequencing platforms.

Exome sequencing has successfully identified mutations responsible for monogenic disorders that would previously have required large pedigrees for linkage analysis and positional cloning. For example, sequencing the exomes of just four affected individuals from three independent families was sufficient to identify the gene responsible for Miller syndrome, a rare Mendelian disorder of (formerly) unknown etiology.[61] Similarly, exome sequencing identified *NBEAL2* as the causative gene for gray platelet syndrome, a recessive platelet disorder characterized by mild thrombocytopenia with large platelets and lack of α-granules.[62]

Whole-genome Sequencing for Complex Disorders

Whole-genome sequencing will likely provide the best means of identifying rare causal variants and filling in the "missing heritability" currently observed in GWAS. It will permit the identification of less common variants that may have relatively large effects on disease risk.[63] Already, whole-genome sequencing for structural variants such as CNVs has led to the delineation of new microdeletion and microduplication syndromes.[64] As NGS costs continue to fall, whole-genome sequencing will become an increasingly routine part of genetic and clinical evaluation, bringing with it the challenges of storing and interpreting tremendous volumes of data.

Perhaps no discovery or technologic advance has transformed genetics research more dramatically than NGS. These powerful new techniques are used to address a myriad of biologic questions with unprecedented implications for clinical medicine and population biology. NGS has been the cornerstone for a number of large-scale projects to explore the range of genetic variation across the world's population, including the 1,000 Genomes Project, which now includes data from 2,500 individuals representing 27 different populations.[65] All data generated are publicly available and are being incorporated into other resources such as the Human Gene Mutation Database (HGMD) (Table 3.3) in order to improve annotations of gene models and disease-associated sequence variants.

STUDYING GENE FUNCTION IN THE POSTGENOME ERA

NGS technologies have enabled a shift in the scope of genetic research from the study of individual genes and their products to global, genome-wide analyses in which many or all gene products are studied simultaneously, an approach sometimes referred to as *functional genomics*.

Transcriptome Data Informs Gene Function

Although the genome itself is virtually identical in most nucleated cells of an organism, gene expression patterns vary dramatically among different tissues and cell types. Differential tissue expression patterns are mediated through the tight regulation of DNA transcription, RNA processing, protein synthesis, and posttranslational modification. The mRNA *transcriptome* reflects the results of DNA transcription, RNA processing, and RNA turnover, and therefore represents the fraction of the whole genome that is transcribed into mRNA (<5% in humans). Similarly, the *proteome* is the combined output of the transcriptome followed by mRNA translation, posttranslational processing (including protein cleavage and modification), and protein turnover.

Quantitative Transcriptomics by Microarray Hybridization or Massively Parallel Sequencing

Genome-wide mRNA expression analysis was previously performed exclusively by DNA *oligonucleotide microarrays*, also known as gene chips or DNA chips.[66] Microarrays are small slides with individual DNA oligonucleotides representing sequences of interest (probes) attached to the solid surface. Probes may be short sections of genes or other DNA elements used to capture and hybridize cDNA molecules in a biologic sample. Microarrays are thus used to measure the expression levels of large numbers of genes simultaneously by differentially labeling sample mRNAs with fluorescent tags and quantifying their relative hybridization to the microarray.

Numerous DNA microarrays are commercially available, many of which are capable of detecting expression of all approximately 21,000 human or mouse genes. Others are used for targeted research initiatives, such as "metabolomics" microarrays that include sequences corresponding to all the known genes involved in metabolic pathways. Hybridization-based microarrays only detect the expression of known transcripts that were purposefully included on the array. Hence, rare transcripts or alternatively spliced mRNA variants are generally missed.

RNA-Seq Reveals the Complexity of Transcriptomes

RNA-seq, otherwise known as massively parallel cDNA sequencing, represents a major advance in gene expression analysis.[67] Compared to microarrays, this technology does not have an upper limit for quantification, and it provides a much expanded dynamic range of expression levels over which transcripts can be detected (>9,000-fold in a recent *Saccharomyces cerevisiae* experiment[68] and spanning a range of five orders of magnitude for analysis of 40 million mouse sequence reads[69]). RNA-seq analysis also enables the identification and quantification of novel transcripts and alternatively spliced forms, as well as the comprehensive, detailed analysis of transcription initiation start sites. Furthermore, it improves the detection of alternatively spliced transcripts and gene fusion transcripts in physiologically normal and disease settings. For example, RNA-seq analysis of platelets from a patient with gray platelet syndrome identified abnormal transcripts resulting from a splice-site mutation (FIGURE 3.5), contributing to the identification of *NBEAL2* as the responsible gene.[70] The large amount of tissue-specific gene expression profiling data that have been generated through microarray and RNA-seq studies has been systematically catalogued in a number of databases (Table 3.3).

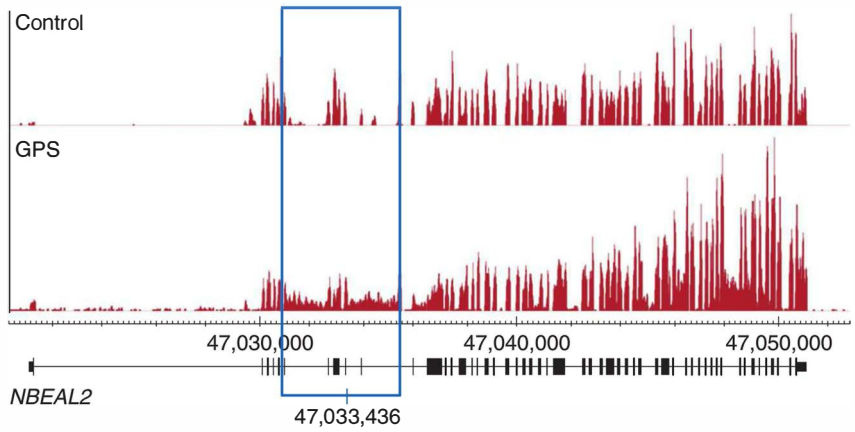

FIGURE 3.5 Abnormal sequence reads in *NBEAL2* transcripts in platelet RNA from an individual with GPS. *NBEAL2* transcripts expressed in platelets isolated from a healthy donor (top) and a patient with grey platelet syndrome (bottom). The red box outlines a region where introns are abnormally retained in *NBEAL2* transcripts from GPS platelets.

Genomes and their Messenger Molecules are Highly Dynamic

Gene expression and transcriptome studies have revealed that genomes exist in highly dynamic states, with numerous regulatory elements and reversible DNA modifications. *Epigenomic modifications* are chemical marks, such as DNA methylation and histone acetylation, which mediate the dynamic regulation of gene expression by influencing which genes are actively expressed and which are repressed. Epigenomic modifications serve as an additional set of instructions and regulatory control for the cell's transcriptional machinery, although they are not part of the actual double-stranded DNA helix. Nevertheless, they may be passed on during cell division from a mother cell to its daughter cells, and in some instances, from one generation to the next.[71,72]

In addition to mRNAs, several other classes of RNAs exist that also play important regulatory roles in the cell.[73] For example, *microRNAs (miRNAs),* a class of RNAs first discovered in plants, add another layer of gene expression regulation. miRNAs modulate protein expression primarily by degrading mRNA or repressing translation by recognizing specific complementary sequences in the target mRNA. Current estimates suggest that more than 60% of human protein-coding genes contain miRNA target sites in their 3′ UTR.[73] miRNAs play important roles in hematopoiesis, including platelet production and activation,[74] the pathogenesis of vascular disease,[73] and presumably many other disorders.

THE ROLE OF MODEL ORGANISMS IN GENETIC RESEARCH

Model organisms represent a powerful research tool for studying the pathophysiology of human disease. Laboratory mice are a widely utilized mammalian genetic model, in large part because they reproduce quickly and because the mouse genome is relatively easy to manipulate.[2] Recent progress has also markedly expanded the toolkit for manipulation of the rat genome, particularly for use in cardiovascular disease research.[75]

Essentially any gene of interest can be inserted into the mouse or rat germline (transgenic animals) or inactivated (i.e., "knocked out") by replacement or disruption of an endogenous gene. Even a specific mutation can be introduced into an endogenous gene in its natural location by creating a "knock in" genetic allele. As a result of this technology, thousands of genetically distinct mouse models are currently available, including unique inbred strains and genetically engineered mutants mimicking many human diseases. These mice are cataloged and available for purchase from The Jackson Laboratory (JAX), the UC Davis Knockout Mouse Project (KOMP), and The European Conditional Mouse Mutagenesis Program (EUCOMM) (Table 3.5). Mouse models have proved to be extremely useful for the study of hemostasis and thrombosis, with genetically deficient mice generated for most known human coagulation factors.[76]

Chemical mutagenesis is another powerful tool for the generation of new animal models, a process in which experimental animals are exposed to DNA-damaging chemicals and screened for resulting phenotypes.[77] This technique has been used to identify genes involved in megakaryocyte and platelet development, among many others.[78,79] *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis has also been used to elucidate pathways in blood and vessel development in zebrafish[80] and to identify modifier genes that lessen the severity of thrombosis in mice carrying Factor V Leiden and tissue factor pathway inhibitor mutations.[33]

PERSONALIZED MEDICINE

GWAS have identified many disease genes and susceptibility alleles, generating much new information with potential clinical importance. However, the synthesis and reduction of this information to practice has not been straightforward.[47] Genetic testing in approved clinical testing laboratories is available for approximately 3,000 single-gene disorders. The result of some genetic tests provides information that clinicians can immediately act upon, thus significantly altering medical management; examples include newborn screening programs and genetic testing for some cancer predisposition syndromes. In contrast, some genetic tests are informative but have no real impact on medical management (e.g., Huntington disease, Alzheimer disease, etc.).[47] The clinical utility and predictive value for many of the remaining genetic tests is often unclear.

For example, genetic factors account for approximately 60% of the overall risk of VTE. Though FV Leiden contributes approximately 25% of the overall attributable risk, the lifetime penetrance of VTE is still only 10% in FV Leiden individuals, and no specific VTE prophylactic treatment is indicated for asymptomatic subjects. In addition, following an initial episode of VTE, the recurrence rate does not differ significantly between patients with and without this common polymorphism. Thus,

FV Leiden testing is not generally indicated on clinical grounds, since current treatment recommendations are not altered by the results of the test.[81]

Despite remarkable progress in identification of genes responsible for most known single-gene disorders, only a small subset of these discoveries have resulted in direct improvements in therapies to treat these diseases.[47] However, some of the most notable exceptions have been in the thrombosis and hemostasis fields, including the successful development of recombinant protein product replacement for hemophilia A and B, and the use of recombinant tPA to treat pathologic thrombosis.

Similarly, the practical implementation of modern pharmacogenomic discoveries to guide choice and mode of therapy has also been disappointing. Some of the most attractive opportunities in pharmacogenetic testing have been identified for hemostatic therapies, notably to guide treatment with the anticoagulant warfarin and the antiplatelet drug clopidogrel.[82]

Though common variants in the *CYP2/C9* and *VKORC1* genes account for approximately 30% of the interindividual variability in response to warfarin, prompting the FDA to include this information in the warfarin package inserts, such testing has not yet been shown to significantly improve clinical outcomes in warfarin-treated patients and is not widely used in clinical practice.[83] Similarly, while several trials are underway to demonstrate the potential utility of platelet reactivity testing for personalized antiplatelet therapy, genetic testing for *CYP2/C9* genotype has not yet proven useful for treatment optimization in the clinic.[84]

DIRECT-TO-CONSUMER GENETIC TESTING

Direct-to-consumer (DTC) genetic testing for large panels of SNPs is now widely available over the Internet, offering customers risk prediction for a broad range of common diseases, including thrombosis and coronary artery disease.[85] However, the changes in risk conferred by these SNPs are generally very modest, and often dwarfed by other easily measured clinical factors such as body–mass index and family history. In addition, risk prediction is highly inconsistent across providers.[86] Considering that some of the testing panels do include large-effect genetic risk factors, consumers may not always receive adequate genetic counseling in conjunction with DTC, and the impact of this testing on the subsequent interactions of these consumers with their physicians is potentially problematic.[87,88]

GENE THERAPY

Since alteration or mutation of genes often results in the synthesis of dysfunctional proteins, the identification of the defective gene for approximately 3,000 Mendelian disorders has raised considerable hope for direct correction of these conditions by *gene therapy*. Potential approaches include insertion of the normal gene into a nonspecific location within the genome to replace a defective gene, or repair of the abnormal gene. Though early progress was disappointing, including unfortunate adverse events,[89] recent success in treating rare immunodeficiency disorders and hemophilia has highlighted the promise and future

potential of this technology, including a recent successful report of adenovirus-associated vector-mediated gene transfer in hemophilia B.[90] In addition, though not generally considered gene therapy, recombinant protein therapeutics (tPA, *FVIII*, IX, etc.) have played a central role in the treatment of hemostasis disorders and will continue to be a mainstay of therapy.

CHAPTER

4 Coagulation Enzymology

SRIRAM KRISHNASWAMY

THE CONTEXT

Blood coagulation is initiated by the exposure of tissue factor to flowing blood following vascular damage.[1,2] A series of highly specific proteolytic activation steps ensue to convert an inactive circulating precursor to an active product. The product in turn participates in a subsequent activation reaction (FIGURE 4.1). Thrombin, formed as a result of these reactions, is the key effector product of coagulation as it is the proteinase responsible for the cleavage of fibrinogen to form the insoluble fibrin meshwork. It also activates platelets, other blood cells, and the endothelium by cleavage of the protease-activated receptors. Thrombin is a self-limiting product. Early in the coagulation response, it functions as a positive feedback effector. It greatly increases flux through the cascade by activating cofactors and factor XI necessary for the earlier steps of coagulation. Later in the response, it acts as a negative feedback effector by binding thrombomodulin (TM) and catalyzing protein C activation, which in turn proteolytically inactivates V and VIII. Their inactivation reduces flux toward thrombin formation. Active thrombin and the other proteinases of coagulation are eliminated by reacting with circulating serine proteinase inhibitors. As a result of this central regulatory role played by thrombin and the critical role played by proteinase inhibitors, the fate of active thrombin formed following the initiation of coagulation exhibits a transient profile, in which the profile for fibrin formation is dictated by the amplitude and timing of the peak as well as its integrated area, reflecting the total amount of active thrombin produced (FIGURE 4.2).

THE PROBLEM

Regulated enzymic function plays a dominant role in modulating the hemostatic response to vascular damage. Proteinase specificity reflects the ability of any one enzyme to selectively act on its cognate substrate in the complex milieu of blood. This becomes an especially important aspect of coagulation enzymology because the coagulation proteinases are trypsin-like enzymes belonging to the S1 family of subclan PA(S) of serine endopeptidases.[3] Their catalytic domains are highly structurally homologous to each other and to the digestive enzymes chymotrypsin and trypsin, the archetypic members of the clan.[3] The nature of the problem is highlighted by the fact that while trypsin can, in theory, act to cleave after any lysine and arginine in any protein, the homologous coagulation proteinases act with marked specificity to cleave after just one or two arginines in a limited subset of structurally related proteins. Thus, rigidly limited proteinase specificity lies at the heart of the hemostatic response. Flowing blood also constrains coagulation enzyme function to a physical regime that differs markedly from those encountered in the "test tube" where formalisms deal with circumstances in which substrates can be quantitatively converted to product. Instead, normal hemostasis derives from activation reactions that occur at a reactive patch, representing the area of vascular damage, to which substrates are constantly being delivered by flowing blood and products are washed away. Membrane-dependent enzyme function localizes many of the coagulation reactions to the site of vascular damage to which inert precursors are delivered by flowing blood. Products that escape the reactive patch are rapidly inactivated downstream by proteinase inhibitors. This chapter focuses on the unique strategies employed by the enzymes of blood coagulation to achieve these essential aspects of function.

PROTEINASE FORMATION

As defined in subsequent chapters, specialized structural domains present in the NH_2-terminal half of each of these zymogens contribute to a variety of aspects of zymogen and resulting proteinase function, including membrane binding by the vitamin K–dependent zymogens. However, the zymogens all possess a (chymo)trypsinogen-like domain at their respective COOH-termini that is converted to the catalytic domain by proteolytic activation.[4,5] Similarity between the catalytic domains of the different enzymes has been established by an abundance of high-resolution x-ray structures. Based on this identity, Bode et al.[6] introduced a uniform strategy of numbering residues in the catalytic domain or its precursor. Topologically equivalent and conserved residues within the family are numbered using the sequence numbers for the equivalent residues in chymotrypsinogen (e.g., I_{c16}, chymotrypsinogen numbering denoted by the subscripted c). When insertion loops unique to the individual coagulation proteins are encountered, they are denoted alphabetically, resuming with the equivalent numbering at the end of the insertion (e.g., P_{c204}-F_{c204A}-N_{c204B}-N_{c205}). This provides a uniform and facile approach for considering the structural correlates of catalytic function in this family of enzymes.

Proteinase formation results from cleavage of the peptide bond following R_{c15}, regardless of other cleavages that may occur in the processing of any particular zymogen by its cognate enzyme. This cleavage reaction produces a new *N*-terminus with variations on the sequence I_{c16}-V_{c17}-G_{c18}-G_{c19} seen in trypsin. The nascent sequence inserts in a sequence-specific manner into an *N*-terminal binding cleft to form a key salt bridge with D_{c194}. The term "Molecular Sexuality," coined by Bode, provides a graphic description of the sequence-specific nature of the insertion process.[7,8] Proteinase formation is impaired in mutants bearing an altered nascent sequence in spite of cleavage following R_{c15}.[9,10]

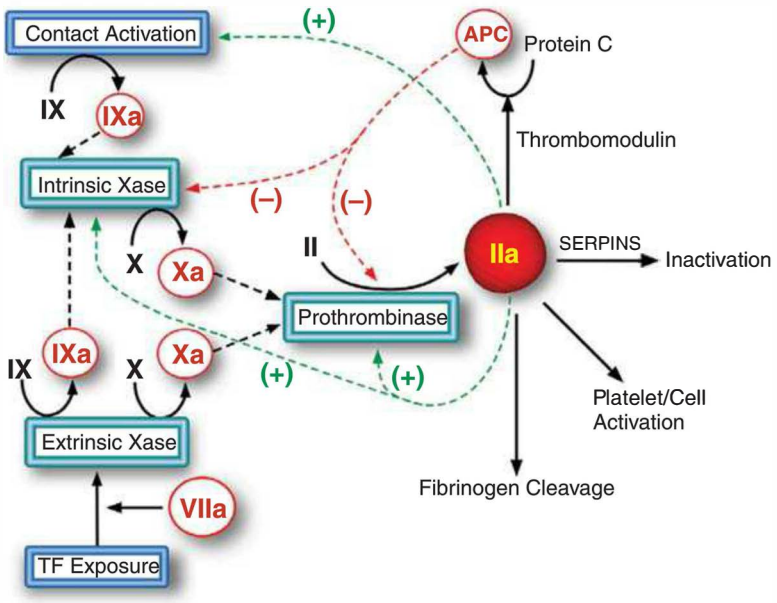

FIGURE 4.1 The blood coagulation cascade. The scheme illustrates zymogen activation steps in the pathway for thrombin formation. The positive feedback reactions of thrombin are illustrated by the *green arrows* and the negative feedback reactions that result from the action of activated protein C are shown by *red arrows*.

Conversely, trypsinogen can be conformationally activated even without cleavage by the addition of a I-V dipeptide but not V-I.[7] Ion pairing is associated with changes in four activation domains (Table 4.1) that are flanked by highly conserved glycines, referred to as glycine hinges.[11] Changes in these activation domains about the glycine hinges lead to optimization of the primary specificity pocket for substrate binding and a flip in the G_{c193} amide bond to form the oxyanion hole necessary for catalysis. These transitions instill proteolytic activity in the product by enhancing the ability of the active site to engage the substrate and by increasing catalytic power. Depending on proteinase, changes in other regions important for ligand binding may also result.

Relatively subtle differences in the main chain traced in x-ray structures of the zymogen and the corresponding proteinase yield the impression that the zymogen to proteinase transition is accompanied by subtle changes in protein structure. However, the effect of cleavage and salt bridge formation is primarily reflected in the ordering of the activation domains, which are otherwise disordered in the zymogen.[12] Thus, very significant ordering effects result from proteinase formation and an associated 10^4-10^5-fold increase in catalytic activity. Since maturation of the proteinase is rooted in conformational transitions that follow irreversible cleavage of the zymogen, it seems reasonable that formation of the fully stabilized proteinase is irreversibly favored following cleavage. However, this idea is not consistent with observations made in early studies of chymotrypsin[13] and studies of VIIa,[14,15] and is increasingly questioned in the case of thrombin.[12,16,17] Conversely, while the uncleaved zymogen is prevented from making the conformational transitions required for proteinase formation, evidence from the related proteins of fibrinolysis suggests that the uncleaved protein can be imbued with catalytic activity as a result of contributions of alternate side chains in the vicinity of D_{c194}.[18] Thus, although the relationship

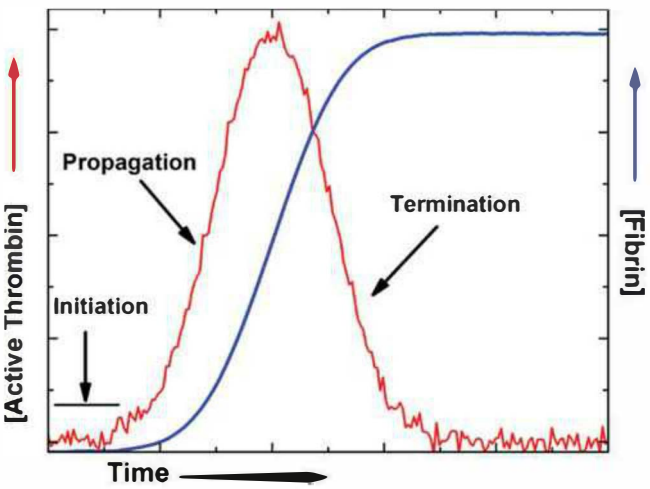

FIGURE 4.2 Expected fate of active thrombin following initiation of coagulation. The regulated hemostatic response results in the transient formation of active thrombin. Positive feedback reactions of thrombin produced at low levels in the initiation phase lead to amplified thrombin generation during the propagation phase. Negative regulation by activated protein C and inactivation by serpins predominate late in the response leading to depletion of active thrombin. The expected course of fibrin formation is also illustrated.

Table 4.1
Activation domains of zymogen activation

Domain	Functional Correlate
c16-c21	*N*-terminal insertion region
c142-c152	Autolysis loop
c184-c194	Region encompassing bottom of specificity pocket, oxyanion hole, and ion pair partner.
c216-c223	Residues framing entrance to S1 site

between cleavage following R_{c15} and proteinase formation is tacitly assumed to be absolute, it need not be so. Ligand-dependent effects on the various transitions along the pathway of conversion of zymogen to proteinase may represent an underappreciated but prevalent strategy for enzyme regulation in hemostasis.

CATALYTIC SPECIFICITY

Specificity for peptide bond hydrolysis results from a catalytic triad of side chains provided by H_{c57}, S_{c195} and D_{c102} that are precisely oriented at the active site.[19] A charge transfer complex is formed by the abstraction of a proton from S_{c195} by H_{c57}, which is in turn stabilized by long-range electrostatic interactions with D_{c102} (FIGURE 4.3). Precise orientation of the scissile bond in the substrate allows covalent nucleophillic catalysis at the carbonyl group by electronegative S_{c195} to yield a tetrahedral oxyanion intermediate. The tetrahedral intermediate is stabilized by electrostatic interactions with the oxyanion hole. Transfer of a proton to the tetrahedral adduct by the action of H_{c57} as a general acid catalyst releases the COOH-terminal fragment, while the NH_2-terminal fragment acylates S_{c195} and remains covalently tethered to the enzyme. Water diffusing into the active site is oriented through orbital steering by H_{c57}, which then acts as a general base catalyst to abstract a proton allowing for the hydrolysis of the acyl-enzyme intermediate. The resulting tetrahedral intermediate is also stabilized by the oxyanion hole before it collapses to release the NH_2-terminal fragment, returning the catalytic triad to its initial state for the next round of catalysis. These steps outline the range of strategies in chemical catalysis employed by serine proteinases to catalyze peptide bond hydrolysis.

BINDING SPECIFICITY

Peptide bond cleavage requires the precise positioning of the polypeptide substrate to subtend the carbonyl group of the scissile bond to the catalytic residues within the active site cleft. Binding specificity that arises from such positioning drives the ability of proteinases within this structurally homologous family to act with high selectivity on their cognate protein substrates. This is accomplished by structures on the proteinase complementary to structural features on the substrate. Selectivity of the coagulation proteinases for cleavage following arginine indicates that they are trypsin-like with a binding pocket optimized to accommodate this side chain leading to the presentation of the scissile bond to the catalytic residues. Because the coagulation enzymes do not cleave after all arginines, additional residues must also contribute to substrate-binding specificity. Drawing from studies with the less specific proteinases in this family, concepts are grounded in the idea that two to four residues preceding the scissile bond are major determinants of binding specificity with their side chains engaging complementary sites in the enzyme. The terminology of Schechter and Berger[20] is followed, where substrate side chains are numbered S1, S2, S3, and so on extending *N*-terminal to the scissile bond and S1′, S2′, S3′, and so on extending in the *C*-terminal direction. Sites on the enzyme complementary to these substrate side chains sites and flanking the catalytic site are labeled P1, P2, P3 or P1′, P2′, P3′ and so on. Ideas regarding the determinants of substrate specificity have historically been developed from work done with peptidyl substrates with readily measureable leaving groups (FIGURE 4.4). As a result, and because of high homology with trypsin, the principal focus has been on the role played by the S residues and P sites in determining substrate specificity with less emphasis on the S′ residues and P′ sites.

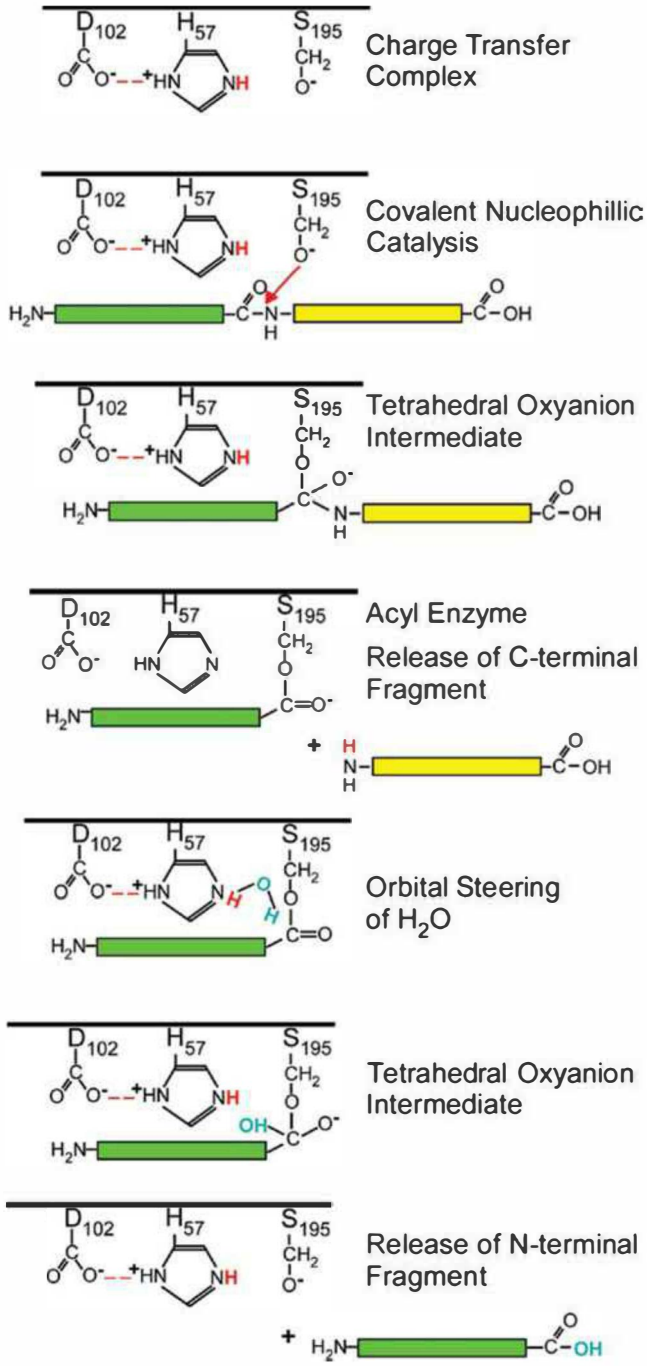

FIGURE 4.3 Peptide bond hydrolysis catalyzed by serine proteinases.

KINETICS OF ENZYME ACTION

Cleavage of a typical peptidyl substrate by a coagulation proteinase requires binding of the substrate to complementary sites on the enzyme to form a Michaelis complex (ES). Positioning

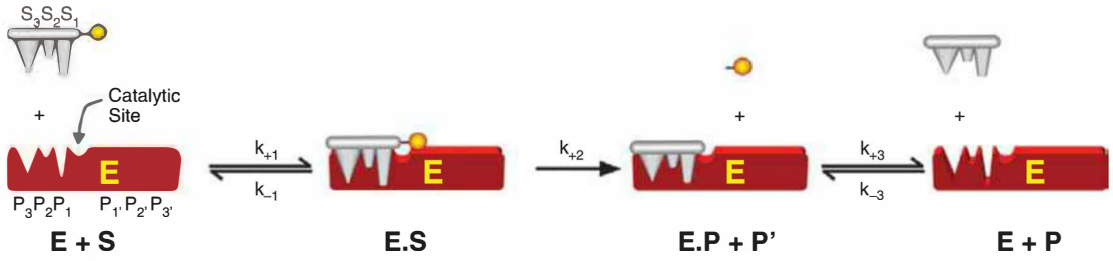

FIGURE 4.4 Kinetic scheme for peptidyl substrate binding and cleavage.

of the scissile bond at the catalytic triad leads to catalysis and release of the chromophore, followed by reversible peptide dissociation and a new round of catalysis. This represents a straightforward platform for the further consideration of the kinetics of enzyme action from simple measurements of the rate of product formation. Despite its simplicity, the scheme yields stiff differential equations that typically require single turnover studies on the millisecond timescale for the resolution of all stepwise rate constants.[21] Although approaches have been presented to solve these rate constants from simple measurements of the rate of product formation at different viscosities, the extraordinary level of data precision required for reliable conclusions makes this approach impractical.[22] Consequently, a meaningful quantitative analysis from simple measurements of the rate of substrate consumption and of product formation requires simplifying assumptions: (a) [E] « [S]. This is an appropriate and reasonable condition, given the catalytic power of the typical enzyme, (b) the initial velocity assumption requires that initial rates are measured before there is significant substrate consumption or product formation. This principally allows product inhibition effects to be ignored, although such effects need to be accounted for in the case of some tight-binding substrates/products, and (c) either the rapid equilibrium or the steady state assumption. In the former case, it is assumed that the binding and dissociation of substrate is very rapid relative to the rate constant for catalysis. In the latter, it is assumed that the system is in steady state during the rate measurement and distributions between the various enzyme species are invariant with time. This yields the familiar equation widely attributed to Michaelis and Menten,[23] wherein the constants take on different meaning depending on the assumptions that apply:

$$v = \frac{dP}{dt} = -\frac{dS}{dt} = \frac{Vmax.S}{Km + S}$$

$$\text{Where, } V_{max} = E.k_{+2} = E.k_{cat} \text{ and } K_m = \frac{k_{-1}}{k_{+1}} \text{ (Rapid Equilibrium)}$$

$$\text{or } K_m = \frac{k_{-1} + k_{+2}}{k_{+1}} \text{ (Steady State)}$$

E, S, and P refer to the total concentrations of enzyme, substrate, and product, k_{+2} (kcat) is the rate constant for catalysis, V_{max} is the maximum rate of product formation at infinite S, and K_m is the Michaelis constant. In the limiting case that ES and E are in rapid equilibrium, K_m reflects the equilibrium dissociation constant (K_d) for substrate binding, but can be significantly larger than K_d in the steady-state case. Therefore, K_m is a measure of the affinity of the enzyme for substrate with smaller values of K_m reflecting tighter binding. At fixed E, the dependence of rate on S is defined by a rectangular hyperbola and Km is the concentration of S at which $v = 0.5\ V_{max}$. When acylation limits the rate constant for catalysis, the leaving group and peptidyl product are produced at an equal rate. When deacylation is rate limiting, the leaving group is produced more rapidly than the peptidyl product. Substrate species that display the latter properties are employed in burst kinetic reactions to determine the concentration of active proteinase.[24]

In the free-energy landscape for the reaction (FIGURE 4.5), the ES complex represents a ground state that needs to overcome the free-energy barrier imposed by the transition state before it can be converted to product. Thus, kcat is inversely proportional to the magnitude of the free-energy barrier ($\Delta G^{\ddagger}$) separating the ground and transition states. Within this framework, an increased kcat requires that $\Delta G^{\ddagger}$ be reduced by stabilizing the transition state and/or destabilizing the ground state. Both ground and transition state effects are accommodated in the catalytic efficiency term (k_{cat}/K_m), which represents the overall second order rate constant for the reaction. In the screening of different substrates with any particular enzyme, preference for a particular substrate is implied by a larger value for catalytic efficiency (also referred to as specificity constant). Considerations developed from peptidyl substrate cleavage studies continue to dominate ideas underlying substrate specificity, and analyses using different peptidyl substrates

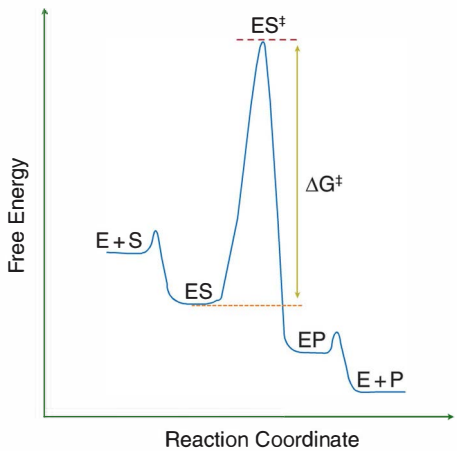

FIGURE 4.5 Free energy diagram for peptidyl substrate hydrolysis by serine proteinases.

continue to represent a primary avenue for the investigation of the substrate preferences of the various coagulation proteinases.

LIMITATIONS OF PEPTIDYL SUBSTRATE STUDIES

Oligopeptidyl substrates are microscopic in relation to the protein substrate and thereby interact in a limited way with the active site of the proteinase. While the protein substrates of the coagulation proteinases must bind to the active site before they are cleaved, these substrates approximate the size of the enzyme and could potentially engage the enzyme far more extensively, with such interactions contributing in a major way to binding specificity. Thus, while kinetic measurements with peptidyl substrates are facile and widely employed, they routinely fail to provide an explanation for cleavage site specificity within the protein substrate.[25–27] This limitation is widely evident in the coagulation proteinases, where extended interactions between enzyme and substrate play a fundamental role in determining macromolecular substrate specificity.

PAN-SPECIFICITY OF THROMBIN

Thrombin is an atypical coagulation proteinase in that it cleaves numerous substrates in reactions that are essential for clot formation and its regulation. Although the S2-S1-S1′ sequence is P-R-S at several cleavage sites in its different substrates, a single consensus pattern flanking the S1 arginine fails to emerge. Early studies with thrombin revealed that proteolysis in its catalytic domain could greatly reduce its ability to cleave fibrinogen without affecting the rate of peptidyl substrate hydrolysis.[28] Dissociation of the two functions provided an early indication that the basis for macromolecular substrate specificity of thrombin lies in enzymic structures beyond those relevant to the hydrolysis of peptidyl substrates. A series of elegant studies of the mechanism of inhibition of thrombin by hirudin from the laboratories of Stuart Stone and Jan Hofstengee established the central role of a basic region distant from the catalytic site in this high-affinity inhibition reaction.[29–33] Subsequently, ample biochemical and structural evidence has established the central role played by this anion-binding exosite 1 (ABE1) region (FIGURE 4.6) in engaging acidic regions found in several thrombin substrates distant from the scissile bond. In these cases, substrate binding to ABE1 likely guides and facilitates active site engagement of structures surrounding the cleavage site leading to catalysis. The interaction with ABE1 can be a major determinant of binding affinity, as well as specificity, since proteolysis of the loops that constitute ABE1 or its occlusion by ligands can abrogate cleavage of substrates that engage thrombin in this way.[28,34,35] These ideas provide a partial accounting for the strategies employed by thrombin to achieve pan-specificity without strict conservation of residues flanking cleavage sites in its various substrates.

ENZYME COMPLEXES OF COAGULATION

While thrombin acts on a range of protein substrates, the other proteinases of coagulation exhibit far more restricted substrate specificity. In addition, many of these reactions are catalyzed by enzyme complexes that assemble from membrane-dependent interactions between a proteinase and a cofactor protein. Thus, there is no basis, *a priori*, to presume that strategies utilized by thrombin for substrate recognition would apply to other reactions.

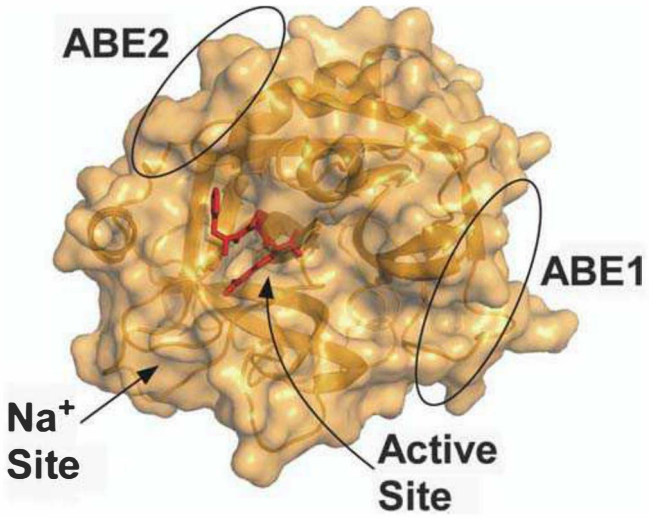

FIGURE 4.6 X-ray structure of thrombin. Structure of thrombin modified by D-FPR-chloromethyl ketone (1PPB) is shown as a rendered surface in the standard orientation.[6] The active site is highlighted by the bound inhibitor shown as *red sticks*. The positions of anion-binding exosite 1 (ABE1) and exosite 2 (ABE2) are indicated as is the Na^+ binding site.

The prothrombinase complex, the enzyme complex that converts the zymogen prothrombin to thrombin, is considered an archetype for the other complexes of coagulation. This is appropriate because of the wealth of biophysical and enzymologic information delineating function and the reversible binding interactions that lead to complex assembly and substrate recognition.[1,4]

Prothrombinase is composed of the serine proteinase, factor Xa, bound to factor Va, its protein cofactor, on a membrane surface (FIGURE 4.7). Although complex assembly *in vivo* requires exposing phosphatidylserine on the outer membrane of activated blood cells such as platelets, and possibly also the endothelium, most of the quantitative information in this system has been developed in defined systems with purified proteins and synthetic membranes containing phosphatidylcholine and phosphatidylserine (PCPS). While factor Xa is a fully competent serine proteinase, its ability to cleave prothrombin is minor in comparison to the rate observed following its incorporation into prothrombinase. Indeed, based on rates, the concentration of thrombin formed in 1 second by Xa saturably bound to Va and membranes would require approximately 5 days by the equivalent concentration of Xa in solution. Thus, the assembly of Xa into prothrombinase is required for rapid thrombin formation following initiation of coagulation, and it is prothrombinase rather than free Xa that is considered the physiologically relevant catalyst for rapid prothrombin activation following vascular damage. The other enzyme complexes are composed of homologous constituents that assemble in an analogous way with comparable functional consequences.

The functional consequences of the reversible interactions of Xa with membranes and Va are evident from steady-state kinetic constants for "prothrombin activation" determined using Xa in

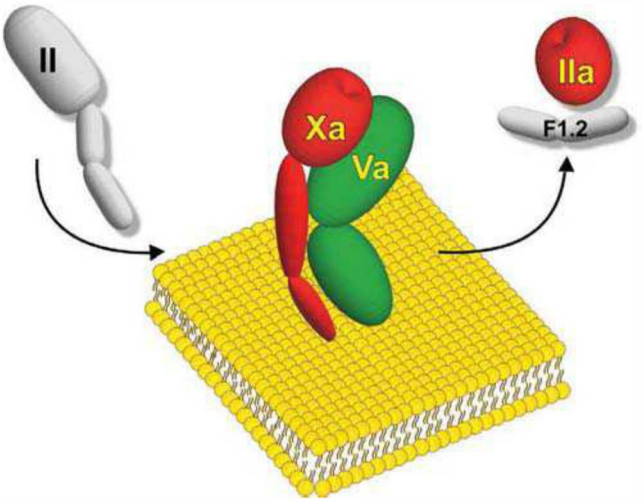

FIGURE 4.7 Schematic representation of prothrombinase. The complex assembles through membrane-dependent interactions of the proteinase Xa with the cofactor protein, factor Va, on membranes containing phosphatidyl-L-serine. The complex converts the zymogen, prothrombin (II) to thrombin (IIa) with the release of the *N*-terminal propiece (F12). Catalytically active species are colored *red*.

solution compared with Xa saturably bound to membranes or Xa saturated with Va and membranes (Table 4.2). Binding of Xa to membranes decreases the apparent affinity of the proteinase for prothrombin, while addition of saturating concentrations of cofactor does not affect Km further, but yields a large improvement in the rate constant for catalysis. At physiologic concentrations of prothrombin (1.4 μM), these kinetic constants reveal that the minimal activity of Xa in solution is increased approximately 500,000-fold upon its incorporation into prothrombinase. These types of observations are generalizable to the other complexes of coagulation. They also exhibit comparable changes in steady-state kinetic constants attributable to membrane binding and cofactor binding. Because these binding interactions are reversible, valid comparisons of the type shown here require knowledge of the bound concentrations of the proteinase in the various binary and ternary mixtures from individual binding constants established by independent physical measurement. Incomplete consideration of the degree of saturation of enzyme components can lead to incorrect conclusions and is probably the root of the persistent idea that prothrombinase assembled on platelets is a far superior catalyst to the complex assembled on synthetic membranes.[36,37] Indeed, the reverse is probably true because of nonproductive interactions of enzyme components with the platelet surface.

Table 4.2

Steady-state kinetic constants for prothrombin activation[a]

Enzyme Species[b]	K_m (μM)	V_{max}/E_T (s^{-1})	Relative Rate[c]
Xa	84	0.01	1
Xa/PCPS	0.7	0.05	203
Xa/Va/PCPS	0.4	108	512,000

[a]Kinetic constants for bovine prothrombin cleavage by bovine Xa alone,[102] or for the activation of human prothrombin by human enzyme constituents in the presence of membranes.[103]
[b]The enzyme species correspond to Xa alone, Xa saturably bound to membranes (Xa/PCPS) and Xa assembled into prothrombinase (Xa/Va/PCPS) using saturating concentrations of membranes and Va.
[c]Relative rates at 1.4 μM prothrombin calculated from the steady-state kinetic constants.

MEMBRANE EFFECTS

The ability of proteinase, cofactor, and substrate to bind reversibly to membranes forms the basis for the ability of membranes to affect the reaction rate. Membrane binding and the resulting enhanced function of the membrane-bound enzyme play primary roles in localizing enzyme function and facilitating product formation at the site of vascular damage. With respect to prothrombinase, one major function of the membrane surface is to enhance the thermodynamics and kinetics of enzyme complex assembly.[4] Because Xa and Va interact weakly in solution (K_d ~ 1 μM), complexation in solution is expected to be negligible at the nanomolar concentrations of these proteins produced in blood following initiation of coagulation.[38] Membrane-dependent complex assembly proceeds through the individual interactions of Xa (K_d ~ 100 nM) and Va (K_d ~ 3 nM) on a contiguous membrane surface expressing phosphatidylserine (FIGURE 4.8).[39] As reversible membrane binding is mediated by a specific domain in each protein, the proteins are bound to the surface in an oriented fashion and are constantly dissociating and being recaptured by the surface.[40,41] Thus, their diffusional translation along the membrane surface occurs under conditions that approximate two-dimensional space leading to greatly accelerated and oriented collisional encounters between the two interacting partners. The resulting binding interaction between membrane-bound Xa and

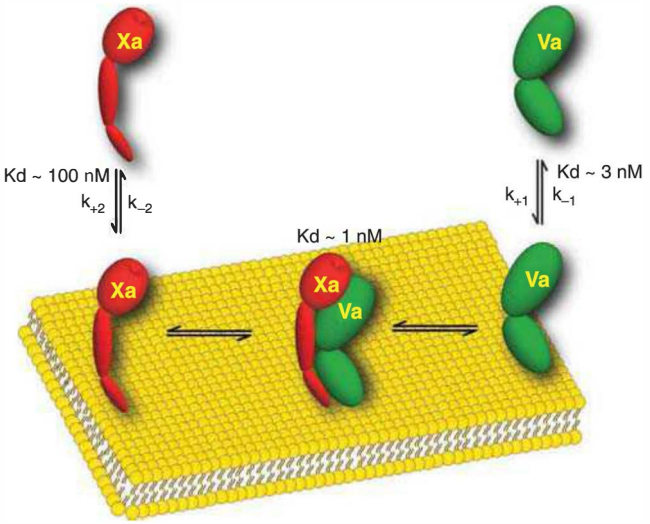

FIGURE 4.8 Membrane-dependent assembly of prothrombinase. Xa and Va bind separately to a contiguous membrane with the noted equilibrium dissociation constants. The membrane-bound proteins then interact efficiently with nanomolar affinity on the membrane surface despite the fact that the solution-phase protein–protein interaction is of micromolar affinity.

Va (K_d ~1 nM) is 1,000-fold tighter than the protein–protein interaction in solution.[42] Furthermore, linkage between protein–protein and protein–membrane interactions further enhances overall affinity, permitting the enzyme to assemble efficiently at picomolar concentrations, much lower than would be predicted from simple knowledge of the individual binding constants.[42]

Similarly, the binding of prothrombin to membranes through its *N*-terminal 4-carboxyglutamic acid-containing domain allows for the accelerated delivery and oriented presentation of the substrate to the membrane-assembled enzyme. This accounts for the major effect of membranes on the apparent affinity of the enzyme complex for the substrate. Apparent affinity is an appropriate term because this effect partly arises from delivery phenomena in step(s) preceding the encounter of substrate with the enzyme.

COFACTOR EFFECTS

Since factor Va increases the kcat for the reaction, it follows that the cofactor must reduce $\Delta G^{\ddagger}$ by changing the catalytic site of Xa within the complex to favor the transition state or by destabilizing the Michaelis complex. It is a long-held view that the cofactor proteins function by modulating the active site of their partner proteinases.[43,44] However, the enhancing effects of Va on catalysis by Xa are limited to observations made with prothrombin and its derivatives and not with peptidyl substrates or transition state-like irreversible inhibitors even bearing the same peptidyl sequence preceding the scissile bond in the protein substrate.[45] This repeats the theme introduced earlier in the chapter with thrombin and indicates that the ability of the cofactor to enhance reaction rate derives from features of the protein substrate that are not approximated by peptidyl substrates that are microscopic in comparison and target the catalytic site of the proteinase in a limited way. It also follows that mechanisms driving macromolecular substrate specificity of the enzyme complex and those underlying cofactor functions cannot be treated separately.

PROTHROMBIN CLEAVAGE

A complicating feature of prothrombin activation derives from the fact that thrombin is produced following two cleavages in the substrate. As a result, there are two possible pathways for prothrombin activation with two possible intermediates (FIGURE 4.9). In either pathway, thrombin is formed following two consecutive enzyme-catalyzed reactions.[46] Thus, kinetic constants that phrase the problem are obtained by varying the substrate for the first reaction and measuring the rate of product formed from the second. Mechanistic ideas grounded in such kinetic constants, which cannot be interpreted in the traditional way, require major reconsideration. Interpretations are further complicated by the fact that the cleavage pathway is dependent on the composition of the catalyst. The reaction proceeds mostly via the formation of prethrombin 2 in the absence of Va and essentially entirely via the formation of meizothrombin when Xa is saturably incorporated into prothrombinase (FIGURE 4.9).[46–48] The rate-enhancing effects of Va are also associated with a change in mechanism, precluding sensible interpretations of how the cofactor might function from measurements that do not take this into account. Such considerations might seem to dwell on the minutiae of a peculiarly complicated case. However, proteolytic processing at multiple sites, sometimes in a seemingly ordered fashion, is commonplace in coagulation and is reflected in the activation of factors IX, XI, V, and VIII, cleavage of fibrinogen, and the proteolytic inactivation of Va and VIIIa.[4]

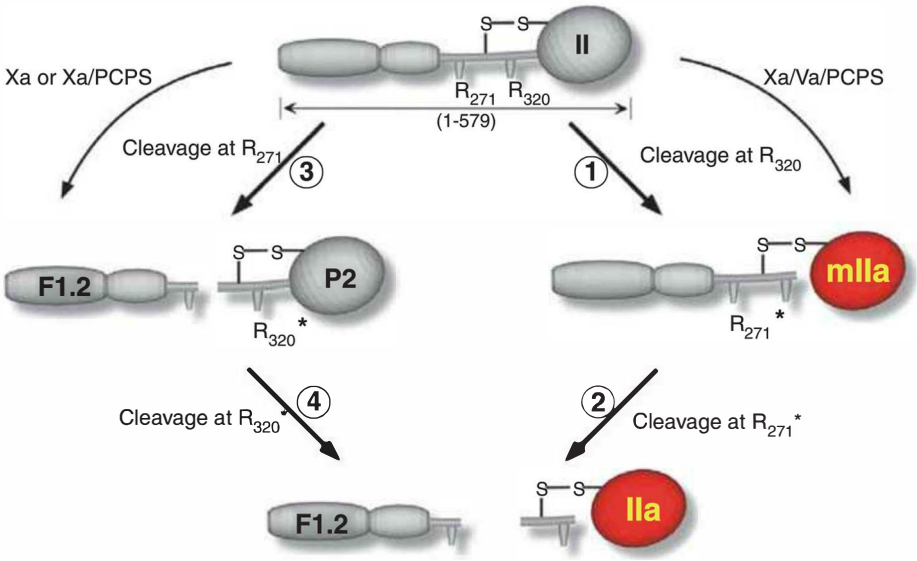

FIGURE 4.9 Pathways for prothrombin cleavage. Thrombin (IIa) formation requires cleavage of prothrombin (II) at R_{271} and R_{320} (numbered sequentially from the mature *N*-terminus of prothrombin). Cleavage through steps 3 and 4 yields the zymogen prethrombin 2 (P2) and the propiece fragment 1.2 (F1.2) as intermediates. This pathway predominates when the catalyst is Xa or Xa bound to membranes (Xa/PCPS). When the catalyst is prothrombinase (Xa/Va/PCPS), the reaction proceeds essentially exclusively through steps 1 and 2, yielding meizothrombin (mIIa) as an intermediate. Functional catalytic domains are colored *red*.

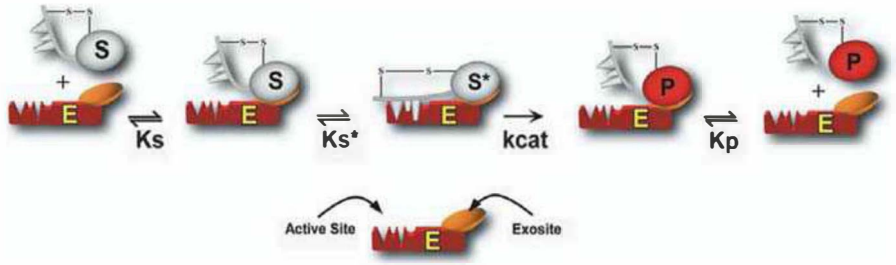

FIGURE 4.10 Kinetic pathway for protein substrate cleavage by prothrombinase. Prothrombinase (E) is represented in stylized fashion to highlight the active site of Xa within the catalyst as well as extended surfaces (Exosite) that contribute to substrate binding. Initial binding of the protein substrate (S) occurs through the exosite (Ks) followed by engagement of substrate structures at the active site (Ks*) leading to cleavage to yield product (P). The cleaved product also interacts with the enzyme through exosite binding (Kp).

MACROMOLECULAR SUBSTRATE RECOGNITION BY PROTHROMBINASE

An analysis of prothrombin cleavage, suitable for reliable interpretation, can be obtained from studies of the four individual half reactions, utilizing intermediates as substrates, and by studies of recombinant prothrombin variants in which one of the two cleavage sites has been rendered uncleavable.[46] For each half reaction, protein substrate recognition proceeds through an equivalent multistep binding pathway (FIGURE 4.10). Initial binding occurs through exosite interactions that are independent of the active site of the enzyme and at least partly involves the *C*-terminal region of the substrate distant from the scissile bond.[49–52] Exosite docking is followed by active site engagement of structures flanking the scissile bond followed by catalysis. The product bound to the exosite of prothrombinase dissociates before a new round of catalysis. This pathway, initially elucidated using the cleavage of prethrombin 2 by prothrombinase as a model reaction, has since been shown to apply to each half reaction of prothrombin activation.[46] Each substrate for the four half reactions and the three possible products bind in an equivalent manner to the exosite, allowing them to bind prothrombinase in a mutually exclusive manner.[46] Because active site engagement follows exosite docking, it now occurs in an intramolecular rather than bimolecular interaction. The individual half reactions can adequately be described by the Michaelis-Menten equation, with new insights provided by the more complex nature of the kinetic constants, derived for illustrative and simplifying purposes using the rapid equilibrium assumption.

$$Km_{obs} = K_{S\cdot}\frac{K_{S\cdot}}{\left(1+K_{S\cdot}\right).}\,k_{cat,obs} = \frac{k_{cat}}{\left(1+K_{S\cdot}\right).}\frac{k_{cat,obs}}{Km_{obs}} = \frac{k_{cat}}{K_{S\cdot}K_{S\cdot}}$$

While the apparent affinity of the enzyme for substrate results from both exosite binding and active site engagement, the apparent rate constant for catalysis also contains the unimolecular binding constant for active site engagement. Thus, large improvements in $kcat_{obs}$ can result from modulation of active site engagement without necessarily stabilizing the transition state or destabilizing the ground state. Since the protein substrate engages the active site of Xa with poor affinity (Table 4.2), the Dock-and-Lock strategy employed by prothrombinase allows exosite binding to efficiently drive an otherwise unfavorable reaction. Thus, it is exosite binding and not active site engagement that dominates the affinity of prothrombinase for its macromolecular substrate.

EXOSITE BINDING AND ENZYME SPECIFICITY

The active site of factor Xa, whether or not assembled into prothrombinase, is permissive and accepts a wide range of peptidyl substrates.[26] This observation has been puzzling, considering the narrow specificity with which this proteinase acts on prothrombin following the sequence Glu/Asp-Gly-Arg.[4] Such seemingly anomalous behavior is readily reconciled when the predominant contribution of exosite interactions in driving substrate binding is accounted for. This concept has been tested with recombinant prothrombins in which the cleavage site residues are replaced with sequences found preceding cleavage sites in the other coagulation zymogens not otherwise cleaved by prothrombinase. These prothrombin variants are readily cleaved by prothrombinase with the same Km_{obs} but with varying values for $kcat_{obs}$.[53] Replacement of the P1 arginine with glutamine yields an essentially uncleavable form. Lack of substrate cleavage in the glutamine variant arises from a defect in $kcat_{obs}$, rather than affecting binding affinity dominated by exosite interactions. This illustrates how specificity for prothrombin arises from the restricting effects of exosite binding that only allow prothrombinase to cleave substrates that can engage the enzyme in this way, despite the fact that the active site of Xa can readily accommodate sequences found flanking the activation sites of the other coagulation zymogens. It demonstrates experimentally that although the subsequent active site engagement step is required for catalysis, this unimolecular binding interaction contributes to $kcat_{obs}$ rather than macromolecular substrate affinity.[53] This clearly sets apart the strategy employed to achieve binding specificity for the protein substrate from that for peptidyl substrates. Consequently, it is not surprising that studies with peptidyl substrates have uniformly failed to provide insights into the function of the enzyme on its protein substrate.

The ability of prothrombinase to selectively act on prothrombin rather than the other coagulation zymogens represents but one level of enzymic specificity. The second reflects the ability of the enzyme complex to discriminate between the two cleavage sites within the substrates. Thus, despite the fact that both cleavage sites are accessible to added proteinase, prothrombinase is

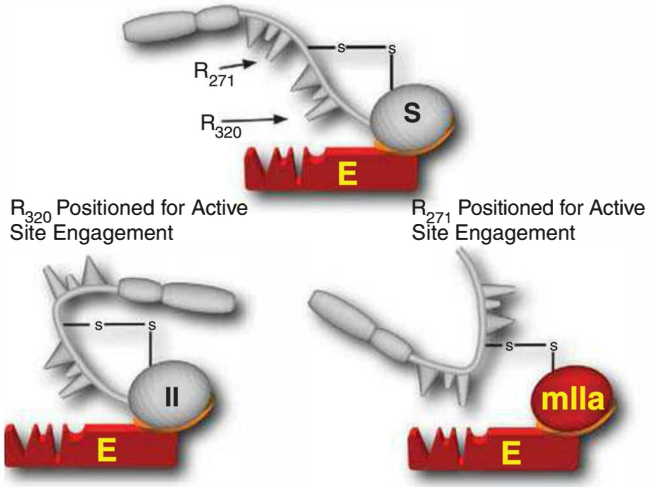

FIGURE 4.11 Exosite-dependent tethering of substrate to enzyme. Ordered cleavage of prothrombin results from the geometric constraints associated with exosite tethering. When the substrate is the zymogen, the R_{320} site is optimally positioned to engage the active site of the enzyme while R_{271} is distant. Following cleavage at R_{320}, otherwise distant R_{271} is brought into the vicinity of the active site to permit its engagement.

essentially only able to cleave following R_{320} in prothrombin. The action of prothrombinase following R_{271} requires prior cleavage at R_{320} and the formation of meizothrombin (FIGURE 4.9). The basis for this discrimination lies in geometric constraints enforced by exosite-dependent tethering of the substrate to the enzyme (FIGURE 4.11). On the basis of modeling and the available structures of prothrombin derivatives, the two cleavage sites are expected to be approximately 40 Å apart.[54] Exosite tethering of prothrombin geometrically constrains the presentation of the substrate, such that structures flanking the R_{320} scissile bond are positioned to preferentially engage the active site of Xa within prothrombinase.[10,55] The R_{271} site is distant, does not effectively engage the active site, and is cleaved poorly. Conversion of the zymogen to proteinase following initial cleavage at R_{320} provides the appropriate structural changes in the substrate, termed ratcheting, to bring the once distant R_{271} site into the vicinity of the active site for binding and cleavage. The essential role for the zymogen to proteinase transition in the presentation of individual cleavage sites for active site engagement is documented by modulation of the pathway for prothrombin cleavage via stabilizing prothrombin in a proteinase-like state or by abrogating the conformational transition to proteinase following cleavage at R_{320}.[10,55]

Discrimination between the two cleavage sites is not absolute and the R_{271} site in prothrombin can indeed be cleaved, but at a 30-fold lower rate.[10] The finite rate of cleavage at R_{271} likely reflects a low probability of capture of the otherwise distant site because of flexibility in the exosite-tethered substrate.[55] This requires consideration of a third level of specificity with broad relevance to proteinases in general. If the catalytic site of Xa within prothrombinase is accepting of a wide range arginine-bearing sequences and the substrate is tethered in a flexible way, why is the substrate not cleaved at other sites? The answer lies in competition between the preferred sites, in terms of geometry as well as affinity, for engaging the active site over other structures.[56] As a result of this competition, cleavage at the suboptimal sites is minimized and only revealed following mutagenesis to eliminate the preferred cleavage sites.[56]

The structural basis for exosite-dependent substrate binding to prothrombinase is not unambiguously assigned, as in the case of thrombin (see above). Current ideas suggest that extended surfaces in both Xa and Va likely contribute to tether the substrate to the enzyme.[57–59,60] By definition, however, membrane binding by the substrate, which mediates its oriented presentation to the enzyme, constitutes another essential component of exosite-mediated substrate recognition. Thus, protein–protein and substrate–membrane interactions contribute to exosite tethering of the substrate. The available evidence suggests that perturbations in any of these interactions will impact the ability of prothrombinase to discriminate between the two cleavage sites by altering the constraints on enzyme-bound substrate. This consideration may bear on some of the disagreements in the field or on the idea that activated platelets, likely providing subsaturating levels of membranes for prothrombin binding, exhibit an altered pathway for prothrombin cleavage in comparison to synthetic membranes.[61,62]

PROTEINASE ALLOSTERY

Ideas centered on the allosteric modulation of proteinase function feature prominently in considering the fundamental role played by cofactor proteins in coagulation enzymology.[4,63] However, there are substantial difficulties in ascribing functional importance to relatively small or subtle changes in proteinase active site function typically associated with cofactor binding.[45,64,65] This is less of a problem in the case of VIIa for which peptidyl substrate hydrolysis is significantly increased upon tissue factor binding.[66–69] Although the 20 to 30-fold increase in peptidyl substrate cleavage is small in comparison to the improvements in X or IX activation, a series of studies have shown that VIIa is zymogen-like despite cleavage following R_{c15} with the nascent *N*-terminus accessible to solvent.[14] Binding to tissue factor is associated with salt-bridge formation arising from the allosteric stabilization of VIIa in the proteinase-like form.[14,15] While M_{c164} is considered the key residue for transmission of allosteric effects arising from tissue factor binding, recent studies have shown analogous stabilization of proteinase-like VIIa by antibodies targeting different regions of the proteinase domain.[15,70]

Allostery is considered an important determinant of the ability of TM to redirect thrombin toward its anticoagulant function.[71] Binding of thrombin to TM yields a large increase in protein C activation with a concomitant loss in function toward its procoagulant substrates.[71–74] This switch in specificity results partly from TM binding to ABE1 with nanomolar affinity, thereby preventing binding of procoagulant substrates that employ interactions with ABE1 to achieve binding specificity.[75] The TM–thrombin complex is most likely an efficient protein C-activator because of optimized ground state interactions permitting its productive binding to the active site of thrombin, which is otherwise nonproductive in the absence of the cofactor.[76–78] The central role of allostery in this switch has been investigated extensively by mutagenesis and structural work, backed by a voluminous literature on the subject (see ref.[79] for a recent review on the subject). Numerous different side chains have been proposed as important for the allosteric transition of procoagulant thrombin to the anticoagulant form. Mutations at these sites yield species considered anticoagulant thrombins with a preference for protein C activation.[80] Na^+

binding to a specific site found in thrombin (FIGURE 4.6) but not in the zymogen is proposed to be essential for promoting allosteric transitions between a putatively inactive E* form, a Na^+-free slow form with preference for the anticoagulant substrate, and a Na^+-bound fast species with procoagulant function.[79] These forms, with varying substrate specificity and revealed by a bewildering range of mutations, have yielded variously distorted structures proposed to represent these specifically regulated states of thrombin.[81–86] Nevertheless, the logical basis for the proposal that Na^+ binding is among the most critical modulators of thrombin function is no longer tenable based on binding constants determined at physiologic temperature and pH.[16]

LIGAND-DEPENDENT REGULATION OF THROMBIN ZYMOGENICITY

A more general framework for the further consideration of thrombin allostery derives from the initial suggestion, subsequently confirmed by thermodynamic and NMR studies, that thrombin can exist in zymogen-like and proteinase-like states depending on its ligation state.[12,16,17] Substrates and inhibitors that ligate the active site and bind the zymogen poorly, if at all, shift the equilibrium in favor of the proteinase-like state (FIGURE 4.12). This is also true for Na^+ binding because the site for this cation is optimally formed in the proteinase but not zymogen.[87] The proteinase-like state is also favored by the binding of ligands to ABE1, which bind more tightly to the proteinase than to pro-ABE1 in the zymogen.[88] In contrast, the propiece F12 binds ABE2 present on the zymogen more tightly than in the proteinase,[16,89] and shifts the equilibrium in favor of the zymogen-like states of thrombin (FIGURE 4.12). Thus, the distribution of thrombin between zymogen-like and proteinase-like states is determined by the complement of ligands bound to these different sites. Although a two-state model (FIGURE 4.12) is sufficient for the formal consideration of such ligation effects,

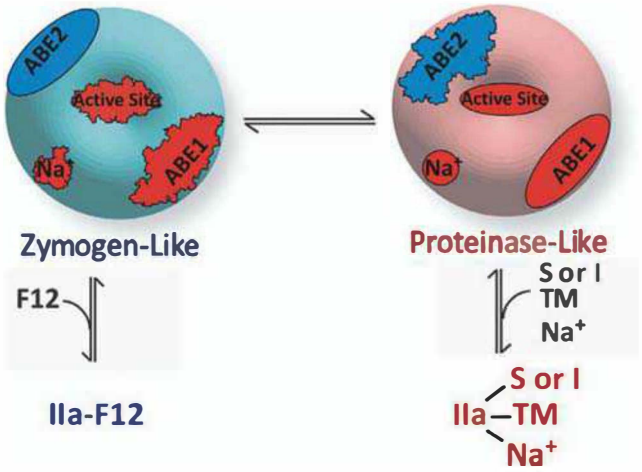

FIGURE 4.12 Ligand-dependent interconversions of thrombin. The active site, Na^+ site and ABE1 are shown as distorted in the zymogen-like form but optimally configured in the proteinase-like form. The reverse is true for ABE2, which is optimally formed in the zymogen-like species and distorted in the proteinase-like form. The distribution of thrombin between these states is determined by opposing effects of ligand binding at these different sites.

the NMR and thermodynamic studies support the ability of thrombin to be reversibly distributed among a range of states with varying zymogen-like or proteinase-like character.[12,16] The basis for this lies in the complete thermodynamic additivity of the various transitions in the activation domains that result from cleavage following R_{c15}.[16] Thus, any destabilizing mutation or removal of Na^+, which is part of the structure of the folded proteinase, would favor zymogen-like forms. The resultant enzyme will exhibit an apparently altered specificity profile dependent on the extent that the tested substrate shifts the equilibrium to favor proteinase. Because one of the activation domains forms the oxyanion hole, the altered specificity profile could be reflected in changes in K_m, k_{cat}, or both.

Major destabilizing mutations, for example, the mutation of a highly conserved disulfide bond,[90] would be expected to cause a large shift in equilibrium to the left, preventing significant rescue by weak ligands or substrates such as fibrinogen. The resulting enzyme would appear to possess little procoagulant function. Because of the much higher affinity for TM binding, the cofactor could partially or fully drive the enzyme to the proteinase-like state. Because TM also blocks the procoagulant function of thrombin, full or partial rescue by TM will yield the appearance of normal or selectively retained anticoagulant function. This provides an accounting for how the pro- and anticoagulant functions of thrombin can be seemingly dissociated by a number of strategies. Accordingly, distorted structures of mutant thrombins considered to reflect specific regulated states are rectified by inhibitors targeting the active site or by ligands directed toward ABE1.[82,91]

THE OTHER COAGULATION PROTEINASES

Growing evidence implicates the strategies outlined for the function of thrombin and prothrombinase as prevalent and applicable to the other reactions of coagulation. The membrane-dependent function of prothrombinase closely parallels the function of the intrinsic Xase.[92] However, it does take on a different character for the extrinsic Xase and for the thrombin–TM complex because the cofactors are transmembrane proteins that are irreversibly anchored in the membrane. In these cases, phosphatidylserine is not absolutely required to facilitate enzyme complex assembly as the soluble extracellular domains of both TF and TM can bind with good affinity to their corresponding enzymes.[66,93] The presence of phosphatidylserine does further enhance function toward their respective membrane binding substrates by facilitating substrate delivery to the membrane-anchored enzyme.[94,95]

Exosite-dependent substrate recognition plays an important role in the function of the extrinsic Xase, intrinsic Xase, as well as IX activation by Xia.[92,94,96] Both the extrinsic Xase and XIa catalyze the cleavage of two bonds in IX, although details of the pathway for ordered cleavage differ for the two catalysts, perhaps reflecting differences in strategies employed for exosite tethering of the substrate and the fact that XIa is dimeric.[97–99] In the case of the extrinsic Xase, exosite-dependent binding of X and Xa to the enzyme complex is an essential feature of its regulation by tissue factor pathway inhibitor (TFPI). TFPI bound to Xa either prior to its dissociation from the enzyme complex or following its release utilizes exosite tethering interactions between Xa and the VIIa/TF complex to achieve rapid and high-affinity inhibition of the enzyme complex. High affinity arises from the summed energetic contributions of the interaction of TFPI

with VIIa and the exosite-dependent binding of Xa to the complex, leading to the essentially irreversible inhibition of VIIa/TF function.[100] A comparable scaffolding strategy to achieve either substrate or product-dependent inhibition of VIIa/TF is also seen in the action of nematode anticoagulant peptide C2.[57,101] In both cases, exosite-dependent tethering of the natural substrate or product, provides for specificity and enhanced energetics for inhibition, despite the fact that either inhibitor can only weakly inhibit VIIa/TF directly.

Ligand-dependent enzyme regulation, by mediating transitions between zymogen-like and proteinase-like forms, has come to the fore in the case of thrombin and has long been known to represent a distinctive feature of VIIa/TF function.[12,15,16] It is presently unclear whether such ideas apply widely to the other reactions of coagulation and whether they reflect a prevalent mechanism by which cofactors may exert their effects. Given their high structural homology, it stands to reason that a variable level of zymogen-like character in the cleaved proteinase is likely to persist in the coagulation proteinases. This suggests new targeting strategies for therapeutic gain wherein proteinase activity can be enhanced or inhibited by tight-binding ligands that can influence the equilibrium distribution between zymogen-like and proteinase-like forms.

PERSPECTIVES

The enzymology of the serine proteinases of coagulation is dominated by the strategies employed by structurally homologous enzymes with similar active sites to act with marked and defined specificity on their respective protein substrates. The underlying theme behind each of these strategies lies in the fact that the substrates approximate the size of the proteinase and are macroscopic in relation to the catalytic site, allowing for extended interactions that lie at the heart of specificity and function. These ideas undoubtedly underlie the function of homologous families of catalysts, such as protein kinases and phosphatases, in signaling pathways also relevant to hemostasis and that are required to act with specificity on their respective protein substrates in reactions that are further modulated by other binding partners.

CHAPTER

5 Cell Biology, Protein Processing, and Cell Signaling

RANDAL J. KAUFMAN AND LAURA POPOLO

In order to perform their multiple functions, eukaryotic cells have evolved an internal structural organization that consists of several organelles and an intricate network of protein filaments, called the cytoskeleton, which determines cell shape and regulates its dynamic changes. Organelles are membrane-bound compartments that play fundamental functions in cellular physiology. The *nucleus* hosts the DNA and is the site where the genetic information is transcribed into RNA molecules that are processed, transported to the cytoplasm, and translated into proteins, the final executors of the genetic program of a cell. The *mitochondria* are numerous in a cell and responsible for the production of most of the ATP molecules derived from the catabolism of organic compounds but are also involved in Ca^{2+} signalling and cell death pathways. *Lysosomes* and *peroxisomes* play specialized functions in the digestion of macromolecules and oxidative and detoxifying reactions. The *endoplasmic reticulum* (ER) is the site for the synthesis of lipids and proteins destined to be part of the cell membranes or secreted into the extracellular space. Proteins exit the ER and enter the *Golgi apparatus* that is a central sorting and processing station where proteins are packaged into vesicles for transport to their final destination.

Due to the complexity of such an internal organization, the elucidation of the molecular mechanisms regulating the synthesis, processing, and transport of proteins to the various intracellular compartments has fascinated cell biologists for years. Studies on protein secretion have taken advantage of the powerful genetic approaches applied to yeast, a lower eukaryote. A striking evolutionary conservation in the basic components of protein trafficking and processing was found between yeast and mammalian cells.

This chapter summarizes the basic principles of mammalian protein synthesis and processing with a focus on the secretory pathway. Many human proteins that circulate in the blood are secreted and extensively modified by specialized cells and play important functions in human physiology. The findings of many years of research provide the basis for our understanding of the molecular mechanisms of cell biology and how malfunctioning of these processes contributes to human diseases including some hematological disorders.

PROTEIN SYNTHESIS AND MATURATION

Protein Synthesis and Regulation

In eukaryotic cells, nuclear protein-encoding genes are transcribed into pre-mRNA molecules (also named heterogeneous-nuclear) that are transported to the cytoplasm after complex processing. In the cytoplasm, mRNAs become templates for translation, a highly energy-consuming process. Beyond 80S ribosomes and aminoacyl-tRNAs, several soluble factors and GTP are required for the initiation, elongation, and termination (also named release) steps of protein synthesis. Accordingly to the stage of translation in which they transiently associate with the ribosomes, the soluble factors are named eIFs (initiation factors), eEFs (elongation factors), and eRFs (releasing factors) with the prefix e- indicating eukaryote. Several ribosomes that are simultaneously engaged in the translation of the same mRNA form a polyribosome (or polysome). Polysomes are either free in the cytosol or bound to the surface of ER membranes.

Translation is also an important target of regulation. Several examples of regulatory mechanisms that control the expression of specific mRNAs in response to a given cue have been reported. The expression of some proteins involved in iron metabolism is regulated at the level of translation initiation or stability of mRNAs.[1,2] Besides specific mechanisms, global translational control exists. A transient arrest of translation is often required to overcome various kinds of stress. For instance, the sudden onset of an unfavorable condition, such as amino acid starvation, heat shock, accumulation of unfolded proteins in the ER, or lack of heme in reticulocytes, triggers a rapid halt in global protein synthesis. This regulation is mediated by specific sensor protein kinases that phosphorylate the alpha subunit of heterotrimeric initiation factor eIF2, a G-protein, on residue Ser51. eIF2α phosphorylation prevents the GDP–GTP exchange on eIF2 because the guanine nucleotide exchange factor (GEF) eIF2B is sequestered by tight binding to the phosphorylated form of eIF2. The GTP-bound form of eIF2 becomes insufficient for the formation of the ternary complex (eIF2-GTP-Met-$tRNA_i$), and protein synthesis slows down. In contrast, ligands that activate signal transduction pathways promoting growth rapidly stimulate protein synthesis. Insulin signalling exemplifies a growth promoting pathway that, through the protein kinase mTOR, activates components of the translational machinery including eIFs and eEFs.[3,4]

Another site of protein synthesis is mitochondria that possess a genetic system and independent mRNA translation machinery. However, mitochondrial protein synthesis, which is from bacterial origin and occurs on 55S ribosomes present in the matrix, is responsible for the synthesis of only a small set of highly hydrophobic proteins that reside within the mitochondrion inner membrane. The rest of the mitochondrial proteins are nuclear encoded, translated on cytoplasmic ribosomes, imported from the cytoplasm, and sorted to the outer membrane, inner membrane, or matrix.

The broad spectrum of functions typical of a specialized cell of metazoans depends on a defined set of proteins that is referred to as the "proteome." The proteome is specific for a

particular physiological cellular condition or stage of development. Furthermore, many proteins are modified by covalent attachment of chemical groups that contribute to increase the complexity of proteins produced by a cell. The analysis of the proteome and its modifications, which is carried out by a huge armamentarium of technologies that were developed in recent years, highlights the qualitative and quantitative changes occurring in pathological conditions with respect to the normal and greatly contributes to the identification of the molecular mechanisms fundamental to the basis of human disease.

Protein Sorting in the Cytoplasm

The great majority of cellular proteins are synthesized on "free" ribosomes in the cytosol and then transported to their eventual destination. Short linear sequences (or three-dimensional patches of particular amino acids) and their cognate receptors govern the sorting events. The sorting decision occurs after approximately 30 amino acids of the nascent polypeptide emerge from the ribosome. In the absence of an "ER signal sequence," most often found near the amino-terminal end of the protein, translation is completed in the cytosol. The protein can either stay in the cytosol or be posttranslationally (after synthesis) transported into one of the organelles (FIGURE 5.1). Alternatively, if the protein does contain an amino-terminal signal sequence, the nascent peptide–ribosome complex is docked on the membrane of the ER and the emerging polypeptide is extruded cotranslationally (during synthesis) into the lumen of this organelle. This marks the entry of the protein into the "secretory pathway," a route that comprises the rough ER-Golgi-plasma membrane-lysosomes and through which a protein can reach the cell surface (FIGURE 5.2). The sorting signals to the various organelles are listed in Table 5.1.

Most of the proteins synthesized on "free" polysomes remain in the cytosol as cytosolic or "soluble" proteins. These include enzymes involved in glycolysis, signal transduction (e.g., soluble protein kinases or phosphatases), factors of the translation machinery, and components of the cytoskeleton. Different mechanisms operate to posttranslationally translocate the cytosolic proteins into the nucleus, mitochondrion, and peroxisome.[5–7]

The nucleus not only imports proteins but also exports proteins to the cytoplasm, and in this sense, the transport in this organelle is bidirectional and regulated. As shown in Table 5.1, nuclear localization (NLS) and nuclear export (NES) signals were identified and shown to be highly selective for nuclear proteins.[8,9] Some proteins that shuttle from the nucleus to the cytoplasm contain both signals.

Protein Folding and Maturation

In order to become a functional protein, the nascent polypeptide chain must collapse into a conformation that is dictated primarily by the amino acid sequence (primary structure). Although this process can occur spontaneously at very low protein concentrations in a test tube, emerging polypeptides require assistance to fold in the highly crowded environment of the cytosol as the protein concentration is approximately 200 to 300 mg/mL. In fact, inappropriate interactions, misfolding, or aggregation occur under these conditions. Thus, nascent chains are guided through their maturation by molecular chaperones that also prevent inappropriate aggregation. The population of chaperones that assist folding in the cytosol is distinct from those that operate within the ER or mitochondria. Most molecular chaperones are members of the heat-shock protein (Hsp) family, so called because their expression is induced by briefly heating cells to 42°C. In general, chaperones attach to nascent polypeptide chains and initiate the folding process even before translation is completed. As the nascent polypeptide is being extruded from the ribosome, it is bound by chaperones that

Table 5.1

Examples of import signals

Organelle	Signal Location[a]	Example
Posttranslational Uptake		
Nucleus	Internal	SP**KKKRK***V**E* (import; NLS of SV40 large T antigen)
		KR-spacer (PAATKKAGQ)-**KKKK** (import, bipartite NLS of nucleoplasmin)
		LQLPP*LE***R**LTL*D* (export, NES of HIV-1 Rev)
Mitochondrion	*N*-terminal	MLGI**R**SSV**K**TCF**K**PMSLTS**KR**L (iron-sulfur protein of complex III)
Peroxisomes	*C*-terminal	**K**ANL (PTS1, human catalase)
	N-terminal	**R**LQVVLG**H**L (PTS2, human 3-ketoacyl-CoA thiolase)
Cotranslational Uptake		
ER	*N*-terminal	MMSFVSLLLVGILFWAT*EAE*QLT**K***CE*VFQ (ovine lactalbumin)

NOTES: [a]Acidic residues (negatively charged) are in italic type; basic residues (positively charged) are in bold type. Amino acids: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; **H**, histidine; I, isoleucine; **K**, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; **R**, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.
ER, endoplasmic reticulum; HIV, human immunodeficiency virus; NLS, nuclear localization signal; NES, nuclear export signal; PTS1, peroxisomal targeting signal-1; PTS2, peroxisomal targeting signal-2; SV40, simian virus 40.

recognize short sequence motifs containing hydrophobic amino acids. By undergoing cycles of binding and release (linked to ATP hydrolysis), these chaperones assist the nascent polypeptide to attain its native conformation, one aspect of which is burying hydrophobic sequence motifs in the protein interior so that they no longer contact the hydrophilic environment of the cytosol. Some properly folded protein monomers are assembled with other proteins to form multisubunit complexes. This also is facilitated by chaperones. Considerable effort is continuously devoted to the understanding of the mechanistic basis of protein folding and chaperone function.

Ubiquitin Addition Marks Proteins for Degradation

Proteins that are not properly folded are targeted for degradation. Such proteins are marked for selective destruction and are degraded to amino acids that are recycled in synthesis of new proteins. Degradation of selected molecules is achieved in two major phases. First, the molecules are tagged with a 76-residue polypeptide, termed *ubiquitin*, which is covalently attached to the target, and sequential attachment of multiple ubiquitin molecules can form a long polyubiquitin chain. Second, the polyubiquitylated molecules are ferried to a cytosolic ATP-dependent protease complex, the 26S proteasome, for destruction. The degradation of some mutated proteins that cannot fold is essential for the cell to prevent accumulation of misfolded or aggregated proteins.[10] Indeed, there is increasing evidence that many human diseases are due to accumulation or aggregation of misfolded proteins.

In addition to carrying out the disposal of damaged and misfolded proteins, ubiquitylation is also responsible for regulating a wide array of cellular processes including cellular differentiation, tissue development, inflammatory responses, antigen presentation, cell cycle progression, and apoptosis.[11–14] This regulation is accomplished through the controlled destruction of selected key regulatory proteins.

Other forms of attachment of ubiquitin (mono- or polyubiquitylation) trigger other types of processes such as endocytosis and DNA repair. Recently, histones were found to be a target of monoubiquitylation that is implicated in the recruitment for nuclear processes such as transcription and DNA repair.[15]

Targeting of Cytosolic Proteins to Membranes via Lipid Attachment

Some cytosolic proteins require the covalent attachment of lipid moieties in order to be inserted into a membrane where they will exert their function. The three main types of lipid attachment are *N*-myristoylation, prenylation, and palmitoylation. *N*-myristoylation consists of the attachment of a fatty acid of 14 carbon atoms (myristic acid) to the second residue, an invariable glycine, after proteolytic removal of the *N*-terminal methionine. This process is predominantly cotranslational, mediated by soluble enzymes, and has a strict consensus sequence (M**G**XXXS/T). The replacement of glycine with alanine abolishes the membrane attachment and consequently prevents the function of the protein at its site of action. This modification occurs in important regulatory proteins such as the proto-oncogene c-Src that is a protein kinase involved in the control of cell proliferation. More recently, members of the Ras family of small GTPases, which act as molecular GDP/GTP switches in many cellular processes, were found to be myristoylated. Among them are the ADP ribosylation factors (Arfs) that regulate membrane traffic through the secretory pathway and are ubiquitously expressed from yeast to humans[16] (see below). The best-characterized member of the Arf family is the yeast Arf1 protein. However, the mechanism of myristoylation of Arfs is not yet fully understood.

Prenylation is a posttranslational process also catalyzed by soluble enzymes. It involves the attachment of a prenyl group—either a farnesyl or a geranyl of 15 or 20 carbon atoms respectively—onto soluble proteins that carry a CaaX motif (C is cysteine, a is an aliphatic amino acid and X any amino acid) located at the *C*-terminal end of the protein. A prenyl group is attached to the cysteine residue, and then the last three amino acids are proteolytically removed and the cysteine is methylated. The Ras proteins undergo this modification that is otherwise rather rare. If the cysteine residue is mutated, the function of Ras in the cell is abolished because it cannot interact with its effectors. Since Ras proteins are activated in some kinds of cancer, inhibitors of prenylation are potential anticancer drugs.

As for the previous two modifications, also the attachment of a palmitic acid (a 16-C atoms fatty acid) to the SH group of a cysteine plays a role in the association of some proteins to the cytosolic side of the plasma membrane (S-palmitoylation). Polytopic membrane proteins catalyze this reaction, implying that it occurs at the cytosol-membrane interface. Palmitoylation is reversible and is often coupled with either *N*-myristoylation or prenylation to regulate the strength of membrane interaction of soluble proteins. Palmitoylation is more than a simple sorting signal. It has been implicated in the process of protein trafficking between organelles, in the segregation or clustering of proteins in the membrane compartment, and its regulatory role is often associated with the reversibility of this modification.[17] It was also reported that covalent attachment of fatty acid to the amino acid in proximity of a transmembrane region provides an additional membrane anchor to the protein. One of such examples is the E2 glycoprotein of the Sindbis virus.

Posttranslational Modifications and Regulation of Protein Function

Many proteins are subjected to further processing in order to become active. Among the vast array of dynamic or persistent modifications of the amino acid backbone, the most common modifications essential for protein functionality are the phosphorylation of specific amino acids or the proteolytic cleavage of a region (propeptide) of the protein precursor.

Protein phosphorylation is a reversible covalent modification catalyzed by protein kinases that transfer the γ-phosphate from ATP to specific hydroxyl amino acids such as serine (95% of the phosphorylated sites), threonine (4%), or more rarely tyrosine (<1%). Protein kinases represent one of the largest families of proteins within the human genome counting about 700 members. The opposite reaction is catalyzed by protein phosphatases that hydrolyze the linkage between the phosphate and the amino acid. Protein phosphorylation influences protein conformation. Cycles of phosphorylation–dephosphorylation control the functionality of many soluble enzymes involved in key steps of metabolic pathways or of plasma membrane proteins such as membrane receptors that are usually phosphorylated in their cytosolic domain upon stimulation by an extracellular ligand. An additional role of phosphorylation of specific residues is to

create docking sites for the binding to other proteins. This occurs in many signal transduction pathways where extracellular signals trigger the phosphorylation of specific amino acids to create binding sites for adaptor proteins that in turn recruit other proteins and activate a downstream cascade of intracellular signalling that culminates in the activation of transcription of responsive genes.

Characterization of the "phosphoproteome" is important to identify new substrates of protein kinases or compare the profile of phosphorylated proteins in different physiological conditions.[18] This can open the possibility to study on a large scale the biology of the response to the activation or inhibition of specific cellular receptors.[18]

Proteolysis is a terminal modification that is often used to activate in a controlled and irreversible manner the precursors of proteins whose activity is potentially harmful. In general, proteases are synthesized as longer precursors (zymogens) that are cleaved to produce the active protein (see further proteolysis in the Golgi). Other mechanisms for regulating protein activity are the interaction with ions or small molecules, such as Ca^{2+}, cyclic AMP, or guanylic nucleotides or with other protein partners.

OVERVIEW OF THE SECRETORY PATHWAY IN ANIMAL CELLS

In the presence of a "signal sequence" for the import in the ER (see Table 5.1), proteins are translocated across (soluble and secretory proteins) or inserted into (transmembrane proteins) the membrane of the ER. After folding and partial maturation in the ER, cargo proteins are loaded into vesicles and transported to the Golgi where proteins fully mature. Specific signals cause proteins to return from Golgi to the ER or to be retained in the ER, Golgi, or plasma membrane. In addition, proteins may be targeted from the Golgi to lysosomes or be transported from the plasma membrane to endosomes (see FIGURE 5.2). Although the map of protein maturation from the ER through the Golgi complex and storage in granules for traffic to the cell surface was charted by George Palade in 1975 by using pulse-chase experiments and ultrastructural analysis by transmission electron microscopy, the molecular dissection of the process was achieved upon genetic analysis of yeast, a unicellular microorganism. Classical genetic approaches led to the isolation of temperature-sensitive yeast mutants that were defective in different steps of secretion at the restrictive temperature (*sec* mutants). Then, recombinant DNA techniques allowed the isolation of the corresponding wild type genes that allowed their mammalian homologues to be cloned and characterized. Many *SEC* gene products are conserved from yeast to mammals, and this underlines the importance of this pathway for the life of eukaryotic cells.

Protein transport through the secretory pathway is mediated by vesicles. Different set of structural and regulatory proteins control the fusion of the appropriate vesicles with the target membrane. Sorting motifs dictate the selective incorporation of cargo proteins into those vesicles and their delivery to their intended destination.

The Endoplasmic Reticulum

The ER is a single and continuous membrane network that is contiguous with the nuclear envelope and is responsible for synthesizing the massive amounts of lipid and protein used to construct the membranes of most cellular organelles. The

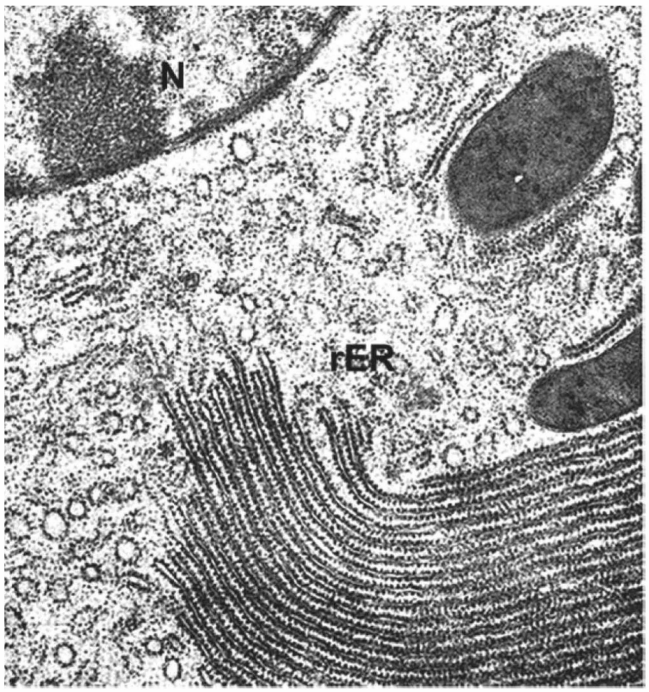

FIGURE 5.3 Electron micrograph of a pancreatic acinar cell. Long sacs are stacked in a regular array. The surface of the ER is studded with polysomes. N, nucleus; rER, rough endoplasmic reticulum.

ER comprises three interconnected domains: rough ER (rER), smooth ER, and ER exit sites. The rough ER is so called because it is studded with bound ribosomes that are actively synthesizing proteins (FIGURE 5.3). The ER-associated protein–ribosome complexes are very abundant, and the rER membrane is extremely expanded in cells producing high amount of secretory proteins. Among them, pancreatic exocrine cells that secrete large amounts of digestive enzymes every day or plasma cells that secrete thousands of antibody molecules (immunoglobulins) per second are the most remarkable examples.

The smooth ER lacks ribosomes, is not very abundant in most cells (except hepatocytes), and is thought to be the site of lipid biosynthesis and of cytochrome P450-mediated detoxification reactions. Finally, ER exit sites are specialized areas of the ER membrane where cargo is packaged into transport vesicles bound for the Golgi apparatus.

Translocation and Protein Processing in the ER

Incorporation of proteins into the ER occurs cotranslationally, a feature that distinguishes import into the ER from that into any other organelle. Nascent secretory proteins are earmarked for import early during their synthesis on cytosolic ribosomes by the presence of an amino-terminal "signal sequence" (see Table 5.1). The signal sequences have a length of about 15 to 30 amino acids, no conservation of primary sequence, and contain a hydrophobic core flanked by polar residues that preferentially have a short side chain in proximity to the cleavage site.

Cotranslational insertion of the nascent "preprotein" into the ER membrane involves the binding of ribosome to the

cytoplasmic side of the ER membrane and the passage of the nascent chain through a membrane channel that is called translocon. As the signal sequence is extruded from the ribosome, it is recognized by the *s*ignal *r*ecognition *p*article (SRP), a ribonucleoprotein, and this binding induces a temporary slowdown in translation.[19] The docking of ribosomes to the ER occurs by interaction of the SRP with the SRP receptor (SR) located in the ER membrane. Upon binding of GTP to both SRP and SR, the ribosome and the nascent chain are transferred to the Sec61 complex allowing translation to resume, and SRP is released to initiate a new cycle. Preproteins translocate through the Sec61 complex in the N to C direction. When approximately 20 largely apolar amino acyl residues enter the translocon, they are released sideways into the lipid bilayer. As the nascent polypeptide emerges from the luminal side of the translocon, its signal sequence is cleaved by a luminal signal peptidase.[20]

In the absence of specific sorting signals, a protein that is completely translocated into the lumen of the ER is secreted with the bulk flow in transit through the secretory pathway (default pathway). Evidence obtained both in yeast and mammalian cells suggests that different proteins are segregated in specific vesicles (see also below) suggesting the existence of parallel pathways of secretion. If a protein has hydrophobic domains (transmembrane domains, TMDs), it remains in the membrane and can assume different topologies. Notably, proteins with a single TMD or multiple TMDs can be oriented with the *N*-terminus end toward the ER lumen (Type I) or the cytosol (Type II), and this orientation will be maintained in the final destination taking into account that the lumen of ER is equivalent to the extracellular space. Sorting signals direct soluble and membrane proteins to the appropriate compartment of the secretory pathway.

Protein Maturation in the ER

Secretory proteins undergo folding in the ER where also a number of other processing reactions including disulfide bond formation, attachment of oligosaccharides (*N*-glycosylation), addition of glycolipids, and modification of specific amino acids take place. Protein chaperones are the key players for folding.[21] Chaperones like the Hsp70 family member, BiP, which is associated with the luminal face of the translocon, assist the folding of the nascent protein. Folding is completed posttranslationally and then oligomerization takes place. Different classes of chaperones are thought to act in sequence to achieve complete folding/assembly. In addition to chaperones, there are folding catalysts that increase the rate of protein folding by promoting reactions such as the formation of disulfide bonds or *cis–trans* proline isomerization that confer stability to the protein structure. Oxidoreductases play a relevant role in disulphide bond formation. The enzyme protein disulfide isomerase (PDI), an abundant ER protein, functions in the formation and isomerization (reshuffling) of disulfide bridges during protein folding in the ER. PDI1 is the best-characterized member of the PDI family that consists of 17 members that share at least one thioredoxin-like domain with the CXXC active site motif.[22] As shown in FIGURE 5.4, the oxidation of two thiols to produce a disulfide bond (S–S) in a substrate protein, concomitantly reduces two thiols of PDI that return to the oxidized state by another thiol-disulfide exchange catalyzed by ERO1, a membrane associated oxidoreductase. ERO1, which is a flavoprotein, returns to the oxidized state by transfer of electrons to molecular oxygen via its cofactor FAD. Glutathione buffers the system and reduces excessive or inappropriate formation of disulfide bonds (FIGURE 5.4).

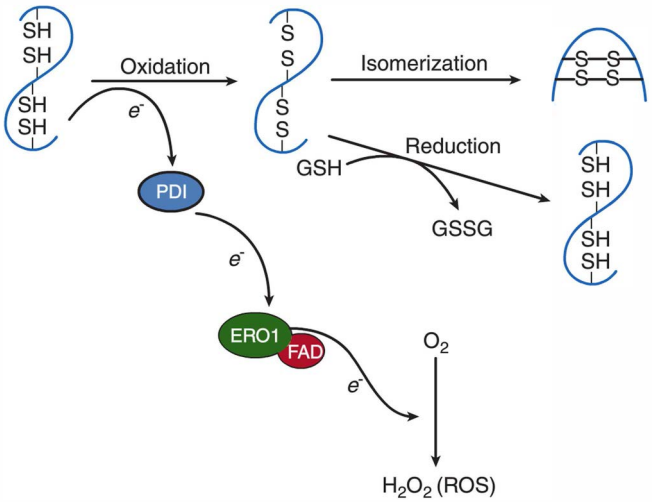

FIGURE 5.4 Disulfide bond formation in the ER. Proteins that fold in the ER acquire disulfide bonds through an oxidation process catalyzed by thiol-disulfide oxidoreductases. FAD, flavin adenine dinucleotide (cofactor of ERO1); GSH, glutathione; GSSG, oxidized form of glutathione; ROS, reactive oxygen species.

N-glycosylation is a biologically important protein modification that initiates in the ER (core-glycosylation) and is further completed in the Golgi apparatus. This process consists in the transfer *en-bloc* of a presynthesized "core" glycan chain from a lipid-linked donor (dolichol pyrophosphate) to the asparagine residue of a nascent protein in a consensus sequence *N*-[X]-S/T where X is any amino acid except proline.[23] Core oligosaccharide chains are composed of a glucose$_3$-mannose$_9$-*N*-acetylglucosamine$_2$ ($Glc_3Man_9GlcNac_2$) structure. The transfer is catalyzed by the oligosaccharyl transferase complex (OST) composed of multiple transmembrane subunits.[24,25] About 75% of the predicted consensus sequences of *N*-glycosylation site are occupied by sugar chains suggesting that steric factors also determine the recognition process by OST. After addition, *N*-linked glycans are processed in the ER where the glucose residues and one mannose residue are removed. This processing continues during their movement through the Golgi where final elaboration of oligosaccharide chains is completed (FIGURE 5.5).

N-glycans are important for the physical properties they confer and for many physiological purposes. Glycans protect proteins against denaturation and proteolysis and are abundant in hinge and spacers that are more susceptible for proteolytic attack. *N*-linked oligosaccharides confer hydrophilicity to the proteins and enhance their solubility. Moreover, *N*-glycans promote secretion and inhibition of *N*-glycosylation blocks secretion, whereas removal of single or multiple *N*-glycosylation sites by mutagenesis may reduce the efficiency of secretion. *N*-glycans can be enzymatically removed from the folded proteins without appreciable effects on protein structure and function. Although *N*-glycans are often not required for the enzymatic activity of many glycoproteins, there are glycans specifically required for the biological activity of some hormones and for mediating interaction with other proteins. Examples are erythropoietin,

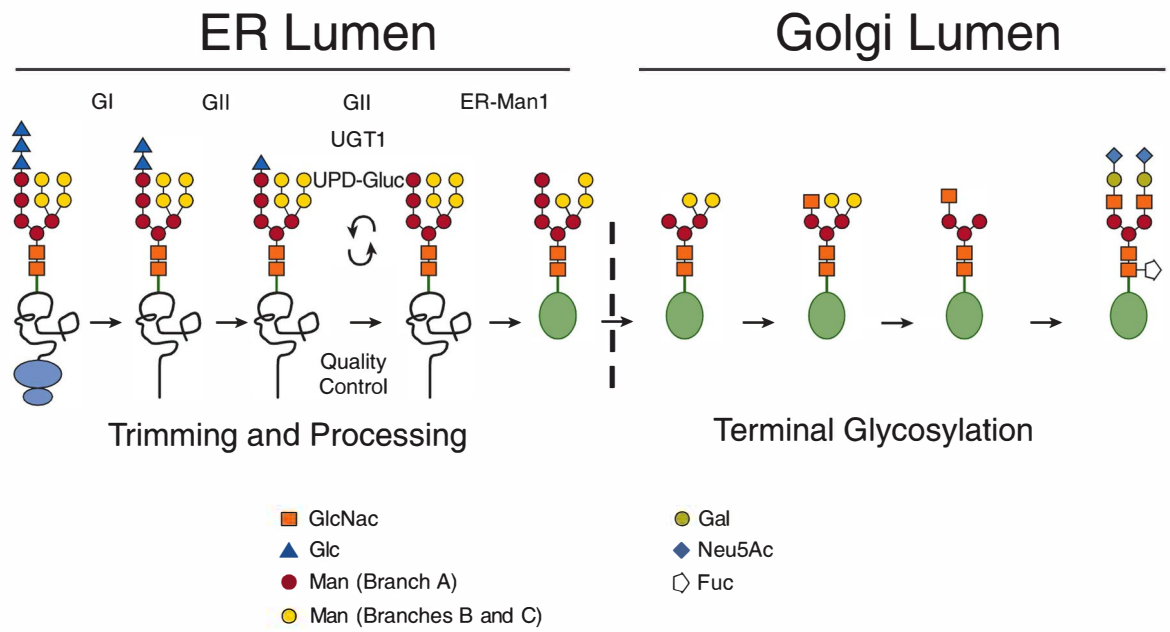

FIGURE 5.5 Processing of *N*-linked oligosaccharide chains in the ER and final maturation in the Golgi apparatus. Nascent glycopolypeptides undergo core *N*-glycosylation into the lumen of the ER. The processing of the *N*-linked chains is strictly coupled with folding and trafficking through the secretory pathway. Glucosidase I (GI) removes the outermost of the three terminal glucose residues. Then, glucosidase II (GII) removes the middle and the monoglucosylated glycoprotein enters the CNX/CRT cycle (not shown in the Figure, see text for detail). When the terminal glucose residue is removed by GII, the glycoprotein dissociates from CNX and CRT and leaves the ER if it is properly folded. The enzyme UDP-glucose: glycoprotein glucosyltransferase (UGGT, also named UGGT1 or UGT1) acts as a folding sensor and reglucosylates incompletely folded glycoproteins for another cycle of folding. The properly folded glycoprotein is represented by the green ellipse. Upon exit from the ER, ER-mannosidase I (ER-Man1) removes a mannose residue. Mannose trimming continues in the Golgi apparatus. Terminal glycosylation generates high-mannose, complex, or hybrid types of glycan structures (see FIGURE 5.7). The figure only shows a pathway leading to a biantennary complex-type glycan, but the number of antennae may vary up to six. In lysosomal soluble glycoproteins, the creation of a M6P signal targets the protein to the lysosome. (From *Angewandte Chemie International Edition*, Lehle L, Strahl S, Tanner W, vol. 45:6802–6818 ©2006 by John Wiley and Sons, with permission.)

the clotting factor IX, and the hormone chorionic gonadotropin that require particular *N*-linked chains for their function. The sugar moiety is required for proper secretion, for direct interaction with the cognate receptors, or to maintain the protein in an appropriate conformation for the interaction with the receptor. Moreover, decades of research have revealed that the carbohydrate moiety of glycoproteins modulate immunogenic properties of proteins and the mechanism by which they are cleared from the circulation. Factor VIII and von Willebrand factor (vWF) are relevant examples.[26]

In addition, several studies have outlined the important role of *N*-glycosylation in promoting folding. The addition of glycans may increase hydrophilicity of the folding peptide and thus prevent aggregation, influence the formation of secondary structures for steric effects and affect the disulfide bond formation. An indirect role concerns the interactions of glycans with specific chaperones with lectin-like properties to monitor folding.[23,27,28] In mammalian cells, core *N*-linked oligosaccharides are substrates for a complex chaperone system composed by the lectin chaperones calnexin (CNX) and calreticulin (CRT), ERp57 (an ER oxidoreductase), two glucose-removing enzymes (glucosidase I [GI] and glucosidase II [GII]), and one folding sensor endowed with reglucosylation activity (UDP-glucose: glycoprotein glucosyltransferase, UGT1). Proteins enter this system after they receive at least two *N*-glycan chains. GI and GII remove two terminal glucoses. The resulting monoglucosylated *N*-linked chain interacts with CNX/CRT and ERp57. Proteins that have not completed the folding process are detected by UGT1 and reglucosylated.[29] The addition of glucoses allows reassociation with the CNX/CRT chaperone system and a new cycle begins. If the protein is not folded after repetitive cycles, it is recognized and directed to degradation by ER-associated degradation (ERAD) (see further). Since the trimming of the glycans marks the disposal of these proteins, a "glycan-code" has been proposed to exist in the ER.[30]

In conclusion, folding requires sequential interactions with distinct chaperones and folding catalysts. An example is provided by major histocompatibility complex class I molecules that exploit both the CNX/CRT cycle and other devoted ER-resident molecules for their assembly.

Glycolipid Attachment

The glycosylphosphatidylinositol (GPI)-anchored proteins are a class of proteins that are usually localized in the outer side

of the plasma membrane.[31] The protein precursor has both a signal sequence and a *C*-terminal sequence that directs the attachment of a GPI anchor to the preprotein. These proteins lack a TMD, and the glycolipid functions as the only means for membrane anchoring. Defects in the human phosphatidylinositol glycan-A gene (PIG-A) involved in the first stage of GPI-biosynthesis is the cause for an unusual form of acquired hemolytic anemia that occurs in adults (paroxysmal nocturnal hemoglobinuria). This disease is due to the lack of expression of certain GPI-anchored proteins. An example of a GPI-anchored protein is the decay-accelerating factor (DAF) that down-regulates complement activation on "self" surface and protects red cells from its action. In the absence of DAF, there is excess reticulocyte hemolysis.

γ-Carboxylation of Glutamic Acid Residues

While glycosylation is a frequent modification in secreted proteins, other modifications are less common but are required for the function of some proteins. A specific set of proteins is posttranslationally modified by γ-carboxylation of glutamic acid residues (Glu).[32] This modification is catalyzed by a vitamin K–dependent γ-glutamyl carboxylase that converts selected Glu to γ-carboxylglutamic acid (Gla) in a ca. 45–amino acid peptide sequence (the Gla domain) that encompasses the *N*-terminal region of the target protein.[33] The Gla residues function to coordinate Ca^{2+} that is essential for the biological activity of multiple factors in blood coagulation.[34] These procoagulant factors are prothrombin and factors VII, IX, and X, as well as the anticoagulants protein C and protein S. Other substrates of the γ-carboxylase are less characterized except for the bone proteins osteocalcin and matrix Gla protein that both require γ-carboxylation for full activity.

γ-Carboxylase is an integral membrane glycoprotein localized to the ER.[35] Its obligate cofactor, reduced vitamin K (KH_2), is produced by the action of vitamin K–epoxide reductase (VKOR) that converts oxidized vitamin K to the reduced form (FIGURE 5.6). VKOR is a small transmembrane protein that is predicted to be localized in the ER as well.[36,37] The activity of VKOR is inhibited by warfarin, a potent anticoagulant compound. Similar to prothrombin and factor V–deficient mice, γ-carboxylase homozygous null mutants manifest dramatic developmental defects with partial midembryonic lethality and postnatal hemorrhage.[38] These findings suggest that components of the blood coagulation cascade are functionally critical substrates for γ-carboxylation.

β-Hydroxylation of Amino Acids

β-Hydroxylation of proline and lysine residues is another posttranslational modification that is typical of procollagen. In addition to this extracellular matrix protein precursor, a subset of secreted plasma proteins involved in blood coagulation, such as factor IX, contains epidermal growth factor (EGF) domains in which an aspartic acid or an asparagine are β-hydroxylated and converted in the ER into β-hydroxyaspartate (Hya) or β-hydroxyasparagine (Hyn).[34] The role of these modifications is uncertain. It has been proposed that formation of Hya negatively regulates fucosylation of the EGF domains.[34]

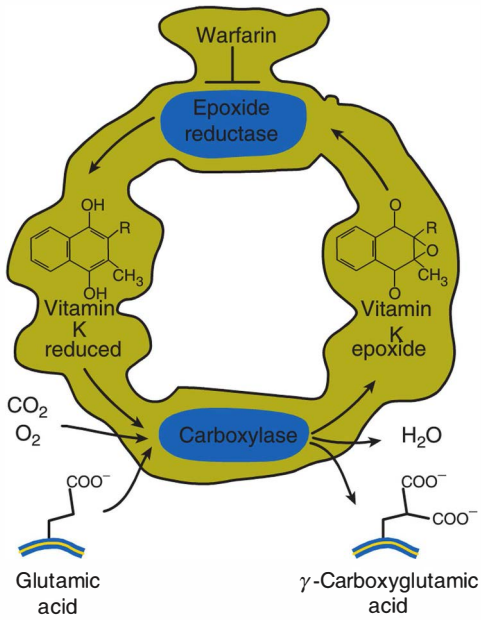

FIGURE 5.6 Protein γ-carboxylation is catalyzed by a vitamin K–dependent carboxylase. Several blood-clotting proteins contain glutamic acid residues that are converted to γ-carboxyglutamic acid by a carboxylase. This enzyme uses reduced vitamin K and oxygen to add a carbon dioxide molecule to the side chain of selected glutamic acid residues producing γ-carboxyglutamic acid. Vitamin K 2,3-epoxide is recycled to reduced vitamin K by vitamin K epoxide reductase, an enzyme inhibited by warfarin. (Adapted from Sadler JE. Medicine: K is for koagulation. *Nature* 2004;427:493–494.)

ANTEROGRADE TRANSPORT FROM ER TO GOLGI

The transport of proteins and lipids from the ER to the Golgi occurs through vesicles. On achieving transport competence, proteins are granted access to higher-ordered membrane domains termed ER exit sites. At ER exit sites, membrane-bound and -soluble proteins are concentrated into transport vesicles for trafficking to a network of smooth membranes called the *ER–Golgi intermediate compartment* (ERGIC). The COPII complex, composed of *co*at *p*roteins, concentrates and packages the cargo proteins into vesicles. COPII binds to cargo molecules either directly, if they span the membrane, or through intermediate cargo receptors and then provides some of the force that causes vesicle budding, thereby linking cargo acquisition to vesiculation.[39] The process has been dissected at a molecular level. On the cytosolic face of the ER membrane, the RAS protein SAR1 is activated by the ER localized GEF SEC12. SAR1 GTP assembles with the SEC23–SEC24 complex whose SEC24 subunit binds directly or through a membrane receptor to specific signals displayed by the cargo. This prebudding cargo complex recruits the outer layer SEC13–SEC31 complex leading to coat polymerization, membrane deformation, and COPII-vesicle formation.[39]

Receptor-Mediated Transport of Factors V and VIII in the Secretory Pathway

To date, the only well-characterized mechanism of cargo recognition in mammalian cells concerns two coagulation factors, factor V (FV) and VIII (FVIII).[40] Combined deficiency of FV and FVIII causes a bleeding disorder characterized by a reduced plasma level of these coagulation factors to 5% to 30% of normal. This reduction is due to a defective trafficking of FV and FVIII from the ER to the Golgi compartment.

One of two genes, *LMAN1* or *MCFD2*, is mutated in patients with combined deficiency of FV and FVIII. LMAN1, *l*ectin *ma*nnose-binding protein1 (also referred to as ERGIC-53), is a transmembrane protein with a *C*-terminal cytoplasmic tail containing an ER-exit-motif (two phenylalanine residues, FF). This motif allows the interaction of LMAN1 with the COPII-coat proteins. In addition, the luminal domain of LMAN1 recognizes mannose residues and binds MCFD2, a luminal protein, in a Ca^{2+}-dependent manner. The LMAN1–MCFD2 complex functions as a cargo receptor that recruits FV and FVIII into specific transport vesicles. The mutant forms of both LMAN1 or/and MFCD2 fail to recruit FVIII into the vesicles. Interestingly, the LMAN1–MCFD2 complex appears to be required only for the secretion of factors V and VIII, as there are no significant reductions in any other plasma proteins.[41]

Retrograde Golgi–ER Transport

ER resident proteins are selectively retained in the ER by both, the absence of export signals and the presence of ER retention signals. Soluble luminal ER residents are retained through a *C*-terminal ER tetrapeptide retention motif KDEL. Frequently, transmembrane proteins have either a *C*-terminal dilysine motif KKXX or an *N*-terminal diarginine motif XXRR, or variants thereof. However, it is more accurate to designate ER localization signals as "retrieval motifs" because proteins bearing these signals can transiently escape from the ER into the ERGIC, from which they are returned to the ER through the retrograde vesicular transport (FIGURE 5.2).

For the KDEL motif of luminal ER proteins, a specific retrieval receptor has been identified, first in yeast and then in mammals. The KKXX motif directly interacts with the COPI coat protein complex that is involved in retrograde transport from ER to the Golgi. Retrograde transport also serves to replenish the vesicle components lost as a result of anterograde (forward) transport. In conclusion, selective protein exit from the ER is achieved by monitoring/regulating (a) transport competence of nascent proteins, (b) capture of cargo in transport vesicles, and (c) protein retention/retrieval for ER-localized proteins.

INTRA-GOLGI TRANSPORT AND PROTEIN PROCESSING

The Golgi complex comprises a stack of flattened, membrane-bound cisternae that is highly dependent on microtubules for its integrity. The stack of cisternae can be subdivided into three parts referred to as *cis, medial*, and *trans* with the *cis* and *trans* sides facing the ER and the plasma membrane, respectively (FIGURE 5.2). Both the *cis* and *trans* faces are associated with tubulovesicular bundles of membranes. The ERGIC comprises the bundle on the *cis* side of the Golgi stack and is the site where incoming proteins from the ER are sorted into those directed for anterograde or for retrograde transport. The tubulovesicular bundle at the *trans* side is the *trans-Golgi* network (TGN, see FIGURE 5.2).

A major feature of the Golgi is polarity. The processing events are temporally and spatially ordered because the processing enzymes have a characteristic distribution across the Golgi stack. Among these enzymes are glycosyltransferases that sequentially modify *N*-linked chains. In the Golgi, additional types of modifications take place as for example protein *O*-glycosylation, phosphorylation of oligosaccharides, and sulfation of tyrosine residues (see further).

Retention of Resident Golgi Proteins

The continuous influx and efflux of proteins through the Golgi poses the question on how this organelle maintains its identity.[42] Extensive analyses have failed to reveal a clear retention motif enabling subdomain-specific retention of resident Golgi proteins. Two possible models have been proposed. The first is based on the finding that the TMDs of Golgi proteins are shorter than TMDs of plasma membrane proteins. These differences should allow a preferential interaction with the Golgi membrane lipid bilayer that is thinner than that of plasma membrane. The second postulates that proteins of a given subdomain of the Golgi membrane can aggregate into large detergent-insoluble oligomers as a way of minimizing lipid–protein contact. This would prevent the entry of proteins into the vesicles and thus their traffic to more distal cisternae. There is evidence in support of both models.

In general, a dynamic process of iterative rounds of retrograde and anterograde transport allow specific proteins, mainly glycosyltransferases, to maintain a compartment-specific distribution.

Protein Trafficking through the Golgi Apparatus

Cargo proteins exit the ER in COPII-coated vesicles that enter the ERGIC and are ultimately delivered to the *cis-Golgi* either in vesicles or along extended tubules. However, the means by which cargo proteins move across the Golgi complex from *cis* to *trans* remains controversial.[43] Two models have been proposed. The vesicular transport model contends that anterograde transport occurs in vesicles or tubules. The second suggests that there is a cisternal maturation. This alternative model proposes that Golgi cisternae are not fixed structures but move forward from the *cis* side to the *trans* side, generating an anterograde movement. As cisternae mature, resident Golgi proteins that belong to more *cis*-like cisternae must be selectively pinched off in vesicles and trafficked back to the *cis* side of the Golgi stack. This would occur by COP-I-mediated retrograde vesicular transport (FIGURE 5.2). Although it is presently unknown which of these models is correct, the majority of the experimental data support the cisternal maturation model.

Protein Modifications in the Golgi Apparatus

As mentioned above, a sequential series of additional carbohydrate modifications occur as proteins transit through the Golgi compartments. Mannose residues are removed by Golgi mannosidase I and II, and then glycosyltransferases catalyze the addition of complex sugars such as *N*-acetylglucosamine (GlucNac), fucose (Fuc), galactose (Gal), and *N*-acetyl neuraminic acid (sialic acid, Neu5Ac) in a spatial and temporal tightly regulated order (FIGURE 5.5). Three types of oligosaccharide structures can be generated: highly complex, high-mannose, and hybrid structures[44] (FIGURE 5.7).

In the Golgi also *O*-glycosylation occurs.[45,46] This post-translational modification involves the attachment of *N*-acetylgalactosamine (GalNAc) to the hydroxyl of serine or threonine residues through an *O*-glycosidic linkage. This reaction is carried out by UDP-GalNAc:polypeptide *N*-acetylgalactosaminyl transferases (ppGalNAcTs) that comprise a striking redundant family of enzymes in eukaryotic cells. Target serine and threonine residues are often clustered together. Mucins represent abundantly *O*-glycosylated proteins and are used as model proteins for studies on protein *O*-glycosylation.

Tyrosine *O*-sulfation also occurs in the *trans*-Golgi network and is mediated by tyrosyl protein sulfotransferases that catalyze the transfer of a sulfuryl group (SO_3^-) from a donor 3'-phosphoadenosine 5'-phosphosulfate to specific tyrosine residues.[47] This modification occurs on many secretory proteins including a number of proteins that interact with thrombin, such as hirudin, a leech-derived anticoagulant, fibrinogen, heparin cofactor II, α-2-antiplasmin, vitronectin, bovine factor X, factor V, and factor VIII.[48]

Proteolytic Processing in the Golgi

Many secretory proteins are synthesized as larger precursors (preproproteins) that after translocation into the ER (proprotein) undergo further maturation by proteolysis in the late compartments of the secretory pathway. Among them are proteins that perform physiological important functions such as hormones, serum proteins, growth factors, and neuropeptides.[49] Consequently, this processing takes place in many different tissues. The proproteins are cleaved internally and the mature product/s result/s from the excision of specific segments. A family of Ca^{2+}-dependent serine endoproteases, called proprotein convertases (PCs), are responsible of the proteolytic processing. PCs hydrolyze the peptide bond on the carboxyl side of a pair of basic residues KK↓ or RR↓. Mammalian PCs are related to Kex2p, a Golgi subtilisin-like endoprotease required for processing of α-factor mating pheromone and killer toxin in the yeast *Saccharomyces cerevisiae*. Kex2p has been the first PC to be identified and was extensively studied taking advantage of genetic manipulation in yeast.[50]

PCs are themselves proenzymes. Mammalian PCs have a canonical signal sequence, a proregion, a catalytic domain, and a P domain but differ in the *C*-terminal region. The activity and localization of PCs are highly regulated. For instance furin/PC1,

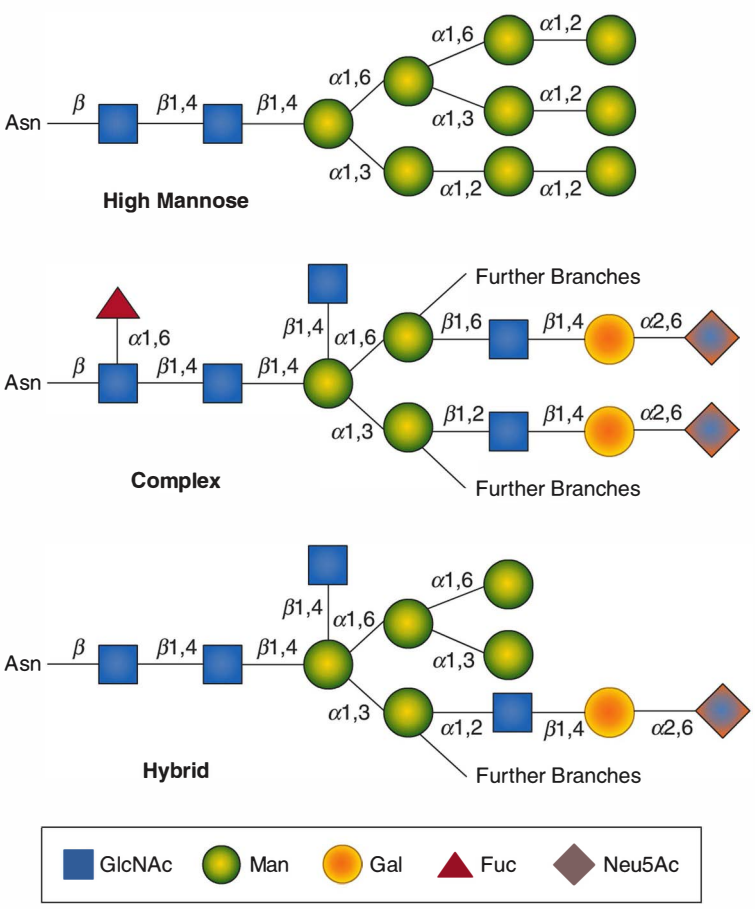

FIGURE 5.7 Scheme of the structure of high-mannose-, complex-, and hybrid-type *N*-linked glycans. (From Skropeta D. The effect of individual *N*-glycans on enzyme activity. *Bioorg Med Chem* 2009;17:2645–2653, with permission © 2009 by Elsevier Ltd.)

involved in the processing of proinsulin, becomes active by autocatalytic cleavage of the proregion that induces folding and exit from the ER. The prodomain remains attached noncovalently until the cleaved inactive enzyme reaches the Golgi where the more acidic pH (pH ~ 6.5) and also the Ca^{2+} enriched environment facilitates dissociation of the prodomain. A second cleavage within the prodomain precludes further inhibitory interactions resulting in full activation. PCs are usually retained in the TGN by virtue of their TM domains and cytosolic tails whereas nonanchored forms localize to secretory granules. In these locations these processing enzymes have access to the many proteins that move toward the cell surface via the constitutive or regulated branches of the secretory pathway. Insight into the catalytic mechanism of substrate specificity and cleavage came from the resolution of the crystal structure of Kex2p and furin.[50]

Another mechanism of proteolytic processing specific to the Golgi was recently identified. It consists of regulated intramembrane proteolysis of ER membrane precursors of transcription factors that are transported to the Golgi upon activation of a signalling pathway. Two remarkable examples are provided by ATF6 (see also section on unfolded protein response [UPR]), a latent precursor of a basic leucine zipper (bZIP) transcription factor, and the sterol-regulatory element binding protein. These proteins are transported from the ER to the Golgi in response to the activation of the UPR or to reduced sterol levels. In the Golgi membrane, proteolytic events catalyzed by two specific proteases (S1P and S2P) cleave the protein and release the soluble active transcription factor that migrates to the nucleus and activates the expression of specific sets of genes.[51]

Protein Assembly in the Golgi

Although the ER is the primary site for folding of secretory proteins, formation of disulfide bonds and multimer assembly for an essential hemostatic glycoprotein—vWF—undergo a remarkable conformational change in the Golgi.[52] The mechanism has probably evolved to bypass the limited capacity of cargo size for ER to Golgi transport vesicles. Sequential changes that occur in the ER, Golgi, and extracellular space were identified. The first assembly step occurs in the ER with "tail-tail" dimerization of vWF precursor. This event is coupled with the formation of disulfide bonds between the *C*-terminal domains of the protein. Then, vWF is transported to the Golgi where a proprotein protease, probably furin, cleaves the propeptide and additional intersubunit disulfide bonds form "head to head" between the *N*-terminal D3 domains.[53] Since the Golgi lacks known chaperones and has an acidic pH that inhibits disulfide bond rearrangement, vWF has evolved an *N*-terminal domain (propeptide) that functions as oxidoreductase at the low pH of the Golgi. More conformational changes occur in the extracellular environment to give origin to large multimers of vWF that are the most effective for hemostasis.[52]

GOLGI TO PLASMA MEMBRANE TRANSPORT AND ENDOCYTOSIS

Overview

The TGN is the station for intracellular sorting, where proteins bound for lysosomes or regulated secretory vesicles are separated from those entering the constitutive pathway of secretion leading to the plasma membrane (FIGURE 5.2). The secretion process is called exocytosis. The molecular basis for diversion of proteins into lysosomes and regulated secretory granules is described below.

Sorting into Lysosomes

Lysosomes are organelles with an acidic internal pH (5 to 5.5). They contain numerous hydrolytic enzymes designed to degrade proteins, carbohydrates, and lipids. In the Golgi soluble hydrolases are recognized by the presence of signal patches and are selectively marked for sorting into lysosomes by phosphorylation of their *N*-linked oligosaccharides that creates the mannose-6-phosphate (M6P) sorting signal. On arrival at the TGN, the modified hydrolase is bound by a cargo transmembrane receptor, the M6P-receptor (M6P-R), which delivers it first to a "late endosomal compartment," where the low pH releases the hydrolase from the M6P-R. Subsequently, the hydrolase is delivered to the lysosome, and the M6P-R is recycled to the TGN.

The motif responsible for targeting M6P-R to lysosomes is YSKV and is recognized by adaptins, multisubunit complexes (AP) that contribute to the assembly of clathrin on the cytosolic side of the vesicle. In this way, APs help the delivery to lysosomes by linking cargo acquisition to vesiculation. Thus, cargo recruitment occurs in a manner similar to the one described for the COPI- and COPII-coated vesicles except that the coat is clathrin. In addition to luminal hydrolases, lysosomes also contain a wide array of membrane proteins that are targeted to lysosomes via one of two consensus motifs: (a) YXXe, where X is any amino acid and e is any amino acid with a bulky hydrophobic side chain and (b) a leucine-based motif (LL or LI). Trafficking of these membrane-bound proteins to lysosomes is indirect, proceeding first to late endosomes or the plasma membrane prior to their retrieval to lysosomes. Failure to accurately target lysosomal hydrolases underlies Hurler syndrome and inclusion-cell (I-cell) disease. In I-cell disease patients, the hydrolases missing from the lysosomes are secreted from the cell and found in the blood.

Autophagosomes and Phagosomes

Lysosomes are also the organelles with which autophagosomes fuse. Autophagosomes are ER-derived organelles into which fragments of other cytoplasmic organelles or cytosolic components are engulfed. After fusion with the lysosomes, the contents of the autophagosome are degraded by digestive enzymes to recycle its constituents. Autophagy is activated in many stress conditions, such as nutrient or growth factor deprivation, hypoxia, oxidative stress, DNA damage, protein aggregation, damaged organelles, or intracellular pathogens.[54–56] Autophagy is a central process of the integrated cell response.[56] Recently, studies on autophagy have received significant attention after the discovery that this process is also required during development.[57] Notably, in mammals, autophagy is essential for the extensive cell reprogramming that occurs during development and cell differentiation. In early oocyte fertilization and early neonatal development, two massive waves of autophagy are triggered. Moreover, during erythroblast differentiation to erythrocytes, loss of organelles occurs. Although the implication of autophagy in this process is still uncertain, recent studies indicate that the mitochondrial clearance in reticulocytes is partly dependent on autophagy and defects in this process cause

reduction of mature erythrocytes (anemia) or compensatory expansion of erythrocyte precursors (reticulocytosis).[57]

Another organelle, the phagosome, derives from lysosomes. Microorganisms, like bacteria or fungi, are ingested by phagocytosis. The phagosome, into which a lysosome transforms to destroy an ingested pathogen, is a specific compartment of professional phagocytes such as macrophages, neutrophils, and dendritic cells that act as a first-line defense to pathogenic organisms. Phagosomes and autophagosomes are examples of the dynamic nature of the structural organization of the cell that changes to meet the needs of the organism.

Sorting into Regulated Secretory Granules

In regulated secretion, proteins are condensed into secretory granules that are stored and released to the plasma membrane after the cell has received an appropriate stimulus (FIGURE 5.2). The significance of this additional secretory system is to provide for rapid secretion of soluble components upon demand. Several examples are the secretion of hormones, neurotransmitters, and digestive enzymes.

After budding from the TGN, the granule proteins are concentrated (up to 200-fold in some cases) by selective removal of extraneous contents from clathrin-coated vesicles. Mature secretory granules are thought to be stored in association with microtubules until the stimulation of a surface receptor triggers their exocytosis. One example of stimulus-induced exocytosis is the binding of a ligand to the T-cell antigen receptor complex on a cytotoxic T lymphocyte. Conjugation of a cytotoxic T cell with its target causes its microtubules and associated secretory granules to reorient toward the target cell. Subsequently, the granules are delivered along microtubules until they fuse with the plasma membrane, releasing their contents for lysis of the target cell. Following release of the granule contents, the granule membrane components are internalized and transported back to the TGN, where the granule can be refilled with cargo proteins.

SPECIFICITY OF VESICULAR TARGETING

As described above, COPI and COPII vesicles transport material early in the secretory pathway whereas clathrin-coated vesicles transport material from the plasma membrane and Golgi. Coating proteins assemble at specific areas of the membrane in a process controlled by the coat recruitment GTPase. While SAR1 is responsible for COPII coat assembly at the ER membrane, ARF1 is responsible for the assembly of COPI coats and clathrin coats at Golgi membranes. Clathrin coat assembly at the plasma membrane is also thought to involve a GTPase, but its identity is unknown. These regulatory proteins also ensure that membrane traffic to and from an organelle is balanced.

After budding, vesicles are transported to their final destination by diffusion or motor-mediated transport along the cytoskeletal network (microtubules or actin) (FIGURE 5.8). The molecular motors kinesin, dynein, and myosin have been implicated in this process. The vesicles undergo an uncoating process before fusion with the correct target membrane. Both transport vesicles and target membranes display surface markers that selectively recognize each other.

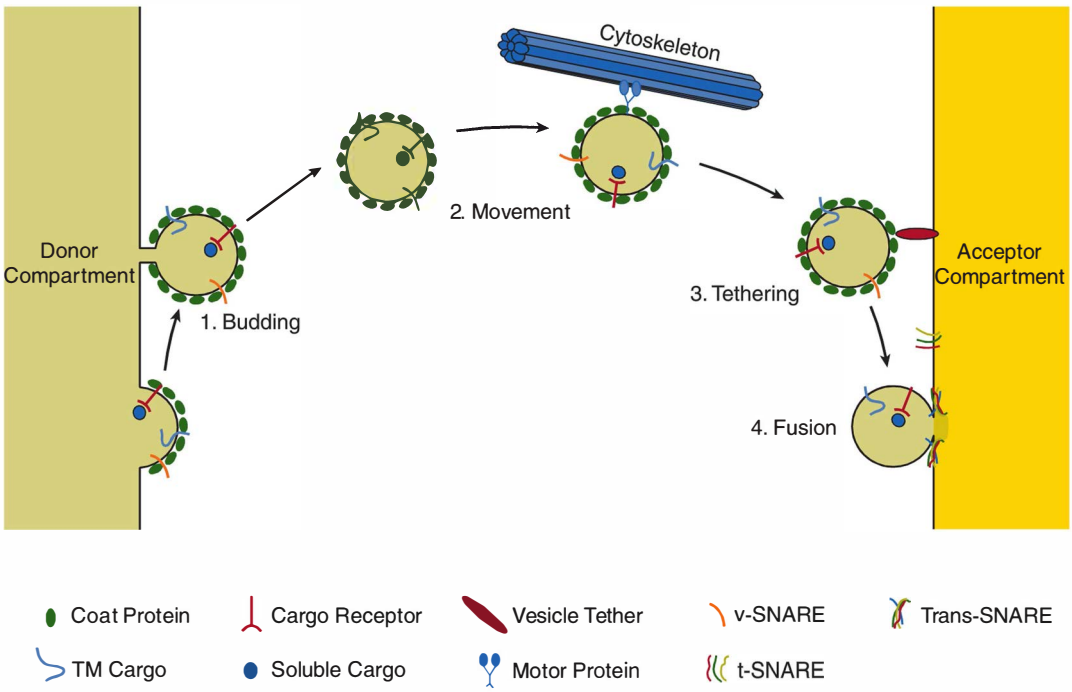

FIGURE 5.8 The essential steps in vesicle transport. The scheme represents: (*1*) budding and incorporation of soluble cargo into a vesicle; (*2*) movement of the vesicle toward the acceptor membrane by diffusion or with the aid of a cytoskeletal track; (*3*) tethering of the vesicle to the acceptor membrane by action of tethering factors in conjunction with Rab GTPases; and (*4*) fusion mediated by the assembly of a four-helix bundle between vesicle-associated and target-membrane SNAREs. (From Cai H, Reinisch K, Ferro-Novick S. Coats, tethers, Rabs, and SNAREs work together to mediate the intracellular destination of a transport vesicle. *Dev Cell* 2007;12:671–682, with permission © 2007 by Elsevier Ltd.)

Three classes of proteins assist the selectivity of vesicle docking and subsequent fusion: (a) a class of GTPases called Rabs, (b) protein complexes, called tethers, that together with Rabs facilitate the initial docking of the vesicles to the target membrane, and (c) complementary sets of *v*esicle SNAREs, v-SNAREs, [Soluble NSF (N-ethylmaleimide-sensitive factor) Attachment Protein Receptor], and *t*arget membrane SNAREs (t-SNAREs) that promote vesicle fusion[58,59] (see FIGURE 5.8).

PROTEIN QUALITY CONTROL IN THE SECRETORY PATHWAY

The main regulation of protein traffic through the secretory pathway occurs at the level of ER where newly synthesized proteins are subjected to quality control. As mentioned before, only properly folded proteins can exit this organelle and transit through the other compartments. Proteins that do not satisfy the necessary requirements are degraded and/or activate a complex response aimed to protect the cell from toxic effects of accumulation of abnormal proteins and to improve protein folding.

Targeting Proteins for Degradation in the ER

Improperly folded proteins are destroyed by ERAD.[60,61] A simple scheme of ERAD is shown in FIGURE 5.9. The recognition process is mediated by ER lectin-like proteins (not shown in the figure) that specifically recognize short glycan chains generated by the action of ER proteins named EDEMs (ER-degradation enhancing mannosidase-like).[62,63] The substrate for EDEMs are misfolded proteins that are probably recognized by BiP or by the CNX/CRT chaperone system due to their exposed hydrophobic patches of amino acids or sugar moieties, respectively. After retrotranslocation to the cytosol through a protein-conducting channel, luminal proteins are polyubiquitylated at the cytosolic face of the ER by the ER associated ubiquitin ligases.[64] The modified proteins are removed from the membrane by Cdc48, a member of the family of ATPases associated with diverse cellular activities (AAA^+) and directed to proteasomal degradation as occurs for misfolded cytosolic proteins.[64] Proteins that misfold their cytosolic, luminal, or membrane-spanning domains are directed to the ERAD-C, ERAD-L, or ERAD-M pathways, respectively.[65]

Another fate of misfolded proteins in the ER is entrapment in aggregates containing BiP. These aggregates are probably destroyed by autophagy. Since many diseases arise from aggregation of misfolded proteins, this area is the object of intense study.

The ER can cope through ERAD with many stress conditions. Thus, an efficient ERAD greatly contributes to homeostasis of the ER.

The Unfolded Protein Response

The homeostasis of the ER can be altered by several conditions that induce acute or chronic ER stress. The ER can be perturbed by accumulation of unfolded proteins that results from inhibition of *N*-glycosylation, high temperature, increased expression of proteins, expression of mutant proteins, Ca^{2+} depletion, and unfavorable growth conditions. Cells counteract such conditions by inducing the UPR.[66–68] The UPR is an adaptive response signaled through three ER-localized transmembrane proteins PERK, IRE1, and ATF6 to limit accumulation of unfolded protein through reducing protein synthesis, increasing the degradation of unfolded protein, and increasing the ER protein folding capacity. IRE1 is conserved in all

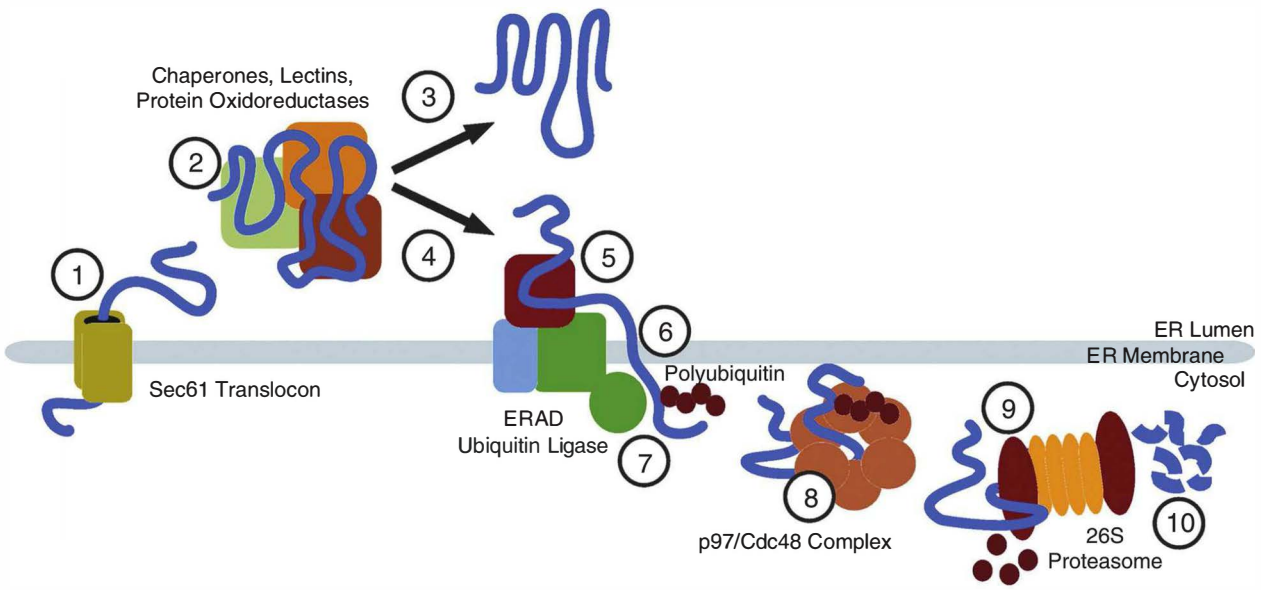

FIGURE 5.9 Model for ER-associated protein degradation (ERAD). Cotranslational translocation and folding of the nascent polypeptide (*1–2*). Attainment of native conformation and transport to the final destination (*3*). The misfolded protein is targeted to retrotranslocation (*4*). Retrotranslocation occurs by an unknown mechanism (*5* and *6*). Polyubiquitylation of the protein by an ER-membrane-bound ubiquitin ligase (*7*). A complex containing the AAA-ATPase p97/Cdc48 binds to the substrate (*8*) and promotes the transport to the 26S proteasome where the protein is degraded (*10*). eukaryotic cells and has protein kinase and endoribonuclease activities that, upon activation, mediate unconventional splicing of a 26 base intron from XBP1 mRNA to produce a potent transcription factor. As mentioned above, ATF6 is a bZIP containing transcription factor that, upon accumulation of unfolded protein in the ER lumen, transits to the Golgi compartment where it is cleaved to yield a cytosolic fragment that migrates to the nucleus to activate gene transcription. Finally, PERK-mediated phosphorylation of eIF2 attenuates general mRNA translation; however, paradoxically, it increases translation of the transcription factor ATF4 mRNA to also induce transcription of UPR genes.[66] If the UPR adaptive response is not sufficient to correct the protein-folding defect, cells enter apoptotic death. Activation of the UPR and defects in the UPR are now known to be important factors that contribute to many disease processes ranging from metabolic disease, neurological disease, infectious disease, inflammation, and cancer.[69]

Glycoprotein Secretion for Therapeutic Use

The advent of the recombinant DNA technology has stimulated the production of many plasma glycoproteins designed for the treatment of hematological human disorders. It soon became clear that microorganisms (bacteria or yeast) are unsuitable for the production of large plasma glycoproteins with complex multidomain organization, and mammalian expression systems were preferred. Recombinant clotting factors VIII, IX, VIIa, and vWF were produced. In many cases, the recombinant protein preserves the same properties of the plasma-derived product although subtle differences can affect some important properties such as the half-life, interaction with other proteins, and immunogenicity. This can be due to differences in post-translational protein processing such as glycosylation (both *N*- and *O*-), γ-carboxylation, tyrosine sulfation, or proteolysis.[70]

Concluding Remarks

In the genome, about 30% of the predicted proteins have a signal sequence for entering the secretory pathway.[71] Blood contains many secretory proteins such as hormones, growth factors, coagulation factors, and proteins required for fibronolysis, inflammation, humoral immunity, etc. Blood specialized secretory cells secrete specific sets of proteins and also small molecules that altogether constitute the secretome. For instance, more than 300 different molecules are secreted by activated platelets that are involved in wound healing by acting on coagulation, stimulation of smooth muscle cell proliferation, and production of cytokines.[72] Research on protein secretion is very active not only for understanding the basic biology of secretory cells but also for the potential application of the discoveries in the design and development of new therapeutic targets and strategies.

CHAPTER

6 Overview of the Immune System

ANDREW H. LICHTMAN

The immune system is a complex collection of molecules, cells, tissues, and organs whose major function is to protect hosts from microbial infection. This function is demonstrated by the fact that increased susceptibility to infections is the major consequence of deficiencies in one or more components of the immune system. In higher vertebrates, the immune system includes two closely interrelated subsystems that confer innate and adaptive immunity, respectively. Innate immunity, which is phylogenetically older, provides constant protection against microbial invasion at epithelial barriers, as well as rapid stereotypical responses of various cell types and molecules throughout the body to many different types of microbes. These rapid responses are critical for survival in a world teeming with microbes. The innate immune system also reacts to tissue injury even without infection, leading to sterile inflammatory responses. Adaptive immunity, which evolved later than the innate immunity, is more specialized and specific for different foreign antigens. Lymphocytes are central to all adaptive immunity, and include B lymphocytes that produce antibodies and T lymphocytes that have many different effector and regulatory functions.

Although the immune system is required for health, immune responses contribute to the primary pathogenesis or secondary manifestation of a large number of diseases. A normally functioning immune system may cause tissue injury and disease as a consequence of its activity in defending against infection. Deregulation of the immune system can lead to excessive responses to pathogenic or even nonpathogenic microbes (e.g., gut flora), as well as to environmental molecules (e.g., allergens). A normal adaptive immune system is generally tolerant of self molecules, but the mechanisms that maintain tolerance can fail, resulting in humoral or T-cell–mediated responses to host molecules and autoimmune disease.

An understanding of the immune system is relevant to the field of homeostasis and thrombosis for many reasons. Some examples are briefly considered here and are covered in more detail in other chapters. There are numerous bidirectional interactions between innate inflammatory responses and the coagulation system. Excessive innate immune responses that occur in sepsis are directly linked to impaired hemostatic functions of endothelial cells, and tissue-factor-dependent thrombosis. Coagulation factors bind to protease-activated receptors on platelets, mononuclear cells, or endothelial cells, thereby inducing expression of immunomodulatory cytokines. Platelets express some of the same adhesion and signaling molecules that are expressed by lymphocytes, dendritic cells (DCs), and phagocytes, which may lead to hemostasis-related complications of targeted immunotherapies. Antibodies produced in the setting of autoimmune disease may recognize platelets or phospholipids and thereby promote hemorrhagic or thrombotic disease. Arterial thrombosis is a frequent terminal event in immune/inflammatory-induced destabilization of atherosclerotic plaque and in transplant failure due to adaptive immune responses to alloantigens. The immune system is also the major barrier toward successful coagulation factor replacement therapy or repeated platelet transfusions. For all these reasons and others, a full understanding of hemostasis and thrombosis requires at least a basic understanding of the immune system.

CYTOKINES AND CHEMOKINES

Cytokines are soluble proteins that are intricately involved in all aspects of the immune system, including development and maintenance of lymphoid tissue architecture, cell trafficking, activation of all cellular components of innate and adaptive immune responses, and regulation of these responses. Because it is difficult to discuss any aspect of immunology without mentioning various cytokines, a brief background of these proteins is warranted at the beginning of this chapter. Cytokines are produced by and act on a wide variety of cell types, including but not restricted to cells whose main functions are related to immune defense. Most cytokines are produced transiently after newly induced gene transcription in recently activated cells. Cytokines bind to high-affinity receptors and usually work in a paracrine fashion and are therefore effective at very low concentration. Some cytokines have systemic effects, sometimes pathologic, and can be detected in the blood as markers of robust immune activity within tissues. Cytokines and their receptors can be grouped into families based on structural features that correlate with receptor signaling pathways,[1,2] such as the type 1 and type 2 cytokines and receptors, which signal by JAK-STAT pathways[1,3–5] and the tumor necrosis factor (TNF) superfamily cytokines and receptors, which are homotrimeric proteins, and signal by TRAF-NF-κB pathways.[6,7] Table 6.1 includes some basic information about selected cytokines that are mentioned in this chapter and play central roles in innate and adaptive immune responses. It is important to note that biologic reagents that block cytokine actions are proving to be some of the most successful therapeutic agents for immune-mediated diseases ever developed, such as anti-TNF regents now in wide use for the treatment of rheumatoid arthritis.

Chemokines are a subset of structurally homologous, approximately 8 Kd cytokines produced by many different cell types, which bind to G-protein–coupled receptors on leukocytes and regulate leukocyte migration and lymphoid tissue architecture.[8] Table 6.2 includes a selection of important chemokines and their receptors, many of which are mentioned in this chapter.

Table 6.1

Selected cytokines of innate and adaptive immunity

Cytokine	Cell Source	Cellular Targets and Effects
Cytokines of Innate Immunity		
Tumor necrosis factor (TNF)	Macrophages T cells	T cells, endothelial cells: activation (inflammation, coagulation) Neutrophils: activation Hypothalamus: fever Liver: synthesis of acute-phase proteins Muscle, fat: catabolism (cachexia) Many cell types: apoptosis
Interleukin-1 (IL-1)	Macrophages, endothelial cells, some epithelial cells	Endothelial cells: activation (inflammation, coagulation) Hypothalamus: fever Liver: synthesis of acute-phase proteins
Interleukin-12 (IL-12)	Macrophages, DCs	T cells: T_H1 differentiation NK cells, T cells: IFN-γ synthesis, increased cytotoxic activity
Type I interferons (IFN-α, IFN-β)	IFN-α: macrophages; IFN-β: fibroblasts	All cells: antiviral state, increased class I MHC expression NK cells: activation
Interleukin-10 (IL-10)	Macrophages, T cells (mainly regulatory T cells)	Macrophages, DCs: inhibition of IL-12 production and expression of costimulators and class II MHC molecules
Interleukin-6 (IL-6)	Macrophages, endothelial cells, T cells	Liver: synthesis of acute-phase proteins B cells: proliferation of antibody-producing cells
Interleukin-15 (IL-15)	Macrophages, others	NK cells: proliferation T cells: proliferation (memory CD8 cells)
Interleukin-18 (IL-18)	Macrophages	NK cells, T cells: IFN-γ synthesis
Interleukin-23 (IL-23)	Macrophages, DCs	T cells: maintenance of IL-17–producing T cells
Interleukin-27 (IL-27)	Macrophages, DCs	T cells: T_H1 differentiation; inhibition of T_H1 cells NK cells: IFN-γ synthesis
Cytokines of Adaptive Immunity		
Interleukin-2 (IL-2)	T cells	T cells: proliferation; apoptosis; regulatory T-cell development, survival NK cells: proliferation, activation B cells: proliferation, antibody synthesis (*in vitro*)
Interleukin-4 (IL-4)	$CD4^+$ T cells (T_H2), mast cells	B cells: isotype switching to IgE T cells: T_H2 differentiation, proliferation Macrophages: inhibition of IFN-γ-mediated activation Mast cells: proliferation (*in vitro*)
Interleukin-5 (IL-5)	$CD4^+$ T cells (T_H2)	Eosinophils: activation, increased production B cells: proliferation, IgA production (*in vitro*)
Interferon-γ (IFN-γ)	T cells (T_H1, CD8+ T cells), NK cells	Macrophages: activation (increased microbicidal functions) B cells: isotype switching T cells: T_H1 differentiation Various cells: class I and class II MHC molecules, increased antigen processing and presentation to T cells
Transforming growth factor–β (TGF-β)	T cells, macrophages, other cell types	T cells: inhibition of proliferation and effector functions B cells: inhibition of proliferation; IgA production Macrophages: inhibition of activation; stimulation of angiogenic factors Fibroblasts: increased collagen synthesis
Lymphotoxin (LT)	T cells	Recruitment and activation of neutrophils Lymphoid organogenesis

Table 6.1

Selected cytokines of innate and adaptive immunity *(Continued)*

Interleukin-13 (IL-13)	$CD4^+$ T cells (T_H2), NKT cells, mast cells	B cells: isotype switching to IgE Epithelial cells: increased mucus production Fibroblasts: increased collagen synthesis Macrophages: increased collagen synthesis
Interleukin-17 (IL-17)	T cells	Endothelial cells: increased chemokine production Macrophages: increased chemokine and cytokine production Epithelial cells: GM-CSF and G-CSF production
Interleukin-21	T cells (T_H17, T_{FH})	T cells: T_H17 differentiation B cell: affinity maturation and memory cell differentiation

CELLS, TISSUES, AND CELLULAR TRAFFIC IN THE IMMUNE SYSTEM

The proper functioning of the immune system depends on many different cell types, which must recognize foreign substances or microbes in specialized lymphoid tissues and respond by performing effector functions that help destroy or remove the microbes.

Phagocytes

Neutrophils (polymorphonuclear leukocytes) and macrophages, the two major types of phagocytic cells in the body, are crucial effector cells for both innate and adaptive immune responses.[9] Detailed descriptions of these cell types are found in hematology and pathology textbooks (and in Chapter 47). Here, we will summarize their main features related to immune responses. Neutrophils are the most abundant leukocytes in the blood, but are not normally present in any healthy tissue. In responses to signals generated by microbial products and injured cells, neutrophils are rapidly recruited into tissue sites.[10] In contrast, resident macrophages are present in the most healthy tissues of the body at all times, but their numbers increase significantly in response to inflammatory stimuli, due to recruitment of blood monocytes that rapidly differentiate into macrophages once they leave the circulation.[11] The resident macrophages in normal tissues are most abundant in the connective tissues underlying epithelial barriers such as the dermis and lamina propria of the gut. Resident macrophages may assume specialized morphologies and functions in particular organs, such as the alveolar macrophages in the lung, Kupffer cells lining hepatic sinusoids, osteoclasts in bone, and microglia cells in the brain. Resident macrophages perform sentinel and first-responder functions, reacting to pathogens or tissue injury by secreting of cytokines and chemokines that promote further recruitment of blood leukocytes, including neutrophils, and blood monocytes.

A major function of both neutrophils and macrophages is the phagocytic ingestion and killing of microbes. Microbial killing is accomplished by generation of reactive oxygen and nitrogen species through the action of phagocyte-oxidase, myeloperoxidase, and inducible nitric oxide synthase, and by proteolysis of the ingested microbes by several different lysosomal enzymes. Neutrophils also produce cytokines and chemokines, which amplify inflammatory responses. Neutrophils are terminally differentiated, cannot divide, and live only a few hours within tissues. They undergo programmed cell death after ingesting microbes. The critical role neutrophils play in innate immunity is reflected by the devastating infectious consequences that are linked to severe reductions in the absolute blood neutrophil counts seen in leukemia and cancer patients. Tissue macrophages may live for years in tissues, and recently recruited macrophages may divide, and live for weeks to months. In addition to microbial killing, macrophages perform the important functions of ingesting dead cells, including neutrophils and tissue debris, and stimulating tissue repair through the production of cytokines and growth factors. Subsets of macrophages have been described that differ in inflammatory and tissue repair functions.[12,13]

Classically activated macrophages are induced by interferon-γ (IFNγ) secreting T cells, and perform proinflammatory and microbicidal functions. Alternatively activated macrophages are induced by interleukin (IL)-4- and -5-producing T cells, and produce anti-inflammatory cytokines (e.g., IL-10) and growth factors, which promote angiogenesis and fibrosis.

Natural Killer Cells

Natural Killer (NK) cells are bone marrow–derived cells of the innate immune system that arise from the common lymphoid progenitor but do not express highly diverse clonally distributed antigen receptors encoded by somatically rearranged genes, like B and T lymphocytes.[14,15] NK cells make up between 5% and 10% of blood lymphocytes, and are morphologically distinguished as $CD16^+$, $CD56^+$, and $CD3^-$ large granular lymphocytes. NK cells are activated by contact with target cells that are infected or otherwise stressed, leading to release of perforin and granzymes from cytoplasmic granules, which cause the apoptotic death of the target cells. This killing mechanism is identical to the way $CD8^+$ cytotoxic T lymphocytes (CTLs) kill targets, described later. NK cells also secrete interferon γ that promotes inflammation. NK cells distinguish healthy cells from infected or stressed targets by a variety of germline-encoded activating receptors that recognize stress-induced proteins, and inhibitory receptors, such as the killer Ig-like receptors, which recognize class I major histocompatibility complex (MHC) molecules that

Table 6.2

Selected chemokines

Chemokine	Original Name	Chemokine Receptor	Major Function
CC Chemokines			
CCL2	MCP-1	CCR8	Monocyte recruitment and endothelial cell migration
CCL3	MIP-1α	CCR1, CCR5	Mixed leukocyte recruitment
CCL4	MIP-1β	CCR5	T-cell, DC, monocyte, and NK recruitment; Receptor is a HIV coreceptor
CCL5	RANTES	CCR1, CCR3, CCR5	Mixed leukocyte recruitment
CCL11	Eotaxin	CCR3	Eosinophil, basophil, and T_H2 recruitment
CCL17	TARC	CCR4	T-cell and basophil recruitment
CCL19	MIP-3β/ELC	CCR7	T-cell and DC migration into parafollicular zones of lymph nodes
CCL20	MIP-3α	CCR6	T_H17 recruitment
CCL 21	SLC	CCR7	T-cell and DC migration into parafollicular zones of lymph nodes
CXC Chemokines			
CXCL1	GROα	CXCR2	Neutrophil recruitment
CXCL4	PF4	CXC3B	Platelet aggregation
CXCL5	ENA-78	CXCR2	Neutrophil recruitment
CXCL8	IL-8	CXCR1, CXCR2	Neutrophil recruitment
CXCL9	Mig	CXCR3	Effector T-cell recruitment
CXCL10	IP-10	CXC3, CXCR3B	Effector T-cell recruitment
CXCL11	I-TAC	CXC3	Effector T-cell recruitment
CXCL12	SDF-1$\alpha\beta$	CXCR4	Mixed leukocyte recruitment; CXCR4 is a HIV coreceptor
CXCL13	BCA-1	CXCR5	B cell migration into follicles
CX3C Chemokines			
CX3CL1	Fractalkine	CX3CR1	T-cell, NK cell, and macrophage recruitment; CTL and NK cell activation

Modified from Abbas, et al. *Cellular and molecular immunology*, 6th ed. Saunders/Elsevier, 2010;Table 12.4 p 280.

are present in most healthy cells. A lack of class I MHC, often termed "missing self," will result in NK cell activation due to a lack of inhibitory signals.

Dendritic Cells

DCs are ubiquitous bone marrow–derived cells that play a fundamental role in immune surveillance.[16–18] They are constitutively present in many tissues but most abundant beneath epithelial barriers (skin, bronchopulmonary, gastrointestinal, genitourinary) and in lymphoid tissues (lymph nodes, spleen). They are named for their morphology in tissues, where they typically display dendrite-like projections that interdigitate between other cells, a feature that maximizes their potential contact with pathogens. DCs perform effector functions of the innate immune system in response to microbial infection, and are essential for initiating adaptive immune responses involving T cells. Two main subsets of DCs, identifiable by cell surface molecules, are conventional DCs and plasmacytoid DCs (pDCs). Conventional DCs are phagocytic cells that take up pathogens or microbial products in infected tissues and transport them into draining lymph nodes for display to T lymphocytes. This function is called antigen presentation, which we will discuss in more detail later in the chapter. Plasmacytoid pDCs are so named because they look like antibody-producing plasma cells but are otherwise unrelated. pDCs respond to viral nucleic acids by secreting abundant type I interferons, which are cytokines that make cells resistant to viral replication.[19] Activation of pDCs by self nucleic acids and resulting abundant type I interferon secretion contributes to the pathogenesis of systemic lupus erythematosus.

Lymphocytes

Lymphocytes are the principal cells responsible for the defining characteristics of adaptive immunity, namely, extraordinary diversity of antigen specificities, specialization of functions that

adapt to different types of microbial infections, and memory. The majority of lymphocytes are located within lymphoid tissues and epithelial barrier tissue such as skin and gut. There is constant trafficking of between these tissues and the circulation, where they number 1–3 × 10^3/mm^3. In blood smears, resting lymphocytes appear as relatively homogeneous round cells with a high nuclear:cytoplasmic ratio and a diameter of approximately 7 μM. This uniform morphologic appearance does not reflect the existence of multiple lymphocyte subsets.

There are several subsets of lymphocytes (see Table 6.3). The two major types are B cells and T cells, typically distinguished by flow cytometric or immunohistochemical detection of lineage-specific surface molecules. B cells are the only cells that produce antibodies. Most B cells in blood and lymphoid tissues express membrane Ig, CD19, and CD20. Most T cells express CD3. Developmentally distinct subsets of B cells include follicular B cells, the most abundant and diverse type, and marginal zone B cells, which have a limited range of specificities. T cells have greater developmental and functional heterogeneity than B cells. The two numerically major subsets of T cells are distinguished by the expression of either CD4 or CD8, which correlate with helper or cytotoxic functions, respectively. Together $CD4^+$ and $CD8^+$ T cells account for approximately 85% to 90% of all T cells, and normally the $CD4^+$:$CD8^+$ T-cell ratio in blood and lymphoid organs is about 2. Among $CD4^+$ T cells, there are several functional subsets, including Th1, Th2, Th17, and regulatory T cells. Other numerically minor subsets of T lymphocytes cell are NKT cells and γδT cells.

Both B and T lymphocytes are also categorized based on their state of functional differentiation, which is related to their prior experience with antigen. B and T lymphocytes that have completed their maturation but have not ever been activated by antigen in the peripheral immune system are called *naïve lymphocytes*. Naïve B and T cells cannot perform protective functions, but they respond to antigen stimulation in lymphoid organs by clonal expansion and differentiation into *effector*

Table 6.3

Types of lymphocytes

Class	Functions	Antigen Receptor and Specificity	Selected Markers	Percent of Total Lymphocytes		
αβ T Lymphocytes				*Blood*	*Lymph node*	*Spleen*
$CD4^+$ helper T lymphocytes (T_H)	B-cell differentiation (humoral immunity) Macrophage activation (cell-mediated immunity)	αβ heterodimers Diverse specificities for peptide-class II MHC complexes	$CD3^+$, $CD4^+$, $CD8^-$	50–60	50–60	50–60
$CD8^+$ CTL	Killing of infected cells, killing of tumor cells	αβ heterodimers Diverse specificities for peptide-class I MHC complexes	$CD3^+$, $CD4^-$, $CD8^+$	20–25	15–20	10–15
Regulatory T cells (Treg)	Suppress other T cells (regulation of immune responses, self-tolerance)	αβ heterodimers	$CD3^+$, $CD4^+$, $CD25^{hi}$, $CD127^{lo}$	Rare	10	10
γδ T lymphocytes	Helper and cytotoxic functions (innate immunity)	γδ heterodimers Limited specificities for peptide and nonpeptide antigens	$CD3^+$, CD4, and CD8 variable			
B lymphocytes	Antibody production	Surface antibody Diverse specificities for all types of molecules	Fc receptors; class II MHC; CD19; CD20; CD21	10–15	20–25	40–45
NK cells	Killing of virus-infected or damaged cells (innate immunity)	Various activating and inhibitory receptors Limited specificities for MHC or MHC-like molecules	CD16 (Fcγ receptor)	10	Rare	10
NKT cells	Suppress or activate innate and adaptive immune responses	αβ heterodimers (Limited specificity for lipid-CD1 complexes)	CD16 (Fcγ receptor); CD3	10	Rare	10

(Modified from Abbas, et al. *Cellular and molecular immunology*, 6th ed. Saunders/Elsevier, 2010. Table 3.2 p 50).

lymphocytes, which are relatively short-lived cells that actively contribute to elimination of antigen. After most microbial antigen-specific B- and T-cell responses wane, a population of long-lived progeny of the expanded lymphocyte clones persists as *memory cells*, which mediate rapid and specialized responses to subsequent exposures to the microbial antigens. Memory lymphocytes can survive for many years, and probably undergo a low level of antigen-independent proliferation to maintain their numbers.[20–22] *In vitro* assays for recall responses to antigens after infection or immunization indicate that most memory T cells express the CD45RO surface protein, while naïve T cells, such as found in neonates, are mostly CD45RA$^+$. Memory T cells also express the IL-7 receptor. Effector T cells are usually localized within lymphoid organs or in infected tissues, and only rarely are they numerous in the blood, such as during acute EBV infections when they appear as lymphoblasts. Specific details of T- and B-cell antigen recognition, subsets, and effector function will be discussed later in this chapter.

Mast Cells, Basophils, and Eosinophils

These three cell types all have numerous cytoplasmic granules whose contents are released upon activation, and perform various proinflammatory and microbicidal functions.[23,24,25] Mast cells are bone marrow–derived, stationary tissue cells ubiquitously present adjacent to small blood vessels in most epithelial tissue. Their metachromatically staining granules contain several vasoactive amines such as histamine. Mast cells express high-affinity receptors for IgE antibodies, and cross-linking of the IgE by allergens causes activation of the cells, including granule release, and secretion of newly synthesized cytokines and eicosanoids. Mast cells are major contributors to allergic reactions and defense against parasites. Basophils share most of the properties just described for mast cells, except they are circulating cells of the myeloid lineage, which may be recruited to inflammatory sites. Their role in innate immunity is uncertain, in part because their numbers are low. Eosinophils are circulating granulocytes with eosinophilic granules containing major basic protein and proteolytic enzymes. Eosinophils are recruited to selective inflammatory sites, such as tissue with parasitic worm infections or sites of allergic inflammation. Their granule contents are toxic to helminths and are responsible for tissue damage and remodeling in chronic atopic diseases, such as asthma.

Lymphoid Organs and Tissues

Lymphocyte development, the process by which progenitor stem cells give rise to mature naïve lymphocytes, occurs in the primary or generative lymphoid organs, namely, the bone marrow and thymus. This process is distinct from differentiation of naïve lymphocytes into effector lymphocytes, which occurs in response to antigen recognition in secondary or peripheral lymphoid organs, including lymph nodes, spleen, and mucosal lymphoid tissues.

Bone Marrow and Thymus

The predominant sites of lymphocyte development are the bone marrow for B cells and thymus for T cells. The hematopoietic stem cell gives rise to a common lymphoid progenitor cell, from which both B- and T-cell lineages are derived.[26,27] The cytokine IL-7 is required for these early steps in lymphocyte development, and antigen receptors play important roles at later stages. Most of the steps of B-cell development take place in the bone marrow, but final differentiation into follicular B cells occurs in lymph nodes or spleen.[28] In contrast, the early progenitors of the T-cell lineage migrate to the thymus and T cells fully develop in that organ. The bone marrow is also the main site where long-lived antibody-producing plasma cells reside; these cells migrate to the marrow from secondary lymphoid organs.

The thymus is a prominent anterior mediastinal organ in children, which involutes at puberty. T-cell development does continue in adults, as shown in adult bone marrow transplant recipients who produce T cells derived from donor stem cells. The site of adult T-cell development is likely in small thymic remnants that persist after thymic involution. The thymic stroma is organized into an outer cortex and inner medulla. Developing T cells, called thymocytes, move from cortex into medulla as they mature. Thymic epithelial cells are stromal cells that produce cytokines such as IL-7 that promote T-cell development. These epithelial cells and bone marrow–derived DCs and macrophages display self-proteins, which positively or negatively select clones of developing T cells and thereby shape the repertoire of antigen specificities of mature T cells.[29] Further details of thymic structure and their relationship to T-cell development can be found in immunology textbooks.[30,31]

Lymph Nodes and Spleen

The lymph nodes and white pulp of the spleen serve as antigen-collecting sites for tissues and blood, respectively. Naïve B and T cells circulate through these organs and survey for the antigens they can recognize. A complex microarchitecture is maintained in both lymph nodes and spleen, such that B cells are localized in follicular structures and T cells are kept in separate interfollicular zones. This segregation is due to the action of constitutively secreted chemokines and different chemokine receptors on each type of lymphocyte. Lymphotoxins (LTs) produced by lymphoid tissue inducer cells are required for initial development of lymphoid tissues.[32,33] The chemokine CXCL13 and its receptor CXCR5 keep B cells in the follicles, and the chemokines CCL19 and CCL21 and their receptor CCR7 keep naïve T cells and DCs in the interfollicular zones.[34] Lymph nodes are encapsulated organs that are supplied with interstitial fluid (lymph) via afferent lymphatics, which empty into a subcapsular sinus. Some antigens are carried by lymph through specialized conduits composed of extracellular matrix proteins and lined by fibroblastic reticular cells (FRCs), into the interfollicular zones.[35] Resident DC antigen-presenting cells (APCs) take up the lymph-borne antigens in these conduits. DCs carrying antigens from the tissues are also delivered to nodes via the lymphatics and migrate into the interfollicular zones. Antigens in the subcapsular sinus gain access to underlying B-cell follicles with the help of macrophages. Lymph drains from lymph nodes via an efferent lymphatic, which may drain into another lymph node, or into larger lymphatics that eventually empty into the bloodstream via the thoracic duct. Naïve lymphocytes enter lymph nodes through an efferent artery and migrate out into the parenchyma through high endothelial venules (HEVs), which are located in the interfollicular zone where DCs are located. Interactions of DCs, T cells, and B cells during immune responses are described later in the chapter.

The immune functions of the spleen are to remove opsonized microbes and immune complexes from the blood, which is accomplished by macrophages lining the sinusoids in the red pulp, and to initiate adaptive immune responses to blood-borne

antigens, which occurs in the white pulp.[36] T cells in the white pulp are located in sheaths around small branches of the splenic artery, and B-cell follicles are arranged adjacent to the T-cell zones. FRC conduits like those in lymph nodes traverse the follicles. The anatomic arrangement of B cells and T cells in the splenic white pulp optimizes antibody responses.

Mucosal Lymphoid Tissues and Regional Immune Systems

Discrete collections of B cells, T cells, DCs, and macrophages found beneath mucosal epithelial barriers play important roles in the specialized immune responses that defend against microbes that traverse these barriers.[37] The best-defined mucosal lymphoid tissues are in the gut, and include Peyer patches in the lamina propria of the small bowel, and similar structures in the appendix and colon. Other mucosa lymphoid tissues are the tonsils and adenoids in the oropharynx, and lymphoid aggregates in the bronchial mucosa. These lymphoid tissues serve specialized functions, such as the generation of B cells that produce IgA antibodies, which are secreted into the lumen of the gut and defend against luminal pathogens. Another specialized function of these tissues is to sample antigens of commensal organisms that are present in enormous numbers outside the mucosal barriers and to induce regulatory mechanisms that prevent potentially harmful responses to those organisms. Immunologists often speak of "regional immune systems" with specialized functions, including the gastrointestinal-associated lymphoid tissues (GALT) and the skin immune system. In fact, based on numbers of lymphocytes located in these tissues, the skin and GALT represent the largest parts of the human adaptive immune system and defend against the largest and most common portals of microbial entry into the body.

Cellular Traffic in the Immune System

Microbial invasion and infections can occur anywhere in the body, and the innate immune system deals with this widespread unpredictable threat by the ubiquitous presence of immunocompetent cells in all tissues, and the rapid delivery of additional cells from the circulation. In contrast, the adaptive immune system produces small numbers of millions of different clones of lymphocytes before exposure to microbial antigens, but a particular microbe-specific clone must be activated by specialized APCs before an effective response can be generated. Thus, the initiation of adaptive immune response requires delivery of lymphocytes, APCs, and antigen to common sites within lymphoid tissues. Within lymphoid tissues, subsets of lymphocytes and APCs must be highly motile to maximize the chances of productive physical interactions. Basic features of whole-body and local immune cell trafficking are described below.

Leukocyte Interactions with Endothelial Cells and Migration from Blood into Tissues

Circulating leukocytes, including lymphocytes and myeloid cells, must interact with the endothelial lining of blood vessels in order to migrate into the tissue sites where they perform their effector functions.[38] This process is regulated by several factors, including flow characteristics of tissue microvasculature, adhesion molecules on both the leukocytes and endothelial cells, and chemokines produced by endothelial cells and tissue cells, which act on the leukocytes (see Table 6.2). Virtually all leukocyte extravasation occurs in postcapillary venules, which have an average diameter of 10 to 15 μM, and flow characteristics that promote margination of leukocytes to the periphery of the blood stream where they interact physically with endothelial cells. The adhesion molecules involved in the process include integrins on the leukocytes, selectins on the cell surfaces of leukocytes and endothelial cells, selectin ligands on leukocytes and endothelial cells, and integrin ligands on the endothelial cells. Chemokines involved in this process are displayed on the surface of endothelial cells and bind chemokine receptors on the leukocytes (see Table 6.2).[39] Extravasation of all types of leukocytes follows a sequential set of steps, referred to as the multistep adhesion cascade, during which leukocytes bind to endothelial cells at appropriate locations, resist the fluid shear stress caused by the blood flow, and exit the vessel. The specific chemokines and adhesion molecules will vary depending on the leukocyte type and tissue site. The sequence of the adhesion cascade begins with low-affinity adhesive interactions and leukocyte rolling on endothelium mediated by P- and E-selectin expressed on activated endothelial cells, which bind to glycoprotein selectin ligands on leukocytes, and L-selectin expressed on leukocytes, which bind ligands on endothelial cells. The next step is activation of leukocyte integrins by chemokines. Chemokines that are produced by phagocytes and endothelial cells in infected or damaged tissues, or are constitutively produced in lymphoid organs, are displayed on the luminal endothelial surface by heparan sulfate glycosaminoglycans, where they can bind to chemokine receptors on rolling leukocytes. Signals generated by the chemokine receptors induce conformational changes in the integrins that enhance their affinity for integrin ligands on the endothelial cells. The next step is stable arrest of leukocytes on endothelium mediated by activated integrins. Leukocyte integrins include leukocyte function-associated antigen (LFA)-1 and Mac-1, which bind to intercellular adhesion molecule (ICAM)-1 on endothelial cells, and very late activation antigen (VLA)-4, which binds to endothelial vascular cell adhesion molecule (VCAM)-1. High-affinity binding of integrins to their endothelial ligands results in cessation of rolling, firm adhesion, and resistance to dislodgement by fluid shear stress. Finally, the leukocytes transmigrate between endothelial cells and out into tissues, a process that requires leukocyte LFA-1 and endothelial ICAM-1, and CD31 expressed on both the leukocyte and the junctional membrane of endothelial cells. VE-cadherin and associated junctional proteins that bridge postcapillary endothelial cells must be temporarily modified to permit passage of the transmigrating leukocytes. Leukocytes may also pass through endothelial cells by a poorly understood process called transcellular migration. Antibody blockade of leukocyte integrins is in clinical use for treatment of inflammatory bowel disease and multiple sclerosis.

Migration of Granulocytes and Monocytes into Infected or Damaged Tissue

Myeloid cells, including granulocytes and monocytes, follow relatively simple traffic patterns after maturing in the bone marrow and entering the circulation. If they are recruited into a tissue inflammatory site, they perform their effector functions, and die at these sites by apoptosis within 1 to 2 days; they do not return to the blood. If they are not recruited into tissues,

blood neutrophils will become senescent in 4 to 5 days, at which time they are recruited into the bone marrow by the chemokine CXCL12, and undergo apoptosis. Blood monocytes live on average 8 to 10 days, but the mechanisms of their clearance are not well defined. Macrophages derived from monocytes may live for many days up to months.

Among blood leukocytes, neutrophils are the first and most numerous responders to infections and tissue injury.[10] Innate response to microbes and injured cells (described later in this chapter) induces the expression of the cytokines IL-1 and TNF by tissue resident macrophages, which stimulate endothelial cells in nearby postcapillary venules to upregulate Sho E-selectin, ICAM-1, and in some tissues VCAM-1. Innate immune responses to infection and tissue injury also induce the local expression of chemokines of the GRO family and CXCL-8, which bind to chemokine receptors on neutrophils, including CXCR1 and CXCR2. In addition, thrombin, generated by the coagulation cascades, acts via thrombin receptors on endothelial cells to mobilize P-selectin from Weibel-Palade bodies to the cell surface. These local responses to infection and injury promote the recruitment of neutrophils, via the multistep cascade, as part of the acute inflammatory response. The recruitment of eosinophils depends on selectins and integrins, but also requires local production of a combination of chemokines, including CCL7, CCL14, and CCL11, which bind to receptors expressed by these specialized granulocytes.

Monocytes are recruited along with neutrophils to sites of acute inflammation, but also to sites of effector T-cell activation and chronic inflammation. In both cases, the monocytes differentiate into macrophages. Monocyte recruitment into tissues involves rolling interactions mediated by endothelial P-selectin and its ligand PSGL-1 on the monocyte as well as L-selectin on the monocyte binding to ligands on endothelial cells. Integrin-mediated stable arrest of monocytes is mediated by VLA-4:VCAM-1 and LFA-1:ICAM-1 interactions. Blood monocytes are heterogeneous, and at least two populations can be distinguished by the chemokine receptors they express.[40] CCR2 expression defines monocytes that are rapidly recruited to sites of infection or injury, in response to the chemokine CCL2 (MCP-1). Another monocyte population lacks CCR2, but expresses CX3CR1, which binds to CX3CL1. Endothelial cells express membrane-bound CX3CL1, which mediates adhesion of $CX3CR1^+$ monocytes.

Lymphocyte Migration into and out of Lymphoid Tissues

Lymphocyte traffic throughout the body is more complex than that of myeloid cells, with a constant movement of cells between the blood and lymphoid tissues, and migration of effectors cells from lymphoid tissues via the blood to infected tissues.[41] These traffic patterns reflect the requirement that rare naïve lymphocytes of one clone and antigen specificity must continuously travel through lymphoid tissue sites of antigen collection in order for effective immune surveillance to take place. Furthermore, many types of effector lymphocytes generated from naïve cells in lymphoid tissues must be delivered by the blood to tissue sites of infection in order to perform their functions. Lymphocyte traffic is best understood for T cells, although some of the patterns and mechanisms are similar for B cells.

Lymphocyte recirculation refers to the movement of naïve lymphocytes from blood into secondary lymphoid tissues, especially lymph nodes, and then back into the blood.[41] Entry of naïve T cells into lymph nodes occurs through specialized postcapillary venules called high endothelial venules (HEVs) because of the tall appearance of their endothelial lining. HEVs express ICAM-1, and a ligand for L-selectin called peripheral lymph node addressin. HEVs also display the chemokines CCL19 and CCL21 made by the HEV endothelial cells and nearby stromal cells, respectively. Naïve T lymphocytes express ICAM-1, L-selectin, and the chemokine receptor CCR7, which binds CCL19 and CCL2. Thus naïve lymphocytes and HEVs have matching molecules that allow for efficient constitutive homing of the lymphocytes into the lymph node parenchyma. Importantly, HEVs are located in the T-cell zone of lymph nodes where DCs displaying antigen are also located. Naïve T cells do not express functional selectin ligands or chemokine receptors that bind inflammatory chemokines produced at sites of infection, and thus they do not enter these sites. If a naïve T cell does not become activated by antigen presentation within a few hours after entering a lymph node, it leaves via efferent lymphatics, and may move to an adjacent lymph node in the same chain. Eventually the naive T cells reenters the blood via the thoracic duct to begin the recirculation cycle over again. A single naïve lymphocyte may visit up to dozens of lymph nodes in a single day.

If a naïve T cell does become activated by antigen in a lymph node, it is retained, and undergoes proliferation and differentiation into effector T cells. Effector T cells do not express CR7 or L-selectin, but express other chemokine receptors and adhesion molecules that enable them to migrate differently from naïve lymphocytes. Some effector T cells that function as helper T cells for antibody responses express the chemokine receptor CXCR5, which binds CXCL13 and directs migration toward B-cell follicles. Other effector T cells will leave the node via efferent lymphatics, and enter the blood.

The exit of naïve and effector lymphocytes from lymphoid organs requires the expression of sphingosine-1-phosphate receptor 1 (S1PR1) and a stable low-to-high concentration gradient of its chemotactic ligand sphingosine-1-phosphate (S1P) between lymphoid tissues and the draining lymph or blood.[42] This gradient is maintained by S1P lyase degradation of S1P within the lymphoid tissues. Entry and exit of naïve and effector T cells from lymph nodes are regulated by dynamic changes in surface S1PR1 expression so that retention time within the lymph node is sufficient for naïve T-cell surveillance of APCs, and for clonal expansion and differentiation of effector cells. The immunosuppressive drug Fingolimod is an S1PR1 ligand that blocks S1P-regulated T-cell egress.

Lymphocyte Migration into Inflamed Tissues

Effector T cells that are generated in lymph nodes and then enter the blood express different combinations of chemokine receptors, integrins, and P- and E-selectin ligands, which promote their migration into different tissue sites of inflammation.[38] As is the case for neutrophils and monocytes, effector lymphocyte migration into these sites is promoted by local innate immune responses, which lead to upregulation of endothelial adhesion molecules, and the production of chemokines. Different subsets

of effector T cells have different migratory phenotypes, which are responsible for their selective migration into different types of inflammatory site tissues or dictate the timing of their appearance at a single site. For example, Th17 cells express CXCR6 and home to inflammatory sites where CCL20 is produced, while Th1 cells express CXCR3 and CCR5, and home to sites where CCL5 and CXCL10 (and other chemokines) are produced. Effector T and B cells may also selectively home to one anatomic location versus another, depending on where they were originally generated from naïve cells. For T cells, tissue-specific homing is imprinted by products of the antigen-presenting DCs from a particular tissue. For example, skin-derived DCs secrete vitamin D, which will instruct naïve T cells to differentiate into effector T cells that express CCR10 and E-selectin ligands that promote their homing back to the skin. Gut DCs secrete retinoic acid, which instructs naïve T cells to differentiate into effector T cells that express the $\alpha 4\beta 7$ integrin and CCR9 that promote their homing to the gut lamina propria.

INNATE IMMUNITY

The innate immune system is the collection of molecules and cells that provide early defense against a broad range of infectious organisms, before adaptive immune responses develop. Components of the innate immune system are present and functional at all times, and unlike adaptive immunity, responses are usually of similar magnitude and quality, regardless of prior history of exposure to the inciting microbe. The innate immune system recognizes and responds to only a limited number of commonly encountered molecular stimuli originating from microbes or damaged tissue cells, and cannot distinguish between and respond to millions of different foreign antigens as the adaptive immune system can. The microbial products that stimulate innate immunity are called pathogen-associated molecular patterns (PAMPs), and are typically molecules made by many species of the same class of microbes, and are essential for microbial survival, such as bacterial cell wall components or genomic nucleic acids. Hence microbes cannot evade innate immunity by loss of expression of PAMPs. Self-molecules that are only produced by and/or released from injured or stressed cells (which simulate innate immune responses) are called damage-associated molecule patterns (DAMPs). Innate responses to PAMPs and DAMPs are essential to prevent lethal infections from the ubiquitous microorganisms in our environment. Molecules induced by innate immune responses are also required, in addition to antigens, to activate naïve lymphocytes and initiate adaptive immunity. Thus adaptive immune responses only occur in response to two signals, namely, danger (indicated by the innate response) and foreign molecular structures (antigen).

Cells of the Innate Immune System

The cells of the innate immune system include phagocytic cells (neutrophils, macrophages, DCs), NK cells, and mast cells, which were described earlier in the chapter. In addition, epithelial barriers (skin and mucosal linings of the gastrointestinal, brochopulmonary, and genitourinary systems) are considered to be integral to the innate immune system. Mucosal epithelial cells secrete mucus, which impedes microbial contact with the barrier, as well as antimicrobial peptides, including defensins and cathelicidins, which damage bacterial membranes.

Cellular Pattern Recognition Receptors of the Innate Immune System

Many cell types express receptors that recognize PAMPs or DAMPs and transduce signals that activate the cells to produce proinflammatory and antimicrobial molecules.[43] As a group, these receptors are called pattern recognition receptors (PRRs), but PRRs include several types of receptors that are structurally distinct and recognize different classes of PAMPs or DAMPs. Phagocytes express the widest variety of these receptors, reflecting their principal function of ingesting microbes and damaged cells. Nonetheless, PRRs on barrier epithelial cells, lymphocytes, mast cells, endothelial cells, and other cell types all contribute to innate immunity. PRRs are located on the cell surface, in endosomal membranes and in the cytosol, which ensures that the innate immune system can respond to extracellular ligands, phagocytosed ligands, and ligands synthesized or delivered to the cytosol. The different types of PRRs are discussed below.

Toll-like Receptors

Toll-like receptors (TLRs) are a family of evolutionarily conserved homologous integral membrane proteins, widely expressed on many cell types, which recognize structurally diverse PAMPs and DAMPs, and engage signaling pathways that activate cells.[44] There are nine functional human TLRs, all of which are expressed as homo- or heterodimers (FIGURE 6.1). Each TLR chain includes an extracellular ligand recognition domain with multiple leucine-rich repeat motifs, and a cytoplasmic tail with a Toll/ IL-1 receptor (TIR) signaling domain, also found in the receptors for the cytokines IL-1 and IL-18. Some TLRs are expressed on the cell surface and recognize bacterial cell wall products such as lipopolysaccharide (LPS) (TLR4) and peptidoglycan (TLR 2), bacterial lipopeptides (TLRs 1, 2, 6), bacterial flagellin (TLR5), fungal beta glucans (TLR2), and host heat shock proteins (TLRs 2, 4). Some TLRs are located in endosomal membranes and recognize microbial (and sometimes host) nucleic acids including dsRNA (TLR3), ssRNA (TLR7), and demethylated CpG repeats (TLR9). Upon ligand binding to the TLRs, the TIR domains associate with either of two adaptor proteins, MyD88 or TRIF, which then engage downstream signaling molecules leading to cellular activation. There are two main pathways of cellular activation. The MyD88 pathway (TLRs 1, 2, 4, 5, 7, 9) activates the transcription factor NF-κB, which promotes expression of proinflammatory genes, including those encoding cytokines such as TNF and IL-1, chemokines, and endothelial adhesion molecules. Other molecules induced by the TLR-MyD88-NF-κB pathway include defensins in mucosal epithelial cells, and T-cell costimulators on DCs. TLR4 and TLR3 use the TRIF pathway, which leads to activation of interferon response factors (IRF3, 7), which in turn promote expression of type I interferons. These cytokines are secreted and act on other cells to induce an "antiviral" state, which is mediated by proteins that interfere with viral replication. TLR signaling also activates the AP-1 transcription factor, and there are crossover effects of MyD88 and TRIF pathways on IRF and NF-κB activation, respectively.

Cytosolic PRRs: RIG-like Receptors, NOD-like Receptors, and Inflammasomes

RIG (retinoic acid–inducible gene)-like receptors (RLRs), including RIG-I and MDA5 (melanoma differentiation–associated gene 5), are cytosolic receptors for viral RNAs, which

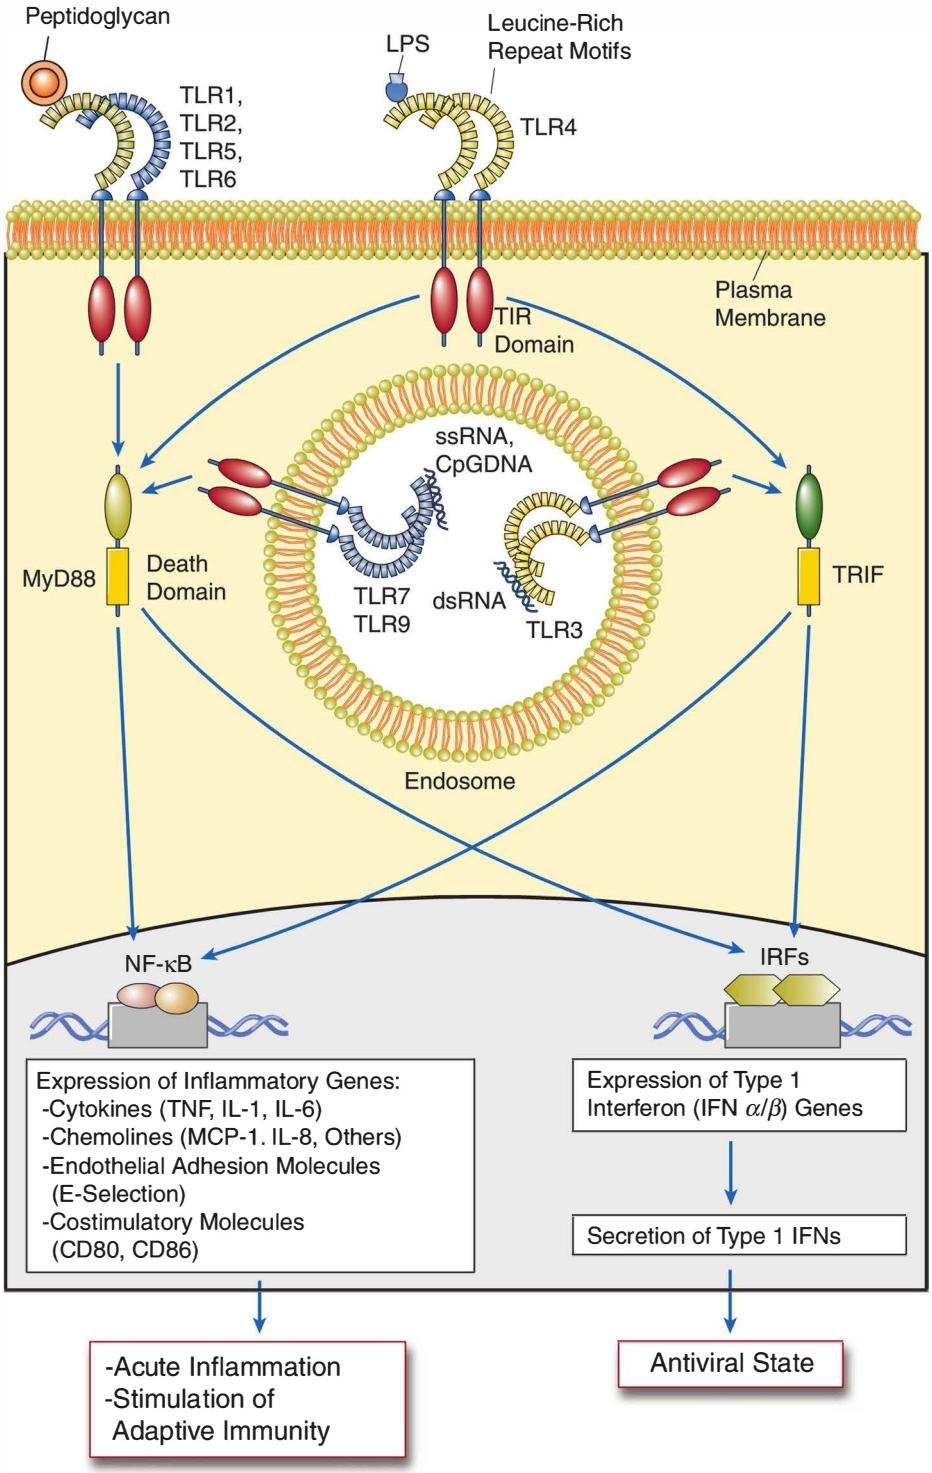

FIGURE 6.1 TLRs. TLRs are the major PRRs of innate immunity. They contain ligand binding domains with multiple leucine rich repeats, and cytoplasmic tails with TIR domains that interact with adaptor proteins. TLRs are expressed on the plasma membrane where they may bind extracellular PAMPs and on endosomal membranes where they recognize nucleic acids of microbes that have been phagocytosed by cells. TLRs 1, 2, 5, and 6 use the adapter protein MyD88 and activate the transcription factors NF-κB and AP-1, leading to inflammatory responses. TLR3 uses the adaptor protein TRIF and activates the IRF3 and IRF7 transcription factors, leading to type I interferon secretion and antiviral immunity. TLR4 can activate both pathways. TLRs 7 and 9 in the endosome use MyD88 and activate both NF-κB and IRF7 (not shown). Cells also contain cytoplasmic sensors of microbial infection (discussed in the text), including the NLRs and RLRs. (Modified from Abbas, et al. *Cellular and molecular immunology*, 7th ed. Philadelphia: Saunders/Elsevier, 2011; Figure 4.3 p. 62).

assemble signaling complexes that activate either NF-κB or IRFs, leading to inflammatory and antiviral responses (Hornung, 2010 #51).

NOD-like receptors (NLRs) are a large family of cytoplasmic proteins that function as PRRs for PAMPs and form signaling complexes that induce inflammatory responses.[45] The ligand recognition domain of these proteins contains leucine-rich repeats, similar to TLRs, and the signaling complexes that form upon ligand binding activate NF-κB. NOD-1 and NOD-2, two of the best studied NLRs, are expressed in the cytoplasm of phagocytes and mucosal epithelial cells, where they recognize peptidoglycans of bacterial cell walls. NOD-2 is particularly abundant in Paneth cells of the intestine, and its ligation in these cells induces secretion of defensins. Polymorphisms in the NOD-2 gene are associated with increased risk of inflammatory bowel disease.

Inflammasomes are NLR-containing multiprotein complexes that assemble in the cytoplasm of cells in response to various PAMPs and DAMPs and catalyze the posttranslational processing of pro-IL-1β and pro-IL-18 into active proinflammatory cytokines IL-1β and IL-18.[46] In the best characterized inflammasome, the recognition component is part of an NLR family protein called NLRP3. In response to cytosolic microbial products or endogenous molecules indicative of cell injury, the NLRP3 proteins undergo oligomerization and recruitment of adaptor proteins and the inactive precursor of the protease caspase-1. The recruited caspase-1 becomes autoactivated and is then able to generate active IL-1β and IL-18. Most inflammasome activity, and therefore most IL-1 secretion, is attributable to macrophages. The stimuli that activate the NLRP3 inflammasome include a diverse array of microbial structures, including flagellin, muramyl dipeptide, LPS, bacterial pore forming toxins, and microbial RNA. Sterile inflammatory responses after tissue infarction are driven by activators of the inflammasome that are released by necrotic cells.[47] In addition, a variety of DAMPs activate the inflammasome, including intracellular crystals of sodium urate and cholesterol, extracellular ATP, and decreases in cytosolic potassium ion. Excessive activation of the inflammasome and excessive IL-1 secretion can cause a pathologic inflammation and tissue injury. This occurs in response to various phagocytosed crystals such as asbestosis, or sodium urate when there is excessive cell death or altered uric acid metabolism, such as in gout. These crystals likely damage phagasome membranes, causing the release of substances into the cytosol that interact with NLRP3. Autoinflammatory diseases, such as familial periodic fevers, are due to genetic mutations in components of the NLRP3 inflammasome, and IL-1 receptor antagonists or anti-IL-1 reagents are effective in treating these disorders.

Other Cell Surface Pattern Recognition Receptors

A variety of other cell surface receptors play important roles in innate immune defense against microbes. Some of these receptors belong to the C-type lectin family, and recognize common microbial carbohydrate structures not found in mammalian cells.[48,49] The mannose receptor (CD206) on macrophages binds to terminal D-mannose residues on prokaryote carbohydrates, and promotes microbial phagocytosis. Dectin-1 and -2 are expressed by DCs and bind fungal β-glucan and high-mannose oligosaccharides, respectively. Ligand binding to dectins induces signals that alter the DCs so they promote helper T-cell differentiation into Th17 cells, which are particularly effective in antifungal adaptive immunity. Scavenger receptors on macrophages including SR-A and CD36 bind a wide variety of PAMPs, including LPS, lipoteichoic acid, nucleic acids, and fungal carbohydrates.[50] Scavenger receptors enhance phagocytosis of microbes, and CD36 is a coreceptor for TLR2/6 recognition of a variety of ligands. Neutrophils and macrophages express *N*-formyl Met-Leu-Phe receptors, which are G protein–coupled receptors (GPCR) that recognize bacterial *N*-formylmethionyl peptides. Signals induced by these receptors stimulate chemotaxis of the phagocytes.

Soluble Pattern Recognition Receptors and Effector Molecules of the Innate Immune System

The innate immune system utilizes several PRRs that are present in blood and extracellular fluids, in order to defend against extracellular microbes. Three major functions of these molecules are to opsonize microbes so they are readily ingested by phagocytes, to directly kill microbes, and to enhance inflammatory responses that deliver phagocytes and more soluble effectors molecules to sites of infection. The major features and functions of these soluble components of innate immunity are described below.

Natural Antibodies

Although antibody responses are generally considered a fundamental part of adaptive immunity, there are B lymphocyte subsets, such as marginal zone B cells, that produce antibodies with only a limited repertoire of specificities and without clear-cut exposure to foreign antigens. These natural antibodies are specific for PAMPs and DAMPs, and therefore are typical of other PRRs of the innate immune system. Most natural antibodies are of the IgM subclass, do not require T-cell help for their production, and bind carbohydrates or lipids. Many natural antibodies are specific for head groups of oxidized phospholipids, including lysophosphatidylcholine and phosphorylcholine, typically exposed on bacterial membranes and apoptotic cells.[51] The anti-ABO blood group natural antibodies, which recognize glycolipid blood group antigens on blood cells and endothelium, are the cause of thrombotic complications in the setting of allografts and transfusions.

Complement

The complement system includes plasma proteins that are activated to generate proteolytic cascades, yielding products with various proinflammatory and antimicrobial functions.[52] The central and most abundant complement protein is C3. There are three pathways of complement activation. The classical pathway is activated by immune complexes of IgM or IgG bound to antigen and by pentraxins. The lectin pathway is activated by microbial surface carbohydrates. The alternative pathway is activated by spontaneous hydrolysis of C3 at microbial surfaces (FIGURE 6.2). The recognition molecules that initiate the classical and lectin pathways are C1q and mannose-binding lectin (MBL), respectively. Each of the three pathways forms an enzymatic complex called C3-convertase that cleaves C3 to form C3a and C3b. C3a is a small peptide that binds a specific GPCR on phagocytes, mast cells and endothelial cells, and has chemotactic and proinflammatory effects. C3b covalently binds to microbial surfaces or antigen–antibody complexes, and acts as an opsonin

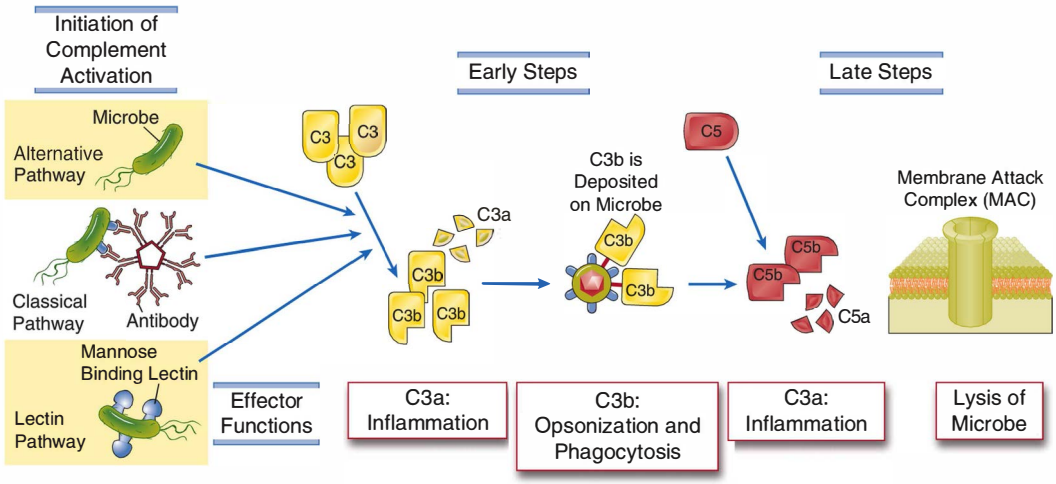

FIGURE 6.2 Pathways of complement activation. The proteolytic cascades of the complement system can be activated by antigen–antibody complexes binding to C1q (the classical pathway), by microbial carbohydrates binding to mannose-binding lectin (the lectin pathway), or spontaneously by C3 hydrolysis near microbial surfaces (the alternative pathway). All three pathways form C3 convertases that generate the opsonin C3b and the proinflammatory fragment C3a. C3b contributes to the formation of C5 convertase that generates the proinflammatory C5a fragments and initiates formation of the MAC that causes membrane damage and death of microbes or host cell membranes. (Modified from Abbas, et al. *Cellular and molecular immunology*, 7th ed. Saunders/Elsevier, 2011; Fig 4.9. p.73).

recognized by complement receptors on phagocytes. After C3b formation, all three pathways converge into a common terminal pathway that first generates a C5 convertase that cleaves C5 to form C5a and C5b. C5a binds to a specific GPCR on phagocytes, mast cells, and endothelial cells, and has similar but more potent proinflammatory effects as C3a. C3a and C5a peptides are called anaphylatoxins because of their ability to activate mast cells. C5a also has prothrombotic effects on the endothelium, including induction of tissue factor. C5b contributes to the common terminal complement pathway by nonenzymatically recruiting several lipophilic proteins named C6 through C9, which form a membrane attack complex (MAC). The MAC perturbs the integrity of some microbial membranes, and also damages host cell membranes in various inflammatory diseases. The complement system is crucial for effective innate immunity, as well as an effector mechanism of adaptive humoral immunity, and patients with genetic deficiencies in C3 are highly susceptible to various lethal bacterial infections.

Pentraxins, Collectins, and Ficolins

C-reactive protein (CRP), serum amyloid P (SAP), and pentraxin PTX3 are members of the pentraxin family of pentameric proteins.[53] They recognize phospholipids on microbes and apoptotic cells, and bind C1q to activate the classical complement pathway. CRP and SAP are acute phase reactants; their hepatic synthesis and plasma levels are upregulated by IL-6 and IL-1. For this reason, these pentraxins are clinically useful biomarkers of innate immune responses. PTX3 is made by neutrophils, DCs, macrophages, and endothelial cells in response to TLR ligands and cytokines.

Mannose binding lectin (MBL) and pulmonary surfactant proteins SP-A and SP-D are members of the collectin family of proteins. MBL binds terminal mannose and fucose residues on bacterial carbohydrates, and either activates the lectin complement pathway of or acts as an opsonin by simultaneously binding the C1q receptor on phagocyte membranes. Some MBL polymorphs are expressed at low levels in blood and are associated with increased susceptibility to infections. SP-A and SP-D opsonize microbes in the lung, promoting phagocytosis by alveolar macrophage. Ficolins are plasma proteins that bind to N-acetylglucosamine and the lipoteichoic acid in the cell walls of gram-positive bacteria. Ficolins act as opsonins or activate the classical pathway of complement.[54]

The Major Functions of the Innate Immunity

The components of the innate immune system described above perform three major functions. First they respond early to infection and cell injury by generating acute inflammation, characterized by increased delivery of plasma proteins and phagocytes to tissues. Complement, antibodies, other effector proteins, neutrophils, and macrophages work in concert to kill microbes and clear dead cells from the affected tissues. Second, some innate responses result in secretion of type I interferons, especially from pDCs, which induces an antiviral state in many cell types otherwise susceptible to viral infection. This function of the innate immune system occurs when viral nucleic acids ligate certain PRRs, such as TLR3 and RLRs. Third, innate immune activation of conventional DCs by TLR singling upregulates expression of various proteins involved in protein antigen processing and presentation to naïve T cells, thereby bridging innate immunity with adaptive immunity.

GENERAL FEATURES OF ADAPTIVE IMMUNITY

The major features of adaptive immunity that distinguish it from innate immunity are an enormous repertoire of specificities of its antigen-recognizing molecules, the inducible

specialization of effector mechanisms to best defend against different types of infections, and memory of first encounters with microbes, which enables more effective immunity to subsequent infections. The diversity of the repertoire of antigen specificities is based on the generation of large populations of B and T cells that express antigen receptors, but only a small number (~1,000) of which belong to a single clone and share the identical antigen specificity. These clones exist prior to foreign antigen exposure, and become activated (clonal selection) and increase in numbers (clonal expansion) when they recognize antigen.

Generation of Diversity of Lymphocyte Antigen Recognition Molecules

Lymphocyte antigen recognition is mediated by membrane receptors, including T-cell receptors (TCR) on T lymphocytes, and membrane immunoglobulin (antibody) on B lymphocytes. In addition, B lymphocytes that are activated by antigen secrete antibodies. The details of the structure of TCR and Ig molecules will be described later in the chapter. Suffice it to say that each receptor with a distinct specificity contains a different amino acid sequence in the antigen-binding region, and each receptor is encoded by a different gene. Since there are millions of different clones of lymphocytes, there are far more antigen receptor genes than the entire number of functional genes in the inherited human genome (~25,000). This tremendous diversity in protein sequence is achieved by somatic rearrangements, only in developing lymphocytes, of a more limited set of gene segments in the germline TCR and Ig loci.[55,56] A functional gene encoding an antigen-binding site for the polypeptides in Ig or TCR molecules is composed of DNA sequences called V (variable) and J (joining) segments. Two of the antigen receptor gene loci also have D (diversity) segments. There are many V, D, and J DNA segments that are spatially separated, and must be brought together by a process called V-D-J recombination, in order to form a functional gene. V-D-J recombination is catalyzed only in developing B and T cells, by the lymphocyte lineage-specific enzymes recombinase-activating gene-1 (RAG-1) and RAG-2,[57] in concert with more ubiquitous DNA repair enzymes. The result is the formation of functional genes that encode membrane immunoglobulin in B cells, or the TCR in T cells. Combinatorial diversity arises because the use of individual V, D, and J segments is random. For example, in the Ig heavy chain locus on chromosome 14 there are about 40 V genes, followed by approximately 25 D genes and approximately 6 J genes. Therefore, there are about 14,000 possible VDJ combinations that will encode heavy chains with antigen-binding sites. Junctional diversity is added because there are mechanisms in developing lymphocytes that add or delete nucleotides between the joining V, D, and J segments. Junctional diversity accounts for potentially millions of different variations in gene sequences in the regions of the antigen receptor genes that encode the antigen-binding sites of TCR and Ig molecules.

T-CELL–MEDIATED ADAPTIVE IMMUNITY

The major roles of T lymphocytes are defense against intracellular microbes, promotion and specialization of antibody responses to extracellular microbes, and regulation of adaptive immunity to prevent autoimmunity or excessive responses to microbes.

T-cell Antigen Recognition

T cells are defined by the expression of clonally distributed antigen receptors called TCRs. Most T cells express TCRs specific for a peptide in complex with an MHC molecule. Because MHC molecules are cell surface integral membrane proteins, T-cell antigen recognition only occurs by interaction with APCs, which display MHC–peptide complexes, and not by directly binding microbes or soluble microbial antigens. The major features of MHC molecules, the generation of peptide–MHC complexes by APCs, and TCRs will now be described.

MHC Molecules

MHC molecules have only one known function, which is peptide display on cell surfaces for T-cell immunosurveillance. In essence, MHC molecules alert the adaptive immune system of the presence of foreign proteins inside cells, and they may target immune responses against those cells. MHC proteins are encoded by highly polymorphic genes in the MHC locus on the short arm of the chromosome 6.[58,59] There are two major classes of MHC molecules and corresponding genes, called class I and class II MHC, which display peptides for recognition by $CD8^+$ or $CD4^+$ T cells, respectively. Three different types of human class I MHC molecules exist, called HLA (human leukocyte antigen)–A, HLA-B, and HLA-C, and there are three different types of human class II MHC proteins, called HLA-DP, HLA-DQ, and HLA-DR. The structure of a class I MHC molecules includes two noncovalently linked polypeptides, an α chain that is an integral membrane protein encoded by an MHC gene, and β_2 microglobulin, which is an entirely extracellular nonpolymorphic protein not encoded in the MHC locus. The *N*-terminal end of the class I MHC α chain forms a closed-ended peptide-binding groove, which accommodates peptides of 8 to 10 amino acids in length derived from other proteins inside the cell. Class II MHC molecules are composed of two noncovalently linked integral membrane proteins, called α and β chains, both encoded by polymorphic MHC genes. The N-terminal ends of both chains together form the class II MHC peptide-binding groove, which has a similar structure to that of the class I MHC β chain, but is open ended and accommodates longer peptides, usually 15 to 24 amino acids in length. Other than the length limitation, the peptide-binding grooves of class I and Class II MHC molecules are promiscuous for many different peptides, although there are constraints based on terminal amino acids that must serve as anchor residues and amino acid side chains that must fit into pockets in the floors of the grooves. Only a few peptides derived from any one protein will be able to stably bind in these grooves and be recognized by TCRs; these peptides are called the immunodominant epitopes of the proteins. As mentioned above, MHC genes are highly polymorphic. For example, there are over 1,000 HLA-A alleles, and over 1,500 HLA-B alleles. The polymorphic amino acid residues encoded by these alleles are concentrated in the peptide-binding grooves, and therefore each allelic form of an MHC molecule will be able to bind a different set of peptides. Consequently, the set of peptides that each individual in an outbred population will be able to display to T cells will be nonidentical, and individuals will vary in their ability to mount T-cell responses to different microbial proteins. However, the high degree of MHC polymorphisms ensures that an entire population will not succumb to a particular pathogen because of a total lack of antigen presentation.

As their name indicates, differences in MHC alleles between genetically nonidentical individuals account for the invariable T-cell–dependent rejection of allografts, in the absence of immunosuppression. Differences in the repertoire of peptides that can be displayed by different MHC alleles also likely explain the strong associations of many autoimmune diseases with particular MHC alleles.

Expression patterns of class I and class II MHC molecules reflect the different functions of T cells they display peptides to. All three types of Class I MHC molecules are simultaneously expressed on almost all nucleated cells in the body. Furthermore, both parental alleles of MHC genes are codominantly expressed, so that most cells express up to six different class I MHC proteins. $CD8^+$ effector T cells are the major defense mechanism against virally infected infections. Viruses can theoretically infect any nucleated cell, and all these cells can display viral peptides on I MHC molecules to $CD8^+$ T cells. All three types of class II MHC molecules are simultaneously expressed on a restricted set of cell types, including DCs, macrophages, and B cells. Some endothelial cells also express class II MHC, and expression may be induced on other cells types by the cytokine IFNγ. Like class I genes, both parental alleles of class II MHC genes are codominantly expressed, and because there are two HLA-DR β chain genes, up to eight different allelic forms of class II MHC molecules may be expressed on a single cell. $CD4^+$ T cells are key regulators of immune responses, and function to help other cell types perform effector functions. Given the potential for $CD4^+$ T cells to drive powerful and diverse adaptive immune responses, it is not surprising that only a limited number of cell types found in specific locations constitutively express class II MHC and are able to activate these T cells.

Antigen Capture, Processing, and Presentation

Conventional DCs are the major APCs responsible for activating naïve T cells. Immature DCs located within epithelial barrier tissues or within the parenchyma of other organs become activated by microbial PAMPs binding to TLRs and other PRRs. The DCs respond by internalizing microbes or microbial proteins, becoming motile, and entering draining lymphatics, which then carry them into lymph nodes. En route, the DCs mature into capable APCs by upregulating costimulatory proteins (described later), MHC molecules, and proteins involved in antigen processing. DCs also upregulate CCR7, the chemokine receptor that allows them to home to the same interfollicular T-cell zone of lymph nodes where naïve T cells are located. Blood-borne protein antigens may be taken up and processed by splenic macrophages and DCs. Antigen processing involves several sequential intracellular events in the APC, including the proteolytic degradation of proteins into peptides, delivery of the peptides to MHC proteins, assembly of peptide–MHC complexes, and expression of the complexes on the cell surface.[60] The details of these steps, which will not be described here, differ for class I and class II MHC. Importantly, the major determinant of whether a protein is processed for display by class I or class II MHC is the location of the protein in the cell. Cytosolic proteins are processed by the class I pathway, and would include most viral proteins that are synthesized in the rough endoplasmic reticulum of an infected cell, or other exogenously synthesized proteins that enter the cytoplasm via movement out of phagocytic vessels (so called cross-presentation). Therefore, viral proteins and proteins from microbes that survive by escaping from phagosomes into the cytosol will largely be displayed by class I MHC, and presented to $CD8^+$ T cells, which are adept at killing the infected cells. Proteins taken up by APCs through phagocytosis or endocytosis and end up in membrane-bound vesicles of the endosomal/lysosomal system are processed by the class II pathway. Therefore, peptide fragments of proteins from extracellular microbes will be displayed by class II MHC molecules and presented to $CD4^+$ T cells, which are adept at enhancing antibody responses and phagocyte activation to kill extracellular and phagocytosed microbes.

The antigen processing machinery does not distinguish between self and foreign proteins, and the vast majority of peptides displayed by class I or class II MHC molecules on the surface of cells are derived from normal self-proteins. A T cell can see and be activated by a foreign peptide–self-MHC complex even if it represents as little as 0.1% of the total MHC complexes on the APC surface. The fact that individuals usually do not react to the self-peptide–self-MHC complexes and develop autoimmunity is attributable to various mechanisms of T-cell tolerance, discussed later in this chapter.

T-cell Antigen Receptors

Over 90% of T cells in the blood and in lymphoid tissues express TCRs composed of a heterodimer of α and β polypeptide chains, which is specific for peptide–MHC complexes.[61,62] iNKT cells express $\alpha\beta$ TCRs with very little diversity that recognize lipid antigens displayed by the nonpolymorphic class I MHC-like molecule CD1. A small subset of T cells expresses a TCR composed of γ and δ polypeptides, which are structurally similar to α and β chains, but their specificities are poorly defined. Each chain of the common $\alpha\beta$ TCR includes a short *C*-terminal cytoplasmic tail, a transmembrane segment, a membrane proximal extracellular constant (C) region, and an N-terminal variable (V) region. The C and V regions have a compact three-dimensional structure first described in Ig molecules, called an Ig-fold or Ig-domain, which includes two adjacent β-pleated sheets connected by a disulfide bond. Proteins with Ig-folds belong to the *Ig superfamily*, and many molecules in the immune system are in this family, including MHC proteins, CD4 and CD8, to name just a few. The variable regions of the TCR are clonally distributed, meaning that one clone of T cells expresses a TCR with unique α and β amino acid sequences that differ from all other clones. The variable regions of both chains form the peptide–MHC binding site. Crystallographic analysis of the TCR structure reveals that the sequences that distinguish the variable region of one TCR α chain or β chain from another are concentrated within three hypervariable loops (also called complementarity determining regions) that connect adjacent strands of the β-pleated sheet of the V domains. The three hypervariable loops of both the α and β chains contribute to the specificity of one T-cell clone for a particular peptide–MHC complex.[63] Some of these loops contact polymorphic residues of the MHC molecules, and others contact side chains of the peptide within the peptide-binding groove of the MHC molecule. Every individual produces millions of different clones of T cells with unique TCRs. This diversity is generated by random somatic gene recombination mechanisms described earlier.

The TCR $\alpha\beta$ heterodimer is always expressed on the T-cell surface in association with a set of invariant signaling proteins, including ζ chains and CD3 proteins, to form the *TCR complex* (FIGURE 6.3). The cytoplasmic tails of these associated proteins

each contain immunoreceptor tyrosine-based activating motifs (*ITAMs*), which become phosphorylated on tyrosine residues when the TCR cell recognizes peptide–MHC on an APC. ITAM phosphorylation leads to a sequence of downstream signaling events that result in activation of the T cell.

Activation of Naïve T cells: Role of CD4/CD8 Coreceptors, Costimulators, and the Immune Synapse

In order for a naïve T cell to be activated by an APC it must engage in several molecular interactions with the APC in addition to TCR binding to peptide–MHC complexes. Effective TCR recognition of antigen also requires simultaneous binding of a coreceptor, either CD4 or CD8 on the T-cell surface with the peptide-displaying MHC molecule. CD4 and CD8 are Ig superfamily integral membrane proteins, expressed mutually exclusively on mature T cells, which bind to a nonpolymorphic region of the class II MHC β chain or class I α chain, respectively. A Src family protein tyrosine kinase called Lck is physically associated with the cytoplasmic tails of CD4 and CD8. Thus, binding of these coreceptors to the MHC molecules that are simultaneously recognized by a TCR brings Lck into the vicinity of the ITAMs in the cytoplasmic tails of the CD3 and zeta chains of TCR complex. Lck then phosphorylates the various substrates, including ITAMs, initiating the signaling cascade that will activate the T cell.

The signaling pathways downstream from the TCR are complex and best described in dedicated reviews[64–66] or textbooks.[30,31] A few major features are mentioned here because they are similar to activation pathways of other immune cells, including B cells and mast cells. Tyrosine phosphorylated ITAMs serve as docking sites for the cytoplasmic protein tyrosine kinase zeta-associated protein-70 (ZAP-70), which then becomes autoactivated and phosphorylates tyrosine residues on several adaptor proteins, including the membrane bound protein LAT. Phosphorylated LAT recruits various other signaling molecules that diversify and amplify downstream pathways, leading to activation of different transcription factors. Among these pathways is the phospholipase Cγ1-Ca^{2+}-calcineurin pathway that activates NFAT, and the Ras- and Rac-MAP kinase pathways, which lead to formation of the Jun-cFos containing AP-1 transcription factor. Antigen recognition by the TCR also activates PI-3 kinase, leading to Itk and Akt kinase activation. The net result of these signaling pathways and transcription factor activation is expression of IL-2 and its receptor, which promotes proliferation, expression of genes required for effector cell differentiation, and expression of antiapoptotic genes. An example of clinical pharmacologic blockade of TCR signaling is the use of cyclosporine and tacrolimus, which blocks calcineurin-dependent NFAT activation, in allograft patients.

In order to undergo productive activation, naïve T cells require additional signals provided by costimulatory molecules on the APC, which must bind to signaling receptors on the T cells at the same time as antigen recognition.[67,68] The expression of these costimulatory molecules on professional APCs, especially DCs, is induced by PAMP-mediated TLR signaling. The best characterized costimulatory molecules are CD80 (B7-1) and CD86 (B7-2), which bind to CD28, expressed on 90% of human $CD4^+$ T cells and on 50% of $CD8^+$ T cells. CD28 ligation activates PI-3 and Akt kinase-dependent signaling pathways, which synergize with TCR complex generated signals to enhance naïve T-cell proliferation, survival, and differentiation. Antigen recognition in the absence of costimulation can lead to T cell death or prolonged unresponsiveness (called anergy), which may protect against activation of self-reactive T cells. The immunosuppressive drug CTLA-4 Ig, which blocks B7-CD28 interactions, is approved for use to treat autoimmune diseases and prevent allograft rejection. Several other molecules on APCs have T-cell costimulatory activity, including ICOS-ligand (CD275) that binds to ICOS (CD278) on T cells, and LFA-2 (CD52) that binds to CD2 on T cells.

The molecular interactions between a T cell and an APC described above are facilitated by the formation of an immunologic synapse, which involves the close physical apposition of the plasma membranes of the two cells and the coordinated sorting of the relevant signaling proteins into centrally located lipid rafts and adhesion molecules to the periphery.[64] On the T-cell side of a typical immune synapse, the TCR complex, CD4 or CD8, and CD28 are centrally located, and LFA-1 is peripherally located. The respective ligands of these molecules on the APC are arranged accordingly. The immune synapse must be sustained for several hours in order for enough signaling to occur to activate the T cell, and prolonged synapse formation is also required for appropriate down-regulation of TCR signaling.

T-cell Clonal Expansion and Differentiation

In response to antigen and costimulatory signals delivered by DCs within secondary lymphoid organs, naïve T cells will undergo several rounds of proliferation to generate thousands of progeny T cells with the identical antigen specificity of the precursor naïve T cell. The magnitude of clonal expansion has been quantified during microbial infections by flow cytometry and the use of fluorescently labeled MHC-peptide tetramers, which bind to the TCRs of one antigen specificity. $CD4^+$ T cells expansion is typically in the range of $2–3 \times 10^4$-fold, while $CD8^+$ T-cell expansion during an acute viral infection is remarkably more than 10^5-fold. During clonal expansion, the T cells undergo differentiation into effector T cells, which have the ability to perform functions related to eliminating microbes. Effector differentiation is very much dependent on cytokines secreted by APCs or other cells in the lymph node microenvironment, as well as the antigen and costimulatory signals. $CD4^+$ T cells may differentiate into one of several subsets of helper T cells, described below (FIGURE 6.4), depending on the cytokines present, and $CD8^+$ T cells differentiate into CTL in response to IL-12 and type I interferons.

Effector T-Cell Subsets

Effector T cells may stay in lymphoid tissues where they were generated, or migrate to peripheral sites of infection. Like naïve T cells, effector T cells are activated by other cells presenting peptide-MHC antigen, and in response, they express surface or secreted molecules, which have various effects on the APCs or neighboring cells. $CD4^+$ T cells and $CD8^+$ T cells have distinct functions, and subsets of $CD4^+$ T cells are further specialized, based largely on the types of cytokines they produce.

CD4+ Helper T-cell Functions and Subsets

$CD4^+$ effector T cells are restricted to recognizing antigen on the limited set of cells that express class II MHC expressing cells, including DCs, macrophages and B cells. Many of the functions of effector $CD4^+$ T cells are to help these other cells perform

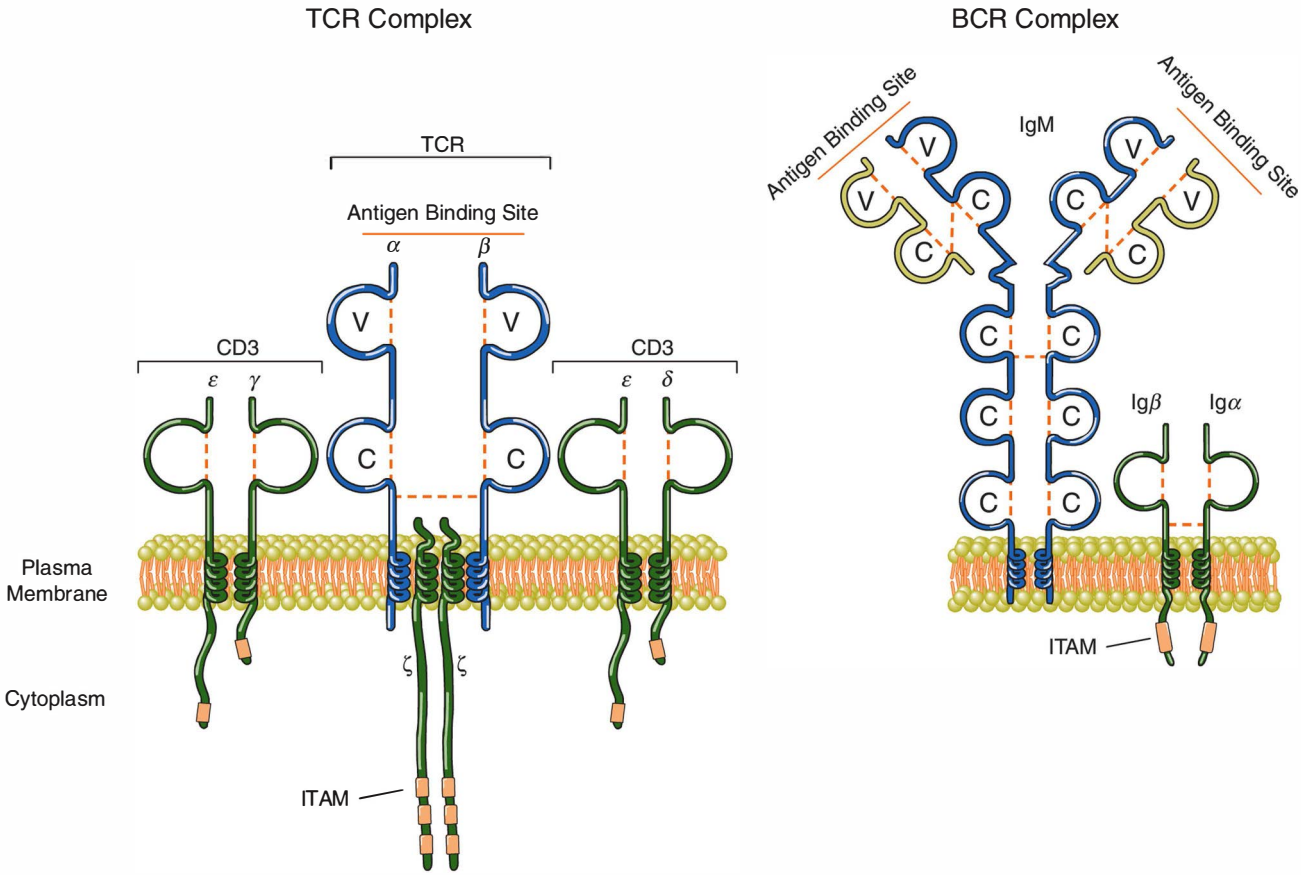

FIGURE 6.3 Antigen receptors of the adaptive immune system. An $\alpha\beta$ T-cell receptor in association with the CD3 and ζ signaling molecules is shown on the **left**, and a B-cell membrane IgM molecule with associated Igα and Igβ signaling molecules is shown on the **right**. The variable (V) and constant (C) Ig-like domains of the TCR α and β and IgM heavy and light chains are shown. Secreted IgM has a similar subunit structure as mIg, except for absence of transmembrane and cytoplasmic portion of the heavy chains. Secreted IgM forms pentamer. Other isotypes of Ig differ in the constant regions of the heavy chains, including the number of C domains. (Modified from Abbas, et al. *Cellular and molecular immunology*, 7th ed. Saunders/Elsevier, 2011; Figure 7.8. p. 147).

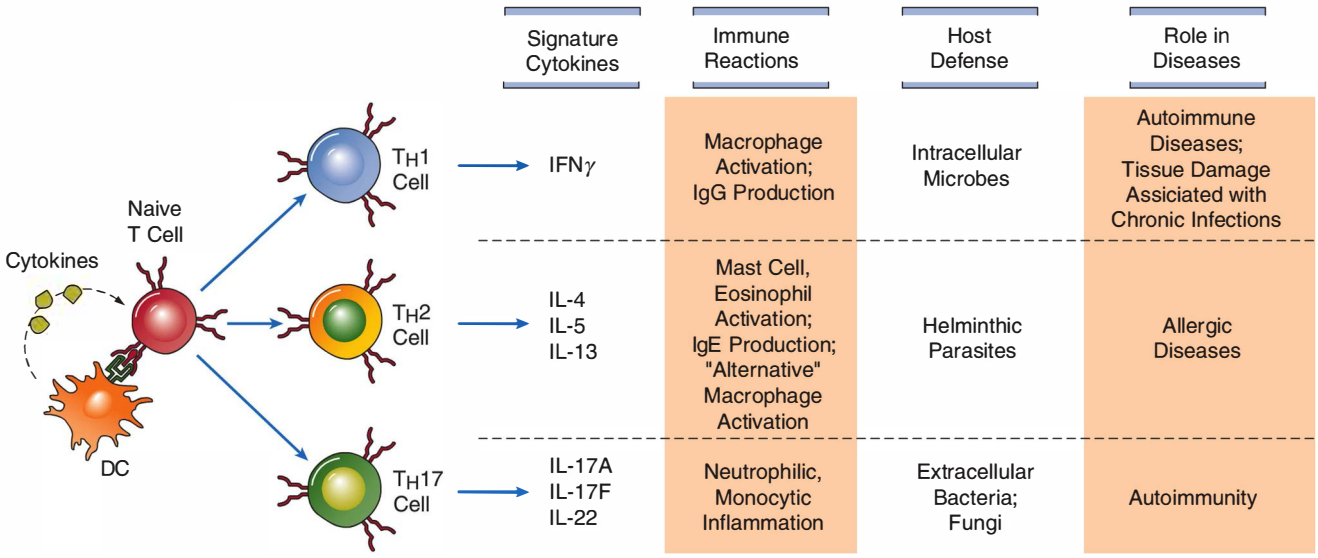

FIGURE 6.4 Helper T-cell subsets.

their functions, hence the moniker "helper T cells." T-cell help is largely provided by membrane CD154 and secreted cytokines. CD154 (CD40-ligand) is a TNF superfamily cell surface protein, which binds to the TNF receptor superfamily protein CD40 on the APC.[69] CD154 is also expressed on platelets, and CD40 is expressed on endothelium; these molecules have effects on homeostasis. Cytokines secreted by helper T cells act in a paracrine fashion by binding to cytokine receptors on the APC. The expression of CD154 and cytokines by the helper T cell requires activation by antigen, which ensures that help is selectively targeted to the appropriate cells, that is, those that have been infected or have phagocytosed microbes, and therefore can present microbial antigens to the helper T cells. In addition, cytokines secreted by activated helper T cells often have important effects on a wider range of neighboring cells besides the APCs, such as proinflammatory effects on endothelial cells.

The helper function of $CD4^+$ effector T cells on DCs is mainly mediated by CD154, and results in activation of the DCs to express more costimulatory molecules, IL-12, and type I interferons, which enhances their ability to simulate the differentiation of naïve T cells, especially naïve $CD8^+$ T cells into effector and memory cells. This function is sometimes called "licensing," and is one way helper T cells promote $CD8^+$ CTL responses to some infections. $CD4^+$ effector T cells help macrophages by enhancing their microbicidal or tissue repair functions, as is discussed for Th1 and Th2 cells below. The helper functions for B cells result in antibody class switching, increases in Ig affinity for antigens, and generation of memory B cells, as is discussed later.

T_H1, T_H17, and T_H2 subsets of $CD4^+$ helper T cells secrete distinct sets of cytokines and perform different roles in adaptive immunity[70,71] (FIGURE 6.4). Th1 cell secretes IFNγ, which together with CD154, enhances macrophage production of reactive oxygen species and lysosomal enzymes, and inflammatory cytokines such as TNF, IL-1, and chemokines. These effects, referred to as classical macrophage activation, enhance macrophage killing of ingested microbes, and promote inflammation leading to recruitment of more T cells and monocytes to sites of infection. Th1 cells are important for defense against microbial pathogens that can live within phagocytes, such as mycobacteria. Th17 cells secrete IL-17 and IL-22. IL-17 acts on many hematopoietic and tissue cell types to promote acute inflammation, and both IL-17 and IL-22 increase epithelial barrier function in the gut and skin.[72] T_H17 cells are required for defense against extracellular bacteria and fungal pathogens. T_H2 cells secrete IL-4, IL-5, and IL-13. IL-4 induces B cells to produce IgE, an antibody isotype that mediates antigen-induced mast cell degranulation, which promotes expulsion of helminths from the gut. IL-5 stimulates production and activation of eosinophils, which release granule contents that are toxic to helminths. IL-4 and IL-13 also simulates macrophages to secrete the anti-inflammatory cytokine IL-10 and growth factors that promote angiogenesis and collagen synthesis needed for tissue repair. These effects of IL-4 and IL-13 on macrophages are called alternative macrophage activation. In addition to their protective functions, T_H1, T_H2, and T_H17 cells are also mediators of tissue damage and disease. For example, prolonged T_H1 and T_H2 activation in the setting of persistent infections can result in granulomatous inflammation and tissue fibrosis. Self-reactive Th1 and Th17 cells are culprits in several autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, and psoriasis. Th2 cells specific for noninfectious environmental antigens promote IgE-dependent atopic disease.

T follicular helper cells (T_{FH}) are a subset of CD4+ helper T cells found in lymph node follicles, which have the specialized function of promoting B-cell differentiation into memory and long-lived plasma cells.[73] T_{FH} cells are characterized by expression of the follicular homing chemokine receptor CXCR5, ICOS, and abundant secretion of IL-21. T_{FH} cells may be heterogeneous with respect to secretion of other cytokines that induce Ig class switching to different isotypes.

CD8+ Cytotoxic T lymphocytes

The two main effector functions of $CD8^+$ CTLs are to directly kill infected (target) cells and to secrete proinflammatory cytokines, especially IFNγ.[74] CTL killing of infected cells requires recognition of microbial peptide-self class I MHC complexes, but costimulatory signals are not required, and therefore any infected class I MHC expressing cell can potentially activate and be killed by a CTL. $CD8^+$ CTL-mediated immunity is most important against viruses and certain bacteria whose proteins gain access to the cytosol. CTLs contain numerous lysosomal granules that contain perforin, a lipophilic protein that polymerizes in membranes, and serine proteases called granzymes, the most important of which is granzyme B. The main mechanism of target cell killing is by exocytic release of CTL granules into an immune synapse between the CTL and target cell, delivery of the granzymes into the target cell cytosol by perforin-dependent permeabilization of target cell membranes, and granzyme initiation of the caspase 3 and mitochondrial apoptosis pathways.[75,76] The DNA degradation that occurs during CTL-induced target cell apoptosis may serve to destroy microbial genomes. CTLs survive their lethal encounter with target cells, and are able to detach and then kill other cells. In addition, CTL may kill target cells by the Fas ligand:Fas (CD95) pathway, which involves caspase 8 proapoptotic signaling via CD95, and not granule CTL exocytosis. Robust CTL responses to an infection can overwhelm phagocytic clearance of apoptotic cells, resulting in proinflammatory necrotic death, and CTL secretion of IFNγ can enhance the inflammatory response. Thus, CTL responses to infection often cause tissue injury and exacerbate disease, such as in viral hepatitis. CTLs are also major contributors to allograft endothelial and parenchymal injury during acute rejection.

Memory T cells

Effector T cells generated in a response to specific microbial antigen are relatively short-lived, and most will die by apoptosis within several days after the microbe or antigen is eliminated. However, a residual population of antigen-specific memory T cells, 10- to 100-fold larger than the original population of naïve T cells specific for the antigen, will survive for months to years.[21,77] Memory T cells are responsible for more robust and specialized T-cell responses upon reexposure to a microbe. It is not known if memory T cells differentiate directly from naïve T cells, or if they arise from effector T cells. Generation of memory T cells depends on costimulation, and for $CD8^+$ T cells, on $CD4^+$ T cell help. Long-term maintenance of $CD4^+$ and $CD8^+$ memory T cells requires IL-7, and survival of memory $CD8^+$ T cells also requires IL-15. Two populations of memory T cells are described. Effector memory T cells are constitutively present in epithelial barrier tissues, and secrete abundant cytokines upon reactivation. Central memory T cells recirculate through lymphoid tissues, like naïve T cells, and undergo robust proliferation upon reactivation.

B CELLS AND ANTIBODY-MEDIATED ADAPTIVE IMMUNITY

Antibodies (immunoglobulins, Ig) are the recognition and effector molecules of the humoral arm of adaptive immunity. Ig molecules are expressed as membrane-bound receptors on the surface of B cells, and as soluble molecules in the blood and extracellular fluids in tissues. Humoral immune responses begin by antigen binding to membrane-bound antibody, which leads to the clonal expansion and differentiation of the B cell into an antibody secreting effector cell. The secreted antibodies perform various functions that protect against microbes, but are also responsible for tissue damage in many immune-mediated diseases. As in T-cell–mediated adaptive immunity, antibody-mediated immunity is characterized by tremendous diversity of antigen specificities, specialization of responses, and memory.

Antibody Structure

All antibody molecules share a basic structure composed of two identical heavy chain polypeptides disulfide-linked together, and two identical light chain polypeptides each disulfide-linked to one of the heavy chains (see FIGURE 6.3). The heavy chains are composed of two or three C-terminal constant (C) domains and a single N-terminal variable (V) Ig domain. The light chains contain one C-terminal C domain and one N-terminal V domain. These C and V domains have the prototypical Ig-domain conformation found in all Ig superfamily members. The antigen-binding site of an antibody molecule is formed by three hypervariable loops of the heavy chain V domain and three hypervariable loops of the light chain V domain, similar to the configuration of the TCR antigen-binding site. Two identical binding sites are formed by the two pairs of heavy and light chains in each Ig molecule, so that the basic structural unit of all antibodies is bivalent. All the antibody molecules expressed by a single naïve B cell have the identical antigen-binding site, but millions of different clones of naïve B cells are generated in every individual, each expressing antibodies with different antigen-binding sites. This diversity is generated by B-cell–specific somatic recombination of germline gene segments in the heavy and light chain loci, as described earlier. There are five different Ig classes or isotypes, named IgD, IgM, IgG, IgA, and IgE, distinguished by differences in the heavy chain constant regions. In addition, there are four subclasses of human IgG (IgG1, IgG2, IgG3, IgG4) and two subclasses of IgA (IgA1, IgA2). The heavy chains associated with each class are named by the Greek letter corresponding to the class name (δ, μ, γ, α, and ε). A single clone of B cells may change the class of antibody it produces, while maintaining the same antigen-binding site, by a process called isotype switch recombination, discussed later in this chapter.

The functions of antibodies depend on interactions of the heavy chain constant regions with other soluble or cell membrane proteins, and the different types of heavy chains perform different sets of functions because they interact with different sets of molecules.[78] The C-terminal heavy chain C domains are often referred to as the Fc region, and receptors on cells that bind heavy chains are called Fc receptors (FcRs). In membrane-bound antibodies of a particular class, there is a hydrophobic membrane spanning group of amino acids and a short cytoplasmic tail at the C-terminus of the heavy chain, while the secreted antibodies of the same class have shorter C-termini lacking these features but containing a secretory tail piece typical of all secreted proteins. Secreted IgA and IgM molecules form dimers and pentamers, respectively, in which the secretory tail pieces are disulfide-linked to the J chain protein. Two light chain isotypes exist, κ and λ with identical functions, and only κ or only λ light chains are produced by any one B cell.

All antibody functions depend on antigen recognition, which is mediated by several types of noncovalent interactions. The antigen-binding site formed from the six hypervariable loops of the heavy and light chain V domains is a planar surface, which can bind to large or small molecules, but small chemical antigens may also fit into clefts between hypervariable loops. Large molecules with different levels of structural organization provide various opportunities for antibody recognition. For example, an antibody specific for a protein may recognize a shape that depends on the native three-dimensional folded conformation, and another antibody specific for the same protein may recognize a short linear sequence of amino acids on an exposed segment of polypeptide. Antibodies can bind virtually any class of molecules produced by living organisms, as well as nonbiologic molecules. In typical immune responses to microbial antigens, the Kd of binding ranges from 10^{-7} to 10^{-11} M.

B-Cell Activation and the Generation of Antibody-Mediated Immune Responses

Two main types of antibody-mediated immune responses are distinguished by the nature of the stimulating antigen and the role helper T cells play. T-cell–independent responses are stimulated by polyvalent nonprotein antigens, such as polysaccharides and nucleic acids. T-cell–dependent responses are mounted against protein antigens and require interactions of $CD4^+$ helper T cells with B cells, both specific for the same antigen. In both types of responses, an initial step is the recognition of the antigen by the B-cell receptor on a naïve B cell.

The B-cell Receptor Complex and CR2/CD21 Coreceptor

The B-cell receptor complex on naïve B cells is made up of membrane IgM or IgD noncovalently associated with two invariant signaling proteins called Igα and Igβ that have ITAMs in their cytoplasmic tails and function in a similar manner to CD3 and ζ proteins in the TCR complex. Recognition of an antigen by membrane Ig leads to tyrosine phosphorylation of the ITAMs of Igα and Igβ by Src family tyrosine kinases, the recruitment of Syk, a protein tyrosine kinase homologous to Zap70, and then Syk-mediated phosphorylation of adaptor proteins and other signaling enzymes, analogous to those in T cells described earlier.[79] These signaling events lead to expression of genes that drive clonal proliferation and differentiation into antibody secreting cells. However, like naïve T cells, other signals besides those originating from the antigen receptor, are required for an effective response to develop. Complement activation provides one such signal, in the form of a C3d, a proteolytic product of C3b, which can be covalently attached to the same microbial surface recognized by membrane Ig. C3d binds to CR2, which is part of a signaling complex on B cells that includes CD19 and CD81. When a C3d-coated antigen engages both the BCR and CR2, the cytoplasmic tail of CD19, becomes phosphorylated by kinases associated with the cytoplasmic tails Igα and Igβb, which then, and amplifies BCR signaling. By this mechanism,

complement activation on a microbial surface or other antigen greatly increases the ability of the B cell to productively respond and develop an antibody response.

T-cell–dependent Antibody Responses

T-cell–dependent antibody responses are specific for protein antigens, and generate high-affinity antibodies of various isotypes, as well as long-lived plasma cells and memory B cells. These responses develop within secondary lymphoid organs by the bidirectional interactions of a B cell and $CD4^+$ helper T cell, each of which expresses an antigen receptor specific for the same protein.[80] Rare naïve B cells in a follicle may express BCRs that recognize some epitope on an intact monovalent microbial protein. The proteins will bind to the IgM receptors on those B cells, which stimulate endocytosis and processing of the protein, and presentation of a microbial peptide-class II MHC complex on the B-cell surface. $CD4^+$ T cells specific for the same microbial peptide-class II MHC are activated by DC APCs in the interfollicular zones, as described earlier, and differentiate into helper T cells. Changes in chemokine receptor expression on the activated B cells and T cells facilitate their migration toward one another at the edge of the follicles, and at this location B cells preset the microbial peptide antigens to the helper T cells. As an antigen-presenting B cell and helper T cell are engaged, the T cell delivers activating signals back to the B cell via cytokines and CD40 ligand. These signals stimulate some degree of B-cell proliferation and differentiation in antibody secreting plasma cells outside the follicle. This involves alternative heavy chain mRNA processing to exclude membrane anchoring sequences and include a secretory tail piece. The secreted antibodies include IgM and, due to isotype switching in some of the B cells, IgGs.

Isotype (class) switching involves rearrangements of DNA segments in the Ig heavy chain locus of a mature B cell that has already undergone V-D-J recombination and expresses antibodies of one isotype, usually IgM.[81] These DNA rearrangements depend on *activation-induced deaminase (AID)*, whose expression is induced by T_H CD154 binding to B cell CD40. AID catalyzes the replacement of cytosine residues in DNA with uracil, leading to generation of double-stranded breaks in specific intronic switch regions upstream of heavy chain gene locus.[82] During the repair of these breaks, various DNA repair enzymes act in concert as a switch recombinase, which deletes the intervening DNA between two DNA breaks, and moves the VDJ cassette from its original location adjacent to an upstream heavy chain gene locus (e.g., the μ locus) to a new downstream location just 5′ of another heavy chain locus (such as γ, ε, or α). The particular downstream heavy chain locus that ends up being used depends on the type of cytokines secreted by the helper T cells, which will enhance accessibility of different switch regions to the recombinase enzymes. For example, IL-4 from a Th2 cell will specifically promote ε heavy chain switching.

Some of the B cells that receive helper T-cell signals migrate back into the follicle and undergo remarkable proliferative expansion to form a germinal center. T_{FH} cells also migrate into the follicle and provide additional CD154 and cytokine signals to the newly expanded clone of B cells. These signals result in two fundamental features of the germinal center reaction, *affinity maturation* and the generation of *long-lived antibody-secreting plasma cells* and *memory cells*. Affinity maturation is the increase in the average affinity of Igs produced to a protein antigen as a T-dependent humoral response progresses. The underlying mechanism of affinity maturation is the generation of random point mutations (somatic hypermutation) in the V region gene segments of the proliferating germinal center B cells, resulting in many different subclones with varying changes in the affinity of the Igs they express. This is followed by the selection for survival of only those subclones that express the highest affinity antibodies.[83] V gene somatic mutations are generated by the same AID enzyme that mediates switch recombination, but in the case of affinity maturation, the repair of the introduced uracils is by base substitution, and not by dsDNA breaks and recombination. The selection of the high-affinity B-cell subclones depends on follicular dendritic cells (FDCs), a cell type unique to B-cell follicles that is not related to conventional DCs that activate T cells. FDCs bind and display intact protein antigens on their surfaces, while the overall concentration of antigen declines as a humoral response progresses. Only B cells that can bind these antigens tightly will receive survival signals, and other B cells will die by apoptosis. CD154 and IL-21 signals delivered by T_{FH} cells are also important for the selection of high-affinity B cells. Many of the selected B cells will differentiate into antibody secreting plasma cells, which are responsible for the rising titer of high-affinity antibodies that occurs during T-dependent responses to infections. Some of these plasma cells migrate to the bone marrow and survive there for months to years, and maintain titers of high-affinity antibody in the blood. Other selected B cells in the germinal center become resting memory cells, which reside within lymphoid tissues, survive for many years, do not actively secrete antibodies, but respond rapidly upon re-exposure to antigen by secreting isotype-switched high-affinity antibodies.

T-independent Antibody Responses

T-independent antibody responses are usually stimulated by polyvalent nonprotein antigens, such as bacterial capsular polysaccharide. This is because helper T cells only recognize peptides derived from protein antigens, so nonprotein antigens cannot elicit T-cell help. BCR signaling by monovalent antigens is usually not strong enough to induce B-cell proliferation and differentiation. However, polyvalent antigens can cause clustering of multiple BCR complexes and achieve a localized concentration of ITAMs and kinases that will generate sufficient signaling to productively activate a naïve B cell. TLR ligands and complement can enhance B-cell responses to these nonprotein antigens. Although some isotype switching to IgG and IgA occurs in response to nonprotein antigens, overall most T-independent responses are dominated by IgM secretion. There is also relatively little long-term memory or generation of long-lived plasma cells in T-independent responses. These properties become shortcomings of vaccines that do not activate T cells, but they have been addressed by the use of conjugate vaccines in which microbial polysaccharide antigens are covalently linked to protein carriers. The modified antigens are recognized by both B cells and T cells, and induce T-dependent antibody responses to the nonprotein component of the vaccine. The same mechanism underlies T-dependent IgE responses to nonprotein drugs (e.g., penicillin) or environmental chemicals (e.g., urushiols from poison ivy). In these cases, the allergens are reactive chemicals that covalently link to amino acid residues of self-proteins, including MHC molecules. In this context, they are called haptens, and can be recognized by antibodies, and by T cells when presented as part of an altered self-peptide bound to MHC.

Functions of Secreted Antibodies

The simplest protective function that antibodies perform is the binding to microbes or their products, thereby blocking their interactions with cellular receptors that promote infection or toxicity. This function, called neutralization, is due to stearic hindrance or by antibody-induced conformational changes in the bound antigens. Neutralization does not involve the constant regions of antibodies, and can be mediated by artificially prepared fragments of antibodies lacking the Fc regions (called Fab or F(ab)2 fragments). The most important neutralizing antibodies are high-affinity IgG molecules in the blood and IgA molecules in mucosal secretions, and the chronic production of neutralizing antiviral antibodies is the mechanism by which most successful viral vaccines work.

A major function of secreted IgG antibodies is opsonization of microbes to promote FcR-mediated phagocytosis and killing. There are several FcRs specific for IgG molecules expressed on different cell types, but the most important for phagocytosis is FcγR1 (CD64) that binds IgG1 and IgG3 with high affinity, when the antibodies are simultaneously binding antigens (i.e., forming immune complexes)[84]. CD64 is associated with a dimer of FcR γ chains, which contain ITAMs in their cytoplasmic tails, and transduce activating signals that enhance phagocytic, microbicidal, and inflammatory responses of the phagocytes. Thus, immune complexes binding to FcγR1 on neutrophils and macrophages induces their phagocytosis, destruction of the antigens, and increased local delivery of more phagocytes and antibodies.

There are several other isotype-specific FcR-dependent functions of antibodies. IgGs bound to surface antigens on infected or stressed host cells can simultaneously engage FcγRIIIA (CD16) on NK cells and thereby activate the NK cell to kill the antigen-bearing cell. This process, called antibody-dependent cellular cytotoxicity, may also contribute to killing of host cells targeted by therapeutic antibodies for cancer (e.g., anti-Her2/Nue) or autoimmune disease (e.g., anti-CD20). IgG and IgA antibodies specific for helminthic parasites bind to FcRs on eosinophils and can stimulate the release of granule contents that are toxic to the worms. Allergens or parasite antigens cross-link IgE that is prebound to high-affinity receptors for IgE (FcεR) on mast cells. This causes release of mast cell granule contents, including histamine, and rapid production of inflammatory cytokines and eicosanoids. The resulting immediate and late phase inflammatory responses have antihelminthic functions, but also cause allergic disease.

IgG1, IgG3, and IgM immune complexes bind C1q and activate the classical complement cascade.[85] As discussed earlier in the chapter, complement activation generates the opsonin C3b, which binds to the antigen–antibody complex, and promotes its phagocytosis by neutrophils and macrophages via the C3b receptor CR1 (CD 35). Complement activation also generates proinflammatory anaphylatoxins (C3a, C5a), and leads to lysis of *Neisseria* species of bacteria by MAC formation.

Dimeric IgA is secreted into the gut lumen where it functions as a neutralizing antibody to protect mucosal barriers from microbial invasion.[86] Secretory IgA is produced by lamina propria B cells, then transported through gut epithelial cells by attachment to the membrane bound poly I receptor, and is released into the lumen by proteolytic cleavage of the receptor. Secretory IgA is also found in airways and mother's milk, and it provides passive mucosal immunity to breast feeding babies. Maternal circulating IgG is transported across the placenta into the fetal circulation by the neonatal Fc receptor (FcRn), and provides critical passive immunity for neonates up to 6 months of age. FcRn is also expressed in endothelial cells and many other cells, where it protects endocytosed IgG from degradation and recycles the antibody back into the blood. This function of FcRn is largely responsible for the very long half-life of circulating Ig compared to other plasma proteins.

Regulation of Adaptive Immune Responses

Multiple mechanisms exist to prevent nonuseful and potentially dangerous immune responses, and to limit the magnitude and duration of useful responses to pathogens. These mechanisms are particularly critical for adaptive immunity because the random generation of antigen receptor specificities in lymphocytes carries the risk of producing self-reactive cells, and because the adaptive immune system is characterized by powerful effector mechanisms and long-lived memory cells. During lymphocyte development, many self-reactive B and T cells are eliminated by apoptotic death at an immature stage if their antigen receptors recognize self-antigens within the bone marrow or thymus.[87] Immature B cells that recognize antigens in the bone marrow may also undergo additional rounds of V-D-J recombination in their light chain loci, so that their specificities are changed; this is called receptor editing.[88] Many self-reactive B and T cells do escape negative selection during development, and enter the peripheral immune system. Additional mechanisms of peripheral tolerance are required to eliminate or suppress these cells. One such mechanism is the presentation of self-antigens to T cells by immature DCs that lack costimulatory molecules, which induces anergy or death of the T cells.[89] By the same mechanisms, costimulatory blockade is a potential therapeutic approach to induce tolerance to newly introduced proteins, such as in the setting of transplantation or gene therapy. T-cell responses are also regulated by inhibitory receptors of the CD28 family, namely, CTLA-4 (CD152), which binds to CD80 and CD86, and PD-1 (CD279), which binds to PD-L1 (C274) and PD-L2 (CD273).[90] Mouse models show the necessity of CTLA-4 to prevent lethal autoimmunity, and human clinical trials of blocking antibodies to CTLA-4 or PD-1 have demonstrated enhanced T-cell-mediated antitumor immune responses.

Regulatory T cells (Tregs) are a heterogeneous population of T lymphocytes that suppress effector T-cell responses, and thereby prevent autoimmune disease.[91,92] Natural Tregs mature in the thymus, and induced or adaptive Treg differentiate from naïve T cells in peripheral lymphoid organs. The best defined Tregs are $CD3^+$, $CD4^+$, $CD25^{hi}$, and $CD127^{lo}$ and express the transcription factor FOXP3, which is essential for their development. Mutations in FOXP3 lead to a lethal autoimmune disease called IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome). It is likely that induced Tregs contribute to the control of normal immune responses to foreign antigens. Tregs function by inhibiting the activation of naïve and effector T cells by APCs, through cell contact–dependent mechanisms and by the actions of secreted TGFβ.

Biostatistics and Epidemiology: The Basic Science of Clinical Research

KERRY L. LEE

In the basic sciences, there is an essential knowledge base and an array of tools and techniques that basic scientists must master in order to conduct state-of-the art laboratory and animal research in areas such as molecular and cell biology, biochemistry, and genetics, and to research the complex molecular or cellular mechanisms related to hemostasis and thrombosis. Similarly, there are vitally important concepts, scientific methods, and tools that must be understood for conducting clinical research, whether that research is in hemostasis and thrombosis, cancer, cardiovascular disease, or other areas of medicine. For example, to rigorously evaluate a promising new compound for reducing the incidence of thrombotic complications in a specific population of patients, a properly designed study with an adequate number of subjects where potential biases are minimized and the data are properly analyzed is required. The key question is how should you design, conduct, analyze, and interpret such a study. The answer to that important question can be found in the body of knowledge and the concepts, principles, and tools of biostatistics and clinical epidemiology. Indeed, the *basic science* of clinical research and the quantitative methodology required for conducting well-designed and properly analyzed clinical investigations largely exists within these disciplines. A basic understanding of biostatistical and epidemiologic methods is also essential to understand and critically evaluate the current medical literature in which the designs and results of clinical trials and observational studies are reported and discussed.

This chapter provides an overview of selected biostatistical and epidemiologic methods that are relevant for researchers who wish to design and conduct a clinical study. In addition, this overview is relevant for clinicians and medical practitioners who need to critically evaluate the published medical literature and use that information to make rational, evidence-based decisions in medical practice. An understanding of these methods is also important for properly synthesizing and summarizing information for the development of guidelines and policy decisions designed to improve health outcomes in the general public.

EPIDEMIOLOGY STUDY DESIGNS

The classical definition of epidemiology found in textbooks on the subject is that epidemiology is the study of the distribution and determinants of disease frequency in human populations.[1–4] This definition embodies two principal areas, namely (a) the study of disease frequency and variation in the occurrence of disease and (b) the search for the determinants of the distribution and frequency of disease and reasons for the variation in its occurrence. Relevant to the methods discussed in this chapter is the concept of *clinical epidemiology*, defined by Weiss[5] as "the study of variation in the *outcome* of illness and of the reasons for that variation." Numerous textbooks have been written on the subject (see for instance references[1–5]), and graduate training programs in epidemiology have been developed at many well-known colleges and universities, particularly in universities with a School of Public Health. Epidemiology, because it is based directly on observations of human subjects, has the advantage of relevance to populations of real people. However, classical epidemiology studies are commonly observational in nature and cannot take place under the controlled conditions possible in a laboratory experiment. Deriving reliable conclusions about cause-and-effect relationships from observational studies is challenging and must be done very cautiously and carefully. Observational epidemiologic studies have the disadvantage that possible confounding factors may bias conclusions about cause-and-effect relationships, and great care must be taken in designing such studies and analyzing the data in order to reduce the likelihood of spurious associations between a disease or disease outcome and a study factor of interest. In the epidemiology literature, the study factor of interest is often referred to as an *exposure variable*.[6]

There are two basic types of epidemiologic studies, which with some variations encompass most of the clinical research studies seen in practice today.[6] These include (a) *case–control* studies, and (b) *cohort* studies. In a case–control study, a group of cases or patients who have a disease of interest and a control group, or comparison series of subjects without the disease, are selected for investigation. Of primary interest is a comparison of the proportions in each group with a particular *exposure* (or factor) of interest. In contrast, in a cohort study, subjects are classified on the basis of the presence or absence of exposure to a particular factor (e.g., a particular treatment), and then followed for a specified period of time to assess the development of the outcome of interest (i.e., development of a particular disease or clinical event of importance) in each exposure group. Both case–control and many cohort studies are often criticized because of the potential for confounding and bias that is inherent in the fact that the design is observational. In a cohort study where the exposure factor of interest (e.g., use of a particular drug or treatment) is either self-selected or chosen by a health care provider, the subjects with that factor (e.g., people who use a particular treatment) may be systematically different from those without the factor (e.g., people who do not use the treatment) in ways that will affect the outcome of interest. In a case–control study, because the outcome of interest has already occurred at the time the exposure is assessed, there is potential for bias in the selection of subjects into the study and in their recall of prior events.

However, there are two principal strengths of observational epidemiologic studies. First, the evaluation of exposure factors that require a long duration before the outcome of interest occurs may be able to be studied productively with one of these designs, particularly a case–control design. Second, if the effect to be detected is moderate to large (on the order of a 50% or greater difference in the disease outcome of interest), then one of these observational designs may suffice. The strong association between smoking and lung cancer observed in the case–control studies conducted by Doll and Hill[7] in the 1950s is an example where although the amount of uncontrolled confounding may have affected the magnitude of the relative risk estimate, the relative risk of lung cancer due to smoking was sufficiently large that even with complete control of confounding factors, it is unlikely to have materially changed the conclusion that there is a strong positive association between smoking and lung cancer.[6]

RANDOMIZED CLINICAL TRIALS

In contrast to case–control and observational cohort studies where the "exposure" factor is observed rather than controlled as part of the experiment, a study design that can be viewed as an important special case of an epidemiologic cohort study is the randomized clinical trial.[6] Since the conduct and publication of the earliest randomized trials in the 1940s, randomized clinical trials have increasingly become accepted as the principal and most reliable method (the "gold standard") for acquiring information required for judging the efficacy and safety of therapeutic interventions. Variations of a "strength of evidence" hierarchy, such as that published in Green and Byar,[8] (FIGURE 7.1) always place the information derived from a well-designed randomized clinical trial as having greater value than information from nonrandomized observational studies. Randomized trials are widely accepted today as a powerful tool and the key to providing information required for rational, evidence-based medical care and prevention of disease.[6,9] Well-designed clinical trials are required by regulatory agencies prior to the registration of new drugs and devices. Clinical trials serve as the critical bridge between initial studies that have provided "proof of concept" of a new therapy and its ultimate widespread clinical application.

It is a legitimate question to ask why clinical trials are so essential. There are many reasons. First, most new interventions for use in clinical care have modest beneficial effects.[10] Relative risk reductions in key clinical outcomes as high as 25% are rarely achieved or exceeded by new interventions, and frequently the benefit is less although still clinically important. Second, few interventions are free of undesirable effects, and both the benefits and risks must be evaluated in order to adequately assess the usefulness of an intervention.[9] Given the uncertainties about the disease course and biologic variation in clinical outcomes, it is usually impossible to reliably judge the effects of a treatment or intervention on the basis of uncontrolled clinical observations. The randomized clinical trial has emerged as the principal research tool for developing evidence to inform and influence clinical practice. This is true in studies of hemostasis and thrombosis, as well as in numerous other areas of medicine.

In the past 20 years, many papers and a number of excellent textbooks have been published describing in considerable detail the methodology of randomized clinical trials. The popular text by Friedman et al.[9] provides an excellent expository overview of the fundamental concepts of clinical trials and the major principles and components of a well-designed clinical trial. Other useful books include Piantadosi's[11] excellent methodologic perspective on clinical trials, Cook and DeMets'[12] introduction to statistical methods in clinical trials, the older, but highly relevant text by Pocock,[13] and the recently published four-volume *Wiley Encyclopedia of Clinical Trials*.[14] In this chapter, selected topics that are pertinent to clinical researchers for planning and conducting a well-designed clinical trial and analyzing and interpreting the results of the study are discussed.

What is a Clinical Trial?

The text by Friedman et al.[9] defines a clinical trial as "a prospective study comparing the effect and value of interventions(s) against a control in human beings." The key elements of this definition are that a clinical trial (a) is prospective, rather than retrospective (i.e., subjects are followed forward in time), (b) involves one or more interventions or intervention strategies, (c) requires a control or comparison group against which the interventions are evaluated, and (d) involves human subjects.

The important prospective element of a clinical trial is in sharp contrast to the case–control epidemiologic study design mentioned earlier where participants are selected on the basis of the presence or absence of an event or condition of interest. Thus, by definition, a case–control study is not a clinical trial. Because a clinical trial involves human subjects, it introduces issues of ethics, safety, compliance, and the inherent biologic variation that exists among human subjects.

"Phase" Designation for Clinical Trials

In the medical literature, clinical trials are often characterized as being of a certain "phase." This terminology generally places clinical trials into four phases (phase I through phase IV).[9] Although preclinical data may be obtained from *in vitro* studies or animal models, phase I studies are generally small studies that represent the initial step or phase of testing a drug or biologic in humans to understand how well it can be tolerated and assess its toxicity. A typical goal of a phase I trial is to estimate how large a dose can be given before unacceptable toxicity is experienced by subjects. Although it does not meet the definition of a clinical trial (there is no control arm), this phase of development for a

new intervention is important and is commonly referred to as a phase I trial, although a "phase I study" is a more appropriate designation.

A phase II trial is one in which the objective is to assess the biologic activity or effect of a new compound, acquire further information regarding the appropriate level of dosing, determine whether there are encouraging signals (typically on surrogate endpoints [discussed later in the chapter]), and obtain data for designing a larger, more definitive (phase III) study that would be required to test the effectiveness of a new therapy in order to obtain regulatory approval. Finally, phase IV studies, generally referred to as postmarketing surveillance studies, are longer-term surveillance studies, designed to obtain additional information on long-term safety issues that may be associated with adoption of a new intervention.

Efficacy versus Effectiveness Trials

The terminology "efficacy" and "effectiveness" is often used in the context of clinical trials.[9] An *efficacy* trial is meant to distinguish clinical trials designed to assess the effects of an intervention in an ideal setting (where subjects and health care providers are highly compliant with the protocol, the best trained and most experienced center(s) are involved, and perhaps the study population and spectrum of risk of the population are narrowly defined). In contrast, an *effectiveness* trial is one in which the effects of an intervention are assessed in a study population enrolled across different types of clinical centers, taking into account the realities of less-than-perfect compliance with the study protocol, and typically involving a broader spectrum of patient risk. Most moderate to large multicenter trials would be considered "effectiveness" trials. The terms "comparative effectiveness trials" and "pragmatic trials" have recently become quite popular, but both terms relate to the general class of studies referred to as "effectiveness" trials.

Study Questions and Endpoints

The planning of a clinical trial depends on the specific objectives and the questions that the investigators wish to address. It is essential that those objectives and questions be well focused, clearly stated, and specified in advance. Closely related to the specific aims of the study and the questions of interest is the choice of endpoints to be examined in a trial. As advocated by Friedman et al.,[9] each clinical trial should have a primary endpoint. This choice is a key decision in designing a trial and is usually the major determinant of the study size. The primary endpoint should be (a) consistent with the primary study question and the hypothesized effect of the intervention, (b) clearly defined and specified in advance, (c) capable of being ascertained as completely as possible (ideally in every subject), (d) measured in the same way for all subjects, and (e) capable of unbiased assessment. For nonfatal endpoints, these last two points may require that the study have a blinded core laboratory to make the endpoint measurements or a blinded clinical events committee to review and adjudicate the clinical endpoints.

Beyond the important choice of the primary endpoint, it is reasonable in a clinical trial to consider one or more secondary endpoints in order to address important secondary or subsidiary questions. Again, prespecification and prioritization of these endpoints is important.

There are a variety of types of endpoint variables, including (a) binary (e.g., developing the disease of interest; whether the patient lived or died), (b) ordinal (e.g., worsening, no change, or improvement; number of significantly diseased arteries), (c) continuous (e.g., cholesterol level; lymphocyte count; distance walked in a 6-minute walk test), and (d) time to event (with censoring) (e.g., time to death or to significant nonfatal events [e.g., stroke] in long-term follow-up studies). Time-to-event endpoints typically arise in studies where patients are followed over a relatively long period of time.

Composite Endpoints

For many therapies under investigation, the goal is not necessarily to reduce mortality, but rather to prevent nonfatal events or improve symptoms. In such cases, a variety of negative outcomes are important (e.g., nonfatal myocardial infarction, stroke, or unstable angina). Furthermore, it is important with a new therapy to be relative certain that excess mortality is not being caused in the pursuit of reduced symptoms or nonfatal events. An approach frequently used is to specify a composite endpoint that includes more than one relevant outcome (e.g., death or stroke; death, myocardial infarction, or hospitalization for unstable angina).[9,15] This type of composite endpoint has been valuable in a number of studies and has led to acceptance of several new therapies in patients with acute coronary syndromes and heart failure. An advantage of a composite endpoint is that by including multiple possible outcomes where the occurrence of any one of them is counted, the event rate will be increased (compared for example to an endpoint consisting of mortality alone), and therefore the number of patients required for the study will be less. However, the interpretation can be problematic, particularly if some components of the composite are affected differently by the treatment being studied compared to its effect on other components. Furthermore, the common approach to analyzing such composite endpoints counts each component with equal weight, which may be somewhat counterintuitive. Some attempts at developing weighting schemes have been used, but clinicians have a difficult time agreeing on appropriate weights.[15,16] If considering a composite endpoint, a useful guideline is to (a) include only components that are expected to be affected by the intervention being studied, (b) include "harder" or more objective measures that are clinically important, (c) include mortality as one component, and (d) limit the number of components to a relatively small number.

Surrogate Endpoints

With clinical events as the primary endpoint, a trial can be quite long and expensive, and therefore consideration is often given to designing trials with a surrogate endpoint, namely a laboratory measurement or physical sign that is used as an alternative to a clinically meaningful endpoint.[9,15,17] Surrogate endpoints are of interest for their potential to reduce the size, cost, and duration of major trials. Furthermore, they may be helpful in explaining the mechanism of action of a therapy on clinical endpoints. Examples of surrogate endpoints might be such things as blood pressure, cholesterol reduction, CD-4 lymphocyte level, or suppression of ventricular arrhythmias. Lowering blood pressure in a population of hypertensive patients is an example of a surrogate for the clinical outcome of death, myocardial infarction,

or stroke. Surrogate endpoints are essential for early-phase studies to elucidate pathophysiological effects, but the pitfalls of assuming that a positive effect of an intervention on a surrogate endpoint will translate into a positive effect on a relevant clinical outcome have been well described. The Cardiac Arrhythmia Suppression Trial[18] and heart failure trials of inotropic drugs[19–22] are classic examples of the failure of surrogate endpoints.

There is a common misconception that if an outcome is correlated with the true clinical event, it can be used as a valid surrogate endpoint and serve as a replacement for the true clinical endpoint of interest. A valid surrogate endpoint must fulfill two criteria.[17,23] First, changes in the surrogate must be predictive of the relevant clinical outcome. The second important requirement, which can be difficult in practice to ascertain, is that a potential surrogate must fully (or nearly so) capture the effect of the intervention on the true clinical outcome. The considerations that underlie this determination are well described in the excellent article by Fleming and DeMets.[17]

Choice of Study Population

An important consideration in planning a clinical trial is the choice of the inclusion and exclusion criteria that define the study population.[9] The impact of these enrollment criteria on the ability to recruit patients and the ability to generalize the results must be considered. As general principles, eligibility criteria should include patients for whom (a) the intervention is likely to have an effect, (b) there is a high likelihood of detecting the hypothesized effect, (c) the possibility of adverse effects or safety concerns do not outweigh the possible benefits, (d) competing risks are minimal, and (e) adherence is not likely to be a major issue. There are tradeoffs between using broad, less restrictive enrollment criteria versus narrow, more restrictive criteria. With broad criteria, the results will be generalizable to a broader population, there will be a larger pool of potential patients, enrollment will be easier, and protocol violations may be reduced. On the other hand, broader inclusion criteria will generally lead to enrollment of some lower risk patients, which will lead to a lower event rate, and therefore require a larger trial. With a more narrowly defined patient population, the study can be restricted to higher risk patients, leading to a higher event rate and a smaller size trial. The negative aspects of narrow criteria are that the study is less generalizable, there will be a smaller pool of eligible patients, enrollment is typically more complicated, and thus protocol violations may be increased.

Sample Size and Statistical Power

One of the most important aspects of designing a clinical trial is to determine the number of patients that must be enrolled to accomplish the objectives of the study. The all-too-frequently used nonscientific approach for making this determination is to (a) assess the amount of money available for performing the study, (b) determine the amount that each patient will cost, and then divide (a) by (b). The adequacy of the sample size has been a deficiency of clinical trials in the past. A review of the statistical power of 71 published randomized trials that failed to find significant differences between groups revealed that 67 of the trials had a >10% risk of missing a true 25% therapeutic improvement, and with the same risk, 50 of the trials could have missed a 50% improvement.[24]

In the context of sample size for clinical trials, the basic concepts of statistical power are briefly reviewed. The power of a study is the probability of a positive result (a statistically significant result) if the intervention under study has a real effect on the primary outcome of the trial. Thus power is the probability of a "true positive" study; of correctly detecting true differences. The level of power depends on the magnitude of the effect of the intervention, and on the number of patients enrolled (sample size). The power of a study equals 1 minus the type II error probability, where the type II error probability is the probability of failing to detect a real difference.

With that basic information as background, the preferred (scientific) approach for determining sample size in a clinical study is as follows:

- Develop an estimate of the outcome expected in the control arm. This could be an event rate if the endpoint is a clinical outcome or a mean ± standard deviation if the outcome is a continuous measure. Typically, such estimates will be based on pilot data, previous studies, or other sources of relevant information.
- Determine the treatment effect to be detected (the effect should be clinically important and realistic).
- Select the desired level of power (90% is preferable; 80% may be acceptable for some studies).
- Specify the desired level of significance (commonly the level used in clinical studies is $\alpha = 0.05$).
- Calculate the number of patients required.

Formulas exist in numerous textbooks for calculating the required number of patients for a binary endpoint, for a continuous endpoint measure, and for comparing groups with respect to time-to-event endpoints.[9,25,26] Commonly available statistical software packages (SAS and others) contain procedures for performing sample size calculations.

For trials with a continuous response, a key parameter that must be specified for sample size and power calculations is the variability of the response (outcome) variable, which is typically characterized in terms of the standard deviation. Greater variability in the outcome variable requires more patients to achieve the same level of power. A continuous outcome also requires specifying a clinically meaningful difference between the mean outcome response in the intervention and control arms that is desired to be able to statistically detect.

For trials with a binary endpoint, the sample size depends on the event rate estimated for the control arm, and the magnitude of the hypothesized benefit from the intervention. Low event rates require a larger sample size for detecting meaningful differences.

For trials with a time-to-event outcome variable, the power is driven by the number of events rather than the total number of enrolled patients. Therefore, the sample size must be selected so that the number of events will be adequate. The sample size calculations involve first determining the number of events needed to achieve the desired level of power, and then based on the projected event rates, the number of patients required can be calculated.[27]

A type of trial design that has been growing in popularity is what is termed as an "event-driven" trial, meaning that the study will continue until the required number of events has been achieved. If the event rate proves to be less than projected, the study must either enroll more patients or extend the duration

of follow-up. The advantage of such a design is that the study is assured of achieving the required number of events. The main disadvantage is that it is more difficult to plan the exact number of patients and the length of follow-up and hence to develop the overall study budget.

For studies with more complex designs or features such that the standard sample size formulas may not apply directly, computer simulation of the proposed design features can be used to perform sample size and power analysis. This would normally require the help of an experienced statistician.

Useful points to remember in determining an appropriate sample size:

- Appropriately account for a realistic amount of patient withdrawals from the study, premature discontinuation of the randomly assigned study treatment, crossover from one arm to another, or other noncompliance with the protocol.
- Avoid overly optimistic projections of event rates and treatment benefit.
- Remember that large studies are required to *reliably* detect moderate treatment effects.

Randomization

Although not specifically mentioned as part of the definition of a clinical trial, a critical component of a well-designed trial is the randomization of study participants to the intervention and control arms of the study.[9]

The unique feature and strength of randomization is that it controls, on average, for the effects of potentially confounding factors that are unknown or unmeasured as well as those that are known. It is this feature that makes the randomized trial such a powerful strategy, especially for studying small-to-moderate effects.

Three important contributions of randomization include (a) it eliminates bias in allocating subjects to the different arms of a study, (b) it ensures that there are no systematic differences between treatment groups with respect to *known and unknown* risk factors, and (c) it provides a valid basis for statistical inference.[28] This third advantage is somewhat more subtle, but means that randomization guarantees the validity of the statistical tests of significance that are used to compare the treatments. Simply stated, this means that the process of randomization makes it possible to ascribe a probability distribution to the difference in outcome between treatment groups receiving equally effective treatments and thus to assign "significance levels" to observed differences.[28] This is the basis of the *P*-values reported in randomized clinical trials or any other randomized experiment.

Stratified randomization is often used in clinical trials and simply means that a separate randomization is performed within prespecified strata, defined by selected patient characteristics such as a prognostic factor known to be strongly related to the outcome of interest.[9,13] Stratification by clinical center is often used in multicenter clinical trials to ensure that treatments are allocated in similar proportions at each center. Stratification may improve balance among treatments with respect to prognostic factors and emphasize subgroups (or strata) of special interest. Stratification by clinical site is usually desirable, but stratifying by more than one or two key other factors is unnecessary and undesirable.[29,30,31]

Blocked randomization, also called "permuted block randomization," is commonly used in clinical trials to avoid any major imbalance or deviation from the desired proportion of patients allocated to each arm. Blocked randomization guarantees that any deviation will never be large, and at certain points the numbers assigned to each group will reflect exactly the correct proportions.[9,13] Blocked randomization is especially desirable if the mix or level of risk of patients enrolled might change over time.

Consideration may be given in a clinical trial to equal versus unequal allocation of patients to the different arms of the trial.[13] There are several points to consider in this matter. Equal allocation will maximize the statistical power of the treatment comparisons for a given number of patients. Equal allocation is more consistent with equipoise (indifference) toward which group a patient is assigned. Unequal allocation (allocating more patients to the experimental intervention) (a) allows obtaining more information and experience with a new therapy with respect to side effects or toxicities, (b) could reduce cost if the comparator (control) therapy is expensive, (c) does not substantially decrease efficiency (i.e., decrease statistical power) as long as the proportions allocated to each treatment arm are not too different (e.g., not more extreme than three to one),[13] and (d) may have the effect of causing participants to think that one arm of the study is preferred or more desirable than other arms.

The term *adaptive randomization* may be encountered in the clinical trials literature. There are various schemes that have been proposed for adaptive randomization, for example, adapting the allocation ratio or making other adaptations during the course of the trial. These schemes are discussed extensively in the textbook by Pocock.[13]

For the practical implementation of a randomization scheme, a commonly used approach, particularly in phase III trials, is to employ a centralized interactive voice response system where a telephone call center can be used to verify patient eligibility and provide the treatment assignment. Internet-based systems for randomization are also growing in use. The older, simple approach of an envelope system is still used in some smaller studies, but is subject to misuse (either intentional or unintentional) such as prematurely opening the envelope containing the randomization assignment before eligibility is fully ascertained or informed consent has been obtained. Selecting envelopes out of sequence is also a potential limitation. Although it is inexpensive, this approach to randomization is generally discouraged.

One important point in planning and conducting a clinical trial is that it is critical that the treatment intervention begin as soon as possible after randomization in order to avoid bias that can arise from events occurring between randomization and initiation of the assigned therapy. Thus whenever possible, it is desirable to delay randomization until the last practicable time before initiation of therapy so that there is not a major delay between randomization and the start of therapy.

Summary principles regarding randomization: (a) blocked randomization is desirable, especially for large trials, (b) stratifying the randomization by center is desirable in a multicenter trial, (c) stratifying by multiple other factors is unnecessary and may simply add complexity, and (d) treatment should be initiated as soon as possible after randomization.

Blinding of Treatment Assignment

Ideally, the treatment assignment in a randomized trial should be unknown both to the patients enrolled in the study and to the medical professionals administering the treatment and following

the patients. This approach, known as double-blinding, is a well-accepted standard in trials where blinding is possible. This feature of trial design is important for avoiding potential biases that can arise during patient assessments and data collection.[9] However, not all studies can be done in a blinded fashion. Trials of surgical procedures or implanted devices or lifestyle changes generally cannot be blinded. In studies where double-blinding is not possible, a single-blind approach (only the caregiver but not the patient is aware of the treatment assignment) may be possible. If this is also not possible, then other measures such as use of a blinded core laboratory for performing key measurements or a blinded events committee to classify and adjudicate relevant clinical outcomes should be incorporated into the study design to reduce potential bias.

Noninferiority Trials

Noninferiority trials are designed to determine whether a new intervention is not worse than an accepted standard intervention by a prespecified amount.[32,33] The setting in which a noninferiority design is most often used is in evaluating a new therapy when an established standard treatment already exists. A new intervention may be very worthwhile if it is as effective as an established therapy (not inferior) and is either (a) easier to administer, (b) has fewer side effects, (c) costs less, or (d) has less negative impact on quality of life. Noninferiority trial designs are relatively common in the pharmaceutical industry where a company wishes to test a new drug therapy against another therapy that has been shown to work, is already in use, and may be considered to be the present "standard." Such comparative trials are often referred to as "active-control" trials or "positive-control" trials.[34,35]

A key element of a noninferiority trial is to specify a value Δ, referred to as the noninferiority "margin." The study is then designed to provide sufficient power to demonstrate with high confidence that the new therapy is not worse than the standard by more than Δ if this is indeed true. The statistical formulation for testing the hypothesis of noninferiority is an interesting reversal of the usual hypothesis testing situation in a trial where the objective is to test for superiority. To explain, the more usual formulation where a trial is designed to detect a difference (i.e., show superiority) is based on testing the null hypothesis of no difference, and assessing whether the data are consistent with that hypothesis or whether the data support a rejection of the null hypothesis. In contrast, with a noninferiority trial, the null hypothesis is that the new therapy is worse than the standard by more than Δ, and the study is designed to assess whether or not the data are consistent with that hypothesis. If this null hypothesis is rejected, the interpretation is that the new intervention is not inferior to the standard. A more intuitive and useful way to conceptualize this situation is that if the upper limit of the confidence interval (typically the 95% confidence interval) for the difference between the new intervention and the standard falls below Δ, then the new therapy can be considered noninferior to the standard. Examples of the various outcomes that can arise in such studies and their interpretation are illustrated in FIGURE 7.2.

There are several caveats to keep in mind with noninferiority trials. The choice of the margin Δ is critical and depends on both knowledge of the effect of the control therapy and good clinical judgment. The sample size is driven by Δ. With a relatively small value of Δ, the study will require a large sample size. On the other hand, if Δ is relatively large, the assessment of noninferiority is not sufficiently stringent, and demonstration that the difference is simply less than a moderately large Δ is not persuasive that the new therapy is noninferior. Again, the choice of Δ is critical, and some guidelines for that choice are discussed in the excellent papers by Temple and Ellenberg,[34,35] and in a new textbook on noninferiority trials.[32] It should be emphasized that well-designed noninferiority trials do not necessarily require a smaller number of patients than a well-designed superiority trial. Indeed, a noninferiority study that is not well planned and rigorous in its attention to sample size, compliance, and the other standards described in this chapter will be biased in favor of noninferiority. In that case, acceptance by the clinical and scientific community is unlikely.

Factorial Study Design

Although there are many different variations and types of study designs that are nicely summarized in Friedman et al.,[9] one in particular that deserves special mention is the factorial design.[9,36,37] In its simplest form, a factorial trial is designed to evaluate two interventions compared with a control in a single experiment. The design is most easily conceptualized in the form

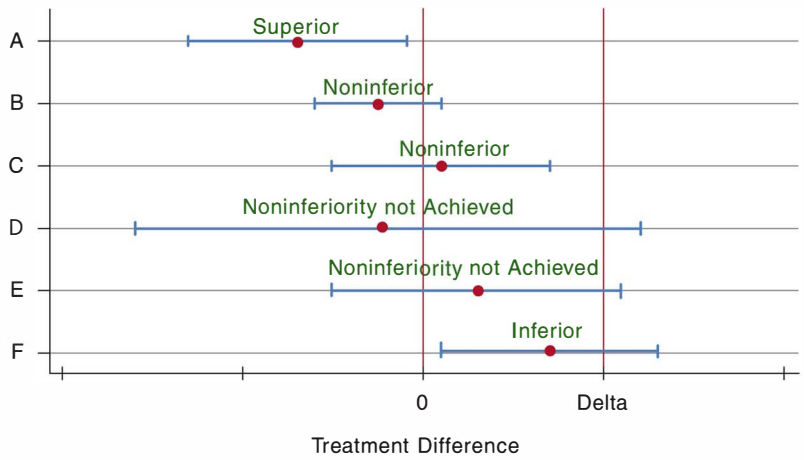

FIGURE 7.2 Illustration of the possible outcomes in a noninferiority clinical trial. The "dot" represents the observed outcome difference between a new intervention and the "standard" or comparator treatment, and the *lines* extending out from the "dot" represent the confidence interval for the true treatment difference. The *vertical line* labeled "delta" represents the noninferiority margin. For scenarios *A*, *B*, and *C* where the upper limit of the prespecified (e.g., 95%) confidence interval is less than delta, noninferiority has been achieved. In fact, for scenario *A*, the new intervention is superior to the "standard." For scenarios *D*, *E*, and *F* where the upper limit of the confidence interval extends beyond delta, noninferiority is not achieved. In scenario *F*, the new intervention is inferior to the "standard."

Study Effects of Two or More *Factors* at the Same Time.

	Drug A	Placebo
Drug B	N_{AB}	N_B
Placebo	N_A	N_O

Use All Patients in Analysis.

Effects of Drug A:

$$(N_A + N_{AB}) \text{ vs. } (N_O + N_B)$$

Effects of Drug B:

$$(N_B + N_{AB}) \text{ vs. } (N_O + N_A)$$

FIGURE 7.3 Illustration of a 2-by-2 factorial design where two different interventions (drugs in this example) are studied in a single trial. The numbers in each "cell" of the design represent the number of subjects allocated to that particular combination. N_A is the number of subjects who received drug A and the placebo for drug B, N_B is the number who received drug B and the placebo for drug A, N_{AB} is the number who received both drug A and drug B, and N_0 is the number who received the placebo for both drugs (i.e., received neither drug A nor drug B).

of a 2-by-2 table such as shown in FIGURE 7.3 and is thus referred to as a 2-by-2 factorial design. All patients are included in the analysis, and the effect of one intervention (drug A) is assessed by comparing the outcomes of all patients in the first column with the outcomes of all patients in the second column (FIGURE 7.3). The effect of the second intervention (drug B) is assessed by comparing the outcomes of all patients in the first row with all patients in the second row. Given the cost and effort in recruiting subjects and conducting clinical trials, the prospect of getting answers to two important questions (i.e., evaluating two interventions) in a single study is appealing. There are numerous examples of factorial designs, including the classic ISIS-2 study,[38] the Physicians' Health Study,[39] and the Women's Health Initiative.[40] The National Institutes of Health funded study of chelation therapy and high-dose vitamins is another example of a factorial design.[41] Some factorial studies are more complex than the 2-by-2 design, involving a third or even a fourth factor. It is also possible to leave some of the cells empty and have a partial or incomplete factorial design. Another variation of a factorial design is the large NIH-funded *Action to Control Cardiovascular Risk in Diabetes* trial, in which three different factors (intensive glycemic control, blood pressure control, and lipid control) were studied in a "double factorial design" in patients with type II diabetes.[42] All patients enrolled were in the glycemia trial, but within that structure, one 2-by-2 factorial trial addressed the blood pressure question and the other 2-by-2 factorial addressed the lipid question, hence the terminology "double factorial."[42]

As outlined in Friedman et al.,[9] the appeal of the factorial design might suggest that there really is a free lunch. However, every design has its strengths and weaknesses. A concern with the factorial design is the possibility of an interaction between the treatment factors and the impact of an interaction on the sample size requirements. In simple terms, the presence of an *interaction* in the 2-by-2 factorial example means that the effect of drug A differs depending on the presence or absence of drug B or *vice versa*. This is more likely to occur when the two interventions are expected to have related mechanisms of action.

If it is reasonable to assume that there is no interaction (which is the usual assumption in a factorial design), then with a modest increase in sample size, the two factors in a 2-by-2 factorial trial can be studied in a single trial—one that is considerably smaller than the sum of the patients that would be required for two independent trials to study the two different interventions individually. If an interaction between the two interventions is expected to exist, a factorial design is the way to rigorously make that assessment. However, since the power for statistically assessing an interaction is less than the power for assessing the "main effects" of each intervention, the sample size would need to be increased in order to provide adequate power for assessing the interaction.

Overall, the factorial design has some distinctive appeal. If there is little chance for an interaction between the treatment interventions or if it is important to determine whether there is an interaction, then such a design with the appropriate sample size can be very informative and efficient.

STATISTICAL ANALYSIS

We live today in the age of information and an era when the technical advances with computers and computer storage devices and sophisticated software make possible an astounding array of tools for processing, analyzing, displaying, and storing large amounts of data. The earlier emphasis in this chapter about avoiding bias in clinical trials applies also to the analysis of the data. Questions of what data should be collected, and how to collect that information, are important topics that are beyond the scope of this chapter. However, the development of case report forms and data collection methods and instruments deserves very careful consideration in the design and conduct of a clinical study. The amount of information and the number of measurements required to be collected on each patient in a study can have considerable impact on the quality and completeness of the information and the resources required to obtain the data.

Baseline Data

It is important for relevant baseline data (e.g., demographics, clinical history, risk factors, and presenting characteristics) to be collected in each study patient before the start of any intervention.[9] This information is important to describe the patients studied and (a) allow the scientific community to compare the study population with those of other studies, (b) allow clinicians to judge the applicability of the results to their specific patients, (c) allow an assessment of whether the study groups were comparable before the intervention was initiated, (d) allow the calculation of change scores (change from baseline to a follow-up measurement, if relevant), and (e) allow assessment of the prognostic importance of various baseline factors. In a randomized trial, ideally baseline measures should be collected prior to any knowledge of treatment assignment, but as close as possible to the time of randomization. In reporting the results of a clinical study, typically one of the first tables presented is a summary of the baseline characteristics.

Basic Analysis Issues

The distribution of continuous variables is often summarized in terms of the mean and standard deviation. These measures are most useful when the distribution of the variable is relatively symmetric (i.e., similar in shape to a symmetric, bell-shaped "normal" distribution). Often in practice, however, continuous variables may have a skewed (asymmetric) distribution, in which case the mean and standard deviation are less useful, because they are unduly influenced by extreme or outlier values. Useful descriptive statistics that are not subject to the influence of extreme values are the median (instead of the mean) and the lower and upper quartiles. The lower quartile is the 25th percentile, the median is the 50th percentile, and the upper quartile is the 75th percentile of a distribution. It is often useful to also report the full range of values, namely the smallest and largest values.

Categorical variables can be descriptively summarized by reporting the frequency and percent (the number and percent of patients) with the particular characteristic.

It is common in practice for the different arms of a study to be statistically compared with respect to the baseline characteristics of the study patients. However, if the study is a randomized clinical trial, calculating and reporting an array of *P*-values for comparing groups defined by randomization with respect to their baseline characteristics does not serve a useful purpose and is therefore unnecessary since such comparisons are not testing a useful hypothesis.[43] If there are any significant differences between groups, such differences are due to chance, since the groups are defined by randomization (unless, of course, something has gone wrong with the randomization). In observational studies where the study groups are not defined by randomization, it is wise to perform statistical comparisons of the baseline data in order to assess comparability and characterize differences between the groups.

Comparisons between two independent groups with respect to a continuous variable is commonly performed using the two-sample *t*-test.[44] It should be noted that this test is based on certain assumptions, namely that the variable has a normal distribution with similar variation in each group and that the observations are independent. Procedures that make such distributional assumptions are referred to as "parametric" tests. The independence assumption is typically satisfied as long as each data point comes from a different subject. However, as stated earlier, many clinical variables do not have a normal distribution. Although the *t*-test is fairly robust to departures from normality, there is a nonparametric analog to the *t*-test (and to numerous other parametric statistical procedures) that does not make any assumptions about the underlying distribution of the data. The nonparametric analog of the two-sample *t*-test is the Wilcoxon rank-sum test (also called the Mann-Whitney test).[45] The Wilcoxon test is almost as sensitive (powerful) as the *t*-test even when normality is satisfied, but importantly, it can be much more powerful otherwise. It represents an attractive alternative to the *t*-test.

Where there are more than two groups to be compared, the parametric generalization of the two-sample *t*-test is analysis of variance, and the nonparametric analog is referred to as Kruskal-Wallis nonparametric analysis of variance.[45] The comments above regarding the statistical power of parametric versus nonparametric procedures apply in this case also.

Comparisons between groups with respect to a categorical variable can appropriately be performed using the conventional chi-square test.[44] In the case where the frequencies in any category of the variable are small (e.g., ≤5), the use of Fisher's Exact Test[44] is recommended.

Analysis of Outcome Data

For group comparisons with respect to outcome data, the methods described above are also applicable. In the case of a binary outcome variable, it is desirable to provide additional descriptive measures of association between the treatment and outcome such as a relative risk or risk ratio. This is simply a ratio of the overall risk of the event in the intervention arm compared to that in the control arm. Another widely used measure to descriptively characterize the effect of an intervention on a binary outcome is the odds ratio, which is the ratio of the odds of the endpoint in the intervention group (the probability that the endpoint will occur divided by the probability that it will not occur) compared to the odds of the endpoint in the control group. An odds ratio of 1.0 indicates no difference between the treatment arms, an odds ratio <1 indicates a reduction of risk in favor of the intervention compared to the control arm, and an odds ratio >1 indicates a higher risk of the intervention compared to the control. A confidence interval can be calculated for the odds ratio (using, for example, the logistic regression model[46]). If the 95% confidence interval does not include 1.0, one can interpret the difference between the treatment arms with respect to the endpoint of interest as significant at the 0.05 level of significance.

If the course of a disease studied in a clinical trial is rapid (e.g., acute liver failure) or the period of follow-up is short (e.g., <30 days), a count of the number of events on each treatment (i.e., considering the endpoint as a binary outcome) is sufficient for analyzing the data. However, if there is considerable time from study entry until the outcome event occurs (as in a trial of a chronic disease) and patients are followed over an extended period of time, it is possible to achieve a more sensitive assessment of the value of each treatment by examining not only how many patients experienced the event of interest, but also how long after study entry the event occurred (i.e., by examining the pattern of when the events occurred).[30,31] Because this type of data is of such relevance, it deserves special discussion. The body of methods for analyzing such data is often referred to in textbooks as "Survival Analysis."[47–50] However, the methods are not restricted to studies where death (or survival) is the endpoint. The methods can be used for any endpoint where the time from enrollment to the time of the event, not just the fact of its occurrence, is an important consideration. These methods permit the comparison of groups with respect to their entire "survival" experience during the follow-up period.

A typical scenario for patient follow-up is shown in FIGURE 7.4. If a patient experiences an event during follow-up, the interval of time from entry into the trial until the event occurred is important. Some patients will experience the event of interest during the follow-up period and others will not. If a patient has not experienced an event prior to termination of the study, we refer to this individual's follow-up as being "censored" at the end of the trial, meaning the patient has not experienced an event, and all that is known for that patient is that their time

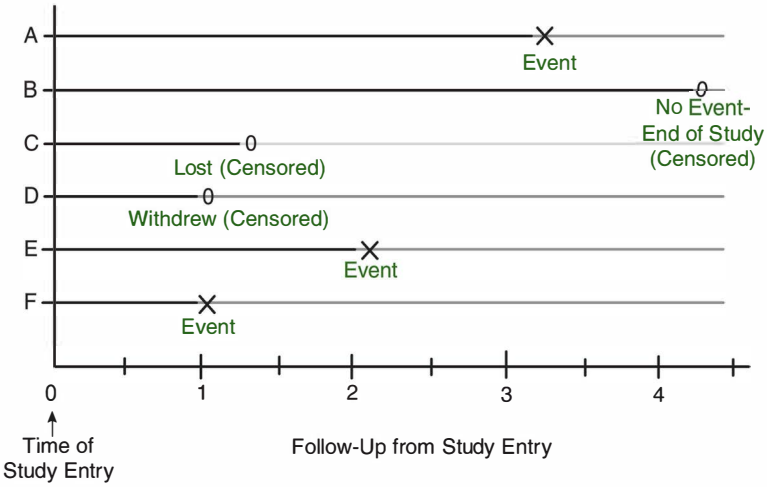

FIGURE 7.4 Typical patient follow-up scenarios in a study involving time-to-event data. Subjects *A*, *E*, and *F* all experienced the outcome of interest, but at different times during their follow-up. *B* is an example of a subject followed to the end of the study who remained event free throughout the follow-up period. *C* and *D* are examples of subjects whose follow-up was censored because they chose to withdraw from the study or became lost to further follow-up.

to an event (if it should occur in the future) is greater than their censoring time. A patient may also be censored if he or she withdraws from the study (refuses to continue to be followed) or if the patient is lost to follow-up (such losses should be kept to an absolute minimum in a well-conducted clinical trial).

With time-to-event data, a description of the results should include a calculation of event rates (or event-free rates) as a function of the length of time from study entry. These rates can be graphically presented in the form of a "survival curve" or "event rate curve" (FIGURE 7.5) and are commonly found in the clinical literature. The most common and popular approach for calculating event rates in the setting of a clinical trial and producing a "survival curve" is the method of Kaplan and Meier.[51] The calculations are straightforward, and software for performing the calculations is available in many commercial statistical software packages. The Kaplan-Meier curve is a step function, with a step at each time that an event occurs. Between adjacent event times, the curve remains constant. The Kaplan-Meier curve for each treatment arm in a clinical trial (or more generally for each defined group in a clinical study) can be viewed as an estimate of the true survival or event rate function for that group (see example in FIGURE 7.5). The precision of this estimate at any time point along the curve can be characterized with a standard error. The most popular formulation for calculating the standard error is known as Greenwood's formula.[50,52]

There are a number of statistical approaches for comparing two or more groups with respect to their pattern of "survival" (pattern of events), that is, for comparing two or more "survival curves." Several "Survival Analysis" textbooks that broadly cover the methods in this area are now available.[47–50] A popular and frequently used approach for assessing survival differences is the *log-rank* test,[49,50] also sometimes referred to as the Mantel-Haenszel

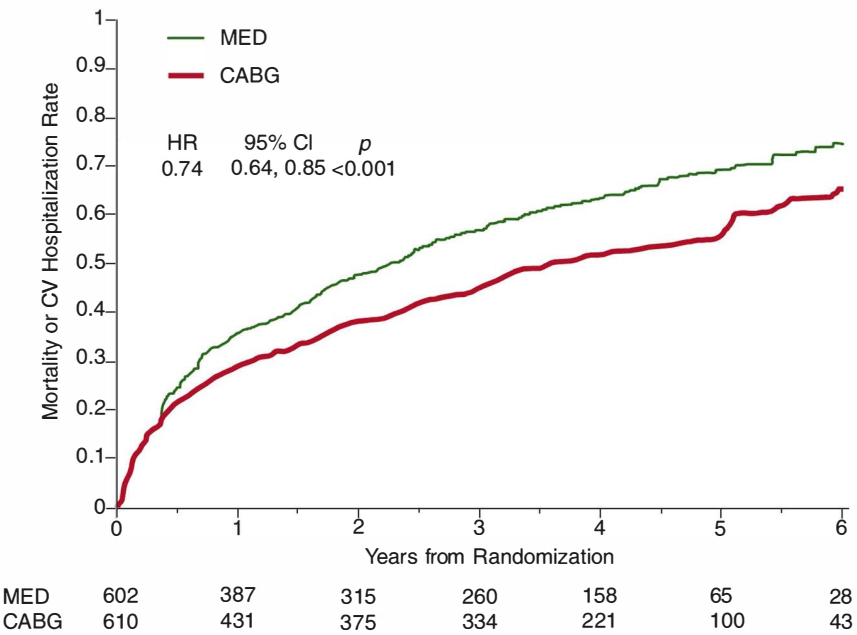

FIGURE 7.5 Illustration of Kaplan-Meier event curves from published results of the Surgical Treatment for Ischemic Heart Failure (STICH) trial comparing coronary artery bypass grafting (CABG) plus optimal medical therapy versus optimal medical therapy alone (MED) (Velazquez et al. *N Engl J Med* 2011;364:1607–1616). The endpoint is the composite of death or cardiovascular hospitalization. HR refers to the hazard ratio comparing CABG versus MED, with its associated 95% confidence interval (CI). The numbers at the bottom of the figure at annual time points are the number of patients in each treatment arm who are still in follow-up, are event free, and therefore remain at risk to experience the endpoint. Curves that depict event rates can easily be converted to event-free curves by simply subtracting the event rate at each time point from 1.0. (Velazquez et al. Coronary-artery bypass surgery in patients with left ventricular dysfunction. *N Engl J Med* 2011;364(17):1607–1616.)

test for survival data. Without providing all the mathematical details, this test simply involves (a) ranking the event and censoring times in ascending order for the study overall, (b) determining at each time point where one or more events occurred, the total number of participants in each treatment group who were at risk just before that time, and the number of events that occurred in each group at that time, (c) with this information forming a series of tables (2-by-2 tables in the case of a two-arm trial), one for each time at which an event occurs. The observed numbers of subjects in each arm who experienced an event and the numbers who did not experience an event comprise the cells of the table. The expected number of events for each arm (under the null hypothesis of no difference) can be calculated from the row and column totals for that group, the variance of the observed number can be calculated, and then the information from the individual tables is combined into an overall test statistic (a chi-square statistic with degrees of freedom equal to the number of treatment arms minus 1) for which a *P*-value and hence the degree of significance can be assessed. Log-rank statistics are seen frequently in the medical literature in connection with reports of major clinical trials.

For comparing treatment groups with respect to "survival" data, there are useful measures of association analogous to the odds ratio for a binary endpoint. In this case, the descriptive characterization of the treatment effect is given by a "hazard ratio," which can be viewed as a measure of relative risk. If the hazard ratio for the intervention arm compared to the control arm is 1.0, this implies that there is no difference in the survival pattern of the intervention group compared to control. A hazard ratio <1.0 is in the direction of some reduction in risk with the intervention arm, and a hazard ratio >1.0 is in the direction of excess risk in the intervention arm. Confidence intervals can be calculated for the hazard ratio (using for example the Cox regression model[53] [discussed later in the chapter]). If the 95% confidence interval does not include 1.0, one can interpret the difference between treatment arms as significant at the 0.05 level of significance. A single hazard ratio to characterize the overall treatment differences assumes that the hazard (risk) difference between the treatment arms is proportional over time. If this assumption is clearly violated, then different hazard ratios over different periods of the follow-up or other methods may be needed to adequately characterize the treatment differences.

"Intention-to-Treat" Analysis

A key question in the comparison of patient groups in a randomized clinical trial is which patients and which groups should be analyzed. The literature on this subject emphasizes that excluding randomized participants or observed outcomes from the analysis can lead to biased results. Analyzing clinical trial data according to the principle of "intention to treat" (ITT) has been strongly advocated in the clinical trials literature and is widely accepted by clinical trialists.[9,37] The ITT approach means that the primary comparison should include all subjects in the trial, with subjects analyzed and endpoints attributed to the treatment arms assigned by the randomization. This comparison is always of interest.

In some studies, it may be appropriate to compare the groups as randomized, but only include patients who actually receive the treatment, which in a drug study is typically defined as having received at least one dose of study drug. The rationale for this choice is that including only treated patients may provide a more sensitive appraisal of the treatment effects. However, this approach is only acceptable in a double-blind trial where knowledge of treatment assignment could not have influenced whether the patient actually received the treatment.

An "as treated" analysis may be performed, where groups are compared according to the treatment actually received. Sometimes in large trials, there are patients who either do not receive the randomly assigned treatment or incorrectly receive the treatment designated for a different arm. Such comparisons must be very cautiously interpreted, but may be useful for comparisons with respect to safety endpoints.

Finally, investigators may choose to do what is termed a "per protocol" analysis where only patients are included who fully satisfied all enrollment criteria and protocol requirements. Such comparisons must be interpreted cautiously. The full benefits of randomization are reduced or even lost when some patients are selectively excluded.

Subgroup Analysis

Regardless of the overall trial outcome, some subgroup analyses are typically performed. If the trial is positive, subgroup analysis may be undertaken to characterize patients who benefit most from the therapy versus those who may benefit less (or derive no benefit at all). If the overall trial is negative, investigators may undertake subgroup analysis in an attempt to identify at least some patients who appear to benefit from the intervention and thereby salvage something positive from the study. Some investigators feel that dividing a trial's results into smaller subgroups may offer clinicians insight into treating individual patients. However, the pitfalls of subgroup analysis have been clearly described by multiple authors in the clinical trials and medical literature.[9,15,31,38,54]

One pitfall that occurs in comparing treatments within selected subgroups in an overall positive trial is finding subgroups where the *P*-value for the treatment comparison within those subgroups does not achieve conventional significance and concluding that there is no treatment benefit for those patients. That is an improper interpretation. A study is never designed with sufficient patients in all major subgroups of interest to provide adequate statistical power for producing statistically significant treatment effects when treatments are compared within individual subgroups. Another pitfall is that the evaluation of multiple subgroups can lead to nominally significant results by chance alone. Even more complex to interpret are results where the subgroups are defined by post-randomization factors (referred to as improper subgroups).[54]

Cautious interpretation of subgroup analysis is clearly very important. It is more relevant to examine the direction of treatment differences and the general consistency of treatment effects across subgroups rather than focusing on the degree of significance in each subgroup. The process of assessing consistency can be aided quantitatively by testing whether interactions exist between the treatment and specific patient strata (i.e., whether there is statistical evidence that the relative benefit of a treatment varies across specific groups of patients). To the extent possible, subgroup analyses should be prespecified. Even then, it is wise to consider subgroup findings, particularly unexpected subgroup findings, as exploratory, subject to confirmation in another trial. Despite the attractiveness of subgroup analyses, the best estimate of the treatment effect to be expected from a qualifying patient treated outside the trial is still the overall estimate observed in the trial.[15,38]

Importance of Confidence Intervals in Interpreting Study Results

One of the important objectives of clinical trials or other clinical studies is to estimate the true effect of an intervention on important patient outcomes. There is often such a focus on *P*-values that the vitally important and valuable information in a confidence interval is sometimes overlooked. In fact, it could be argued that a confidence interval is more important than a *P*-value. In reality both are important. However, the confidence interval for the treatment effect provides valuable insight into the range of effects that are plausible based on the data. The narrower the confidence interval, the more certain we can be as to the true effect of the intervention. More studies should be designed with the objective of obtaining an estimate of the true treatment effect that is as precise as possible, rather than focusing solely on whether that effect meets the criterion for statistical significance. The case for greater use of confidence intervals in clinical trials was strongly advocated by Borenstein.[55]

Interim Analysis in Clinical Trials

The interim monitoring of safety data and often efficacy data has become a standard component in the design of major clinical trials, especially phase III trials designed to obtain regulatory approval of a new drug or device as well as many phase II studies. Such monitoring is typically performed by an independent Data and Safety Monitoring Board (DSMB) who may recommend early stopping of a clinical trial based on safety concerns, clear benefit, or other study-related information. Very cautious interpretation of interim analyses is required, and a body of statistical techniques has been developed involving various monitoring boundaries for judging statistical significance of treatment differences at interim time points.[56,57–60] Approaches have also been developed for judging "futility" (i.e., where there is a very low likelihood of obtaining a positive result if the study were to continue).[61–63] The important work of DSMBs and practical guidelines for their monitoring activity are well described in the clinical trials literature, including the excellent textbook on Data Monitoring Committees by Ellenberg et al.[64]

Number Needed to Treat

Another way of presenting the results of a clinical trial to patients, clinicians, the public, and policymakers is in terms of the number needed to treat (NNT). This quantity is the inverse of the absolute risk reduction and can be calculated with the formula $1/(p_c - p_E)$, where p_c is the rate of events in the control arm and p_E is the rate of events in the experimental intervention group. A confidence interval can be calculated for NNT using a straightforward formula.[65] The NNT, like the absolute risk reduction, provides an estimate of the absolute benefit of a therapy, in contrast to other commonly used measures of treatment effect such as an odds ratio and relative risk described previously. An example from Laupacis and Sackett[65] is illustrative of different ways of characterizing the results of a trial. Suppose patients with atrial fibrillation have a risk of stroke of 4.5% per year, which can be reduced to 1.4% per year with warfarin therapy. The relative risk reduction in this example is $(0.045 - 0.014)/0.045 = 0.69$. The absolute risk reduction is $(0.045 - 0.014) = 0.031$. The NNT is $1/0.031 = 32$. The results from this trial can thus be presented in a number of ways: (a) warfarin decreased the annual chance of having a stroke by 69%, (b) the absolute risk of stroke during 1 year is decreased by 3.1% with warfarin, and (c) 32 patients would need to be treated with warfarin for 1 year in order to avoid one additional stroke. The enthusiasm of patients, clinicians, and policymakers may be markedly affected by how the results are presented. Considering study results based on different summary measures provides a healthy perspective of the data and is helpful in developing an overall interpretation of a clinical trial.

MULTIVARIABLE ANALYSIS

In many clinical investigations, the questions of interest involve multiple variables (i.e., multiple factors or multiple measures) that are relevant to the investigation. Of considerable interest is how these factors interrelate and jointly influence the response (outcome) that is being studied. The traditional approach used in epidemiologic studies in the past has been to produce a cross-classification of the multiple factors and assess relationships with the outcome of interest by considering the individual "cells" created by this cross-classification and examining variations in the outcome across the spectrum of those cells. This approach quickly becomes impracticable as the number of variables to be investigated increases. For example, with five variables, each having two levels, the cross-classification of those variables produces thirty-two different cells. With 10 such variables, there are 1,024 cells. If the 10 variables each had three levels, this amounts to 59,049 cells. Without appropriate methods to deal with this type of data, it is impossible to identify and visualize meaningful relationships and patterns with this amount of data. Therefore, methods are required to facilitate the simultaneous assessment of the effects of multiple characteristics on the clinical outcome of interest. Fortunately, such methods do exist and are generally referred to as *multivariable analysis*, although the terms *multivariable statistical models* or *multivariable regression analysis* are also used frequently in this context.

The objective of multivariable analysis is to study the relationship between a single response or outcome variable (typically designated by the letter Y) and a set of multiple explanatory factors or characteristics (designated by $X_1, X_2, \ldots, X_p$). Y could be a continuous response variable (e.g., the change in a hematologic variable or cell count following a particular intervention), and the X variables could be factors such as age, sex, race, blood pressure, a treatment factor, and other variables of interest. The outcome variable Y could also be a discrete variable, such as the development of a thrombotic complication (yes or no), and again the X variables could be demographics or other clinical or treatment characteristics of importance. Y could also be length of patient survival or length of survival free from clinical events such as stroke or myocardial infarction. Such data could arise in either a clinical trial or an observational study. Again the X variables could be a treatment of interest and other demographic or clinical factors that may have an important prognostic relationship with the outcome.

The basic approach to this type of analysis is to study relationships using a model of the form

$$Y = F(X_1, X_2, \ldots, X_p) + \varepsilon$$

where $F(.)$ is a mathematical function, and the quantity ε designates an error term, since no model will perfectly fit all of

the data points. Sometimes the model may need to be slightly more complicated and take the form

$$G(Y) = F(X_1, X_2, \ldots, X_p) + \varepsilon$$

where G and F are different mathematical functions. The X variables are referred to as independent variables or predictor variables or explanatory variables, and Y is referred to as the dependent variable or response variable or outcome variable.

Linear Regression Analysis (Continuous Outcome Variable)

The most basic and simplest type of regression model is one in which Y is a continuous response, and there is a single predictor variable X. This model is referred to as *simple linear regression*. The model is expressed as $Y = \beta_0 + \beta_1 X + \varepsilon$, with parameters β_0 (which can be interpreted as an intercept) and β_1 (interpreted as a slope) which must be estimated from the data. If β_1 is positive, the value of Y tends to increase with increasing values of X. If β_1 is negative, the value of Y tends to decrease with increasing values of X. The most common approach for estimating β_0 and β_1 is the method of "least squares."[66] In this simple case, β_1 is a scaled version of the usual linear correlation coefficient. Once the parameters are estimated, the resulting regression line can be used to estimate the average value of Y corresponding to each value of the independent variable X. Thus, for two variables (Y and a single X variable), which could be visually conceptualized as a scatter plot, the regression line serves the role that an average does for a single variable. That is, the regression line is an estimate of the average value of Y for each value of X.

When there is more than one predictor variable (more than one X variable), the model generalizes to

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p + \varepsilon$$

where again Y is a continuous response, and the X's may be either continuous (such as age or blood pressure), discrete (such as race), or dichotomous (such as gender or whether a particular treatment was administered). The parameters β_1, β_2, …, β_p are regression coefficients that must be estimated (computed) from the data. As in the case of a single X variable, the parameter estimates are typically obtained using the method of "least squares." The parameter β_i can be interpreted as the amount by which Y changes (on average) when X_i changes by one unit and all other X's remain constant. As a simple example, suppose we postulated the model $Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon$, where Y represents systolic blood pressure (SBP), X_1 represents AGE (a continuous variable), and X_2 represents whether or not the subject is a current smoker (SMK) (a dichotomous variable). Suppose the fitted model is SBP = 48.1 + 1.7AGE + 10.3SMK. Interpreted, this means that SBP increases by 1.7 mm Hg (on average) when age increases by 1 year (and smoking status remains constant), and also SBP is increased by 10.3 mm Hg for smokers compared to nonsmokers (when age remains constant). This simple model thus enables an assessment of the relationship of age with blood pressure, controlling for smoking status, and also the relationship of smoking status with blood pressure, controlling for age.

Relationships are assessed with these types of models by testing hypotheses about the regression coefficients. The basic idea is that if a predictor variable has little or no association with the response variable, its regression coefficient will be zero, or at least near zero. Thus, hypothesis tests of whether the regression coefficients are significantly different from zero are helpful in interpreting the statistical significance of these multivariable relationships.[67]

Logistic Regression (Binary Endpoint)

Frequently in medical research, the response variable Y is a binary outcome (e.g., presence or absence of a particular disease, development of a thrombotic complication [or not], alive or dead following an acute procedure, etc.), and the questions of interest involve how a set of predictor variables may relate to whether study subjects experience the outcome of interest. Such a binary response variable is typically coded as 0 or 1, where 1 indicates that the event of interest occurred and 0 indicates that the event did not occur. The regression model commonly used in this situation is referred to as logistic multiple regression, or simply the logistic regression model. The formulation of the model is expressed in terms of the probability that the event will occur, that is, the probability that $Y = 1$. Denoting this probability by the notation $P = Pr[Y = 1]$, the logistic model can be expressed as

$$P = Pr[Y = 1] = 1/\exp[-(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p)].^{46,68,69}$$

The model is also often expressed in terms of the log odds of the event that $Y = 1$, namely $\log(P/(1-P))$, which is also referred to as the logit of P. In this form, the model can be expressed as

$$\text{logit}(P) = \log_e(P/(1-P)) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p$$

where $\log_e$ refers to the natural logarithm. In this form, the model more closely resembles the classical multiple regression model for a continuous response variable.

The logistic model was popularized in the 1960s as a result of work by the statistician, Jerome Cornfield[70] in analyzing Framingham data and examining the relationships of various risk factors with the development of coronary heart disease. Cornfield used a different approach for estimating the regression coefficients than the "maximum likelihood" approach that is commonly used today.[68]

The interpretation of the regression coefficients in the logistic model is similar to ordinary multiple linear regression, except in terms of the log odds of the outcome event. The coefficient β_i is the amount by which the logit of risk (the log odds) changes when X_i changes by one unit and all other X's remain constant. A positive coefficient β_i means that the risk (or the likelihood) that $Y = 1$ (i.e., that the event will occur) increases with increasing values of X_i, whereas a negative coefficient means that the risk decreases with increasing values of X_i. As in conventional multiple linear regression (where Y is a continuous variable), relationships of various predictor variables with a binary outcome can be assessed with the logistic model through hypothesis testing of the regression coefficients.

The formulation of the logistic model lends itself nicely to calculating odds ratios and their associated confidence intervals to enhance the descriptive summarization of the relationships. For example, if the variable X_i is an indicator for treatment, that is, $X_i = 1$ for subjects who received a particular treatment and $X_i = 0$ for subjects in the control arm, then $\exp[\beta_i]$ is the odds ratio for comparing the treatment arm to the control arm, controlling

for all other variables in the model, where exp[.] represents the exponential function.[46]

Cox Proportional Hazards Regression Model (Time-to-Event Outcome)

The final multivariable model discussed in this section is one that was developed specifically for the analysis of "time-to-event" or "survival" data. The most widely used model for this type of data is the Cox proportional hazards model.[53] The Cox model, like the Kaplan-Meier method and the log-rank test described earlier, takes into account the overall structure of survival curves and accommodates varying lengths of patient follow-up and censored observations. It uses information on the time from study entry to the event of interest (the order in which the events occur) rather than simply enumerating the number of events. With this model, relationships can be studied between a "time-to-event" outcome variable and multiple patient baseline characteristics, which may be either continuous or discrete variables. A mathematical expression for the model is given by the equation

$$\log_e(\lambda(t)/\lambda_0(t)) = \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_p X_p$$

where $\lambda(t)$ is the hazard function at time t, $\lambda_0(t)$ is an arbitrary (unspecified) underlying hazard function, $X_1, X_2, \ldots X_p$ are patient characteristics, and $\beta_1, \beta_2, \ldots \beta_p$ are regression coefficients estimated from the data. The hazard function is similar to an event rate (e.g., death rate). Mathematically, it is the probability that a subject will have an event within an arbitrarily small interval of time $(t, t + \Delta t)$ given that the subject is event free prior to time t. An assumption of the Cox model is that the hazard functions for any two subjects are proportional over time. The regression coefficients are estimated by forming a (partial) likelihood function developed from the expression above, and then maximizing that likelihood function. To assess whether a particular characteristic is a significant independent predictor of "survival," a test of significance is performed on the corresponding regression coefficient to determine if it is significantly different from zero.[48,53]

The formulation of the Cox model nicely lends itself to calculating hazard ratios and their associated confidence intervals to enhance the descriptive summarization of the relationships. For example, if the variable X_i in the Cox model is an indicator for treatment, and $X_i = 1$ for subjects who received a particular treatment and $X_i = 0$ for subjects who did not, then $\exp[\beta_i]$ is the hazard ratio for subjects receiving the treatment compared to those who did not, controlling for all other variables in the model. Again, exp[.] represents the exponential function. The hazard ratio is often used as a measure of relative risk in comparing two different treatment groups in a clinical study. Confidence intervals for the hazard ratio can also be readily calculated with the Cox model. The log-rank test mentioned in an earlier section is a special case of treatment comparisons that can be performed within the framework of the Cox model.[48,50,53]

A final point about the various different models and approaches to multivariable analysis is the need to carefully check the assumptions of these models, including the linearity and additivity of the relationships.[71] Methods for assessing the fit of these models in a particular dataset, along with helpful examples, can be found in currently available textbooks.[47,50,72,73,74] The excellent book by Harrell[74] is especially noteworthy in its presentation of state-of-the-art regression modeling strategies for the analysis of medical data. A useful expository discussion of the Cox model with examples is provided in the paper titled "A Plain Man's Guide to the Proportional Hazards Function."[75]

META-ANALYSIS OF MULTIPLE STUDIES

Often referred to as a systematic overview, meta-analysis is a formal process for summarizing and combining data from multiple studies in a single analysis.[76] The objectives are to (a) compile and compare all of the available evidence for a particular treatment or treatment class, (b) obtain a more precise estimate of the true treatment effect, (c) strengthen the power to judge small but clinically important treatment effects, (d) assess the homogeneity of effects across multiple studies, (e) address questions of treatment effect in specific subgroups that may not be possible in a single trial, and (f) evaluate the generalizability of the results across trials, populations, and specific interventions.

There are important steps in a meta-analysis just as there are important steps in designing and analyzing a single clinical trial. Key among those steps is to prespecify the process for identifying the studies that will be included, abstracting the data from those studies, and then analyzing the data. Much has been written about meta-analysis, including textbooks on the subject that outline the requirements for a rigorous meta-analysis.[76–78] As far as the analytic methods are concerned, two contrasting approaches have been used, namely combining study results using so-called "fixed effects" models and alternatively using "random effects" models.[76] Fixed effects models assume that every study included in the analysis has estimated exactly the same parameters, and various approaches have been proposed for combining this information across the different studies. In contrast, random effects models allow for random variation in the effects between studies, and again various approaches have been developed for combining the information across studies. Some statisticians prefer the fixed effects approach while others prefer the random effects approach. Often in practice, the two approaches will lead to a similar interpretation of the data.

CONCLUDING SUMMARY

In this chapter, we have introduced concepts and methods that constitute the important *basic science* of clinical research. There are many aspects of planning and conducting a well-designed clinical research study that require careful consideration of the concepts and methods that have been presented. The remarkable advances of computer technology in recent years and the availability of a broad array of well-developed commercial software packages for performing statistical analyses make it possible to apply the methods outlined in this chapter with relative ease. This does not mean, however, that sound clinical research and the appropriate application of state-of-the-art biostatistical methods have simply become "push-button research" where computer software can easily perform a set of calculations, but little thought given to the appropriateness of the computer-generated results. Medical researchers today can shift their focus from concerns about computation to strengthening their understanding of appropriate methods for study design and statistical analysis and how to properly interpret the data resulting from their research. Readers of medical journals, now more

than ever, need to understand these methods in order to critically evaluate studies that deal with important issues regarding the natural history of disease, new treatments for a specific disease, and the public health benefit of implementing new treatment innovations.

There are additional details of the methods covered in this chapter that could not all be addressed due to space limitations. There are also other specialized methods (such as the analysis of longitudinal data) that were not covered. However, references are provided to a number of textbooks that provide greater depth of the methods that are covered and information on other topics. In addition, it would be of great value to serious researchers to establish a collaborative and collegial relationship with an experienced statistician.

We conclude by emphasizing that although some useful information can be derived from observational epidemiologic studies, a key take-home message from this chapter is that randomized clinical trials of adequate size that are carefully designed, conducted, and analyzed provide the strongest and most direct evidence on which to make a judgment about a cause-and-effect relationship. It is the evidence derived from randomized clinical trials that will have the greatest impact in our understanding of the effects of innovations in hemostasis and thrombosis as well as in many other areas of medicine.

PART II

Basic Principles of Hemostasis and Thrombosis

CHAPTER 8

Overview of Basic Coagulation and Fibrinolysis

GILBERT C. WHITE, II, VICTOR J. MARDER, SAM SCHULMAN, WILLIAM C. AIRD, AND JOEL S. BENNETT

The development of a fibrin clot occurs after a series of enzymatic reactions that lead to the generation of thrombin. These reactions were originally described as an enzyme cascade[1] or waterfall,[2] a model that remains conceptually useful today (see FIGURE 8.1A). Notions of this process have evolved over the past 45 years as proteins have been purified, their function characterized, and additional factors identified. For example, factors VIII and V, which were originally depicted as enzymes in the waterfall and cascade hypotheses, were identified as nonenzymatic proteins that function as catalysts to increase the rate of activation of factor X and prothrombin, respectively. More importantly for the clinician, the idea evolved that clotting was initiated by either contact activation via a so-called *intrinsic pathway* (termed because all of the components were contained in blood) or activation by tissue factor via an *extrinsic pathway* (termed because the initiator, tissue factor, was considered extrinsic to blood). This separation into two pathways, measured by different *in vitro* clotting assays, was useful for the diagnosis of bleeding disorders and helped tie the biology closer with diagnostic testing (FIGURE 8.1B).

Over the past decade or two, concepts regarding the initiation of coagulation have continued to develop, leading to further evolution of the models for coagulation. Tissue factor and factor VIIa are now considered to be the major initiators of coagulation *in vivo*,[3,4,5] not the contact activation system, which is thought to be a key link between coagulation and inflammation. Accordingly, humoral blood coagulation is believed to initiate *in vivo* through a cell-based system (FIGURE 8.1C) that occurs when tissue factor, a membrane-associated lipoprotein that is present in most cells, is released upon cell damage or is secreted by cells such as monocytes and platelets.[6,7,8] Tissue factor forms a complex with and activates factor VII, which in turns activates factor X leading to the generation of small amounts of thrombin. This is called the "initiation phase" of coagulation. The next phase is an "amplification phase" in which the thrombin that is generated is then able to activate factor IX which activates more factor X, leading to more thrombin. The various proteins involved in coagulation, their genes, their function, and their enzymology are described in the chapters that comprise this section of the text. In this introduction, we highlight some of the features of the coagulation process. The reader is also referred to Chapters 3, 4, and 5 in the initial section of the text for background reading.

EVOLUTION OF COAGULATION PROTEINS

Just as this text is written at a point in time, the coagulation system as we describe it in this book is at a point in time. The human coagulation system has evolved over hundreds of millions of years to become the complex system it is today.[9] In lower-order organisms, thrombosis was not an issue—hemostasis was key; breeches in the vascular system had to be plugged as quickly as possible or exsanguination occurred. As reviewed in Chapter 2 of this text, the first coagulation systems were very simple, consisting of a fibrinogen, a thrombin molecule, and an activator. As organisms grew in complexity, the coagulation system evolved through domain duplication and insertion and through protein duplication. Factor VIII is a good example, a protein that has evolved over the past 450 million years to become what it is today (see FIGURE 8.2). Factor VIII is composed of three A domain repeats, a B domain, and two C domain repeats. The A domains are involved in protein–protein interactions, the B domain is removed during activation and may play a role in protein synthesis, and the C domains are involved in phospholipid binding. The A domains have their origin in blue-green algae. Over millennia, the A domain in algae duplicated and then triplicated, each A domain repeat evolving independently, to eventually form a ceruloplasmin precursor protein containing three A domain repeats, each with about 30% identity to each other. At the same time, a primordial C domain that was present in *dictyostelium* duplicated, and each C domain evolved independently. Somewhere in evolution, the ceruloplasmin precursor protein with its triplicated A domains and the duplicated C domains came together to form an A3-C2 precursor protein. Different evolutionarily unrelated B domains were inserted into the A3-C2 protein in the same position, between the A2 and the A3 domains, one B domain for factor VIII, and one B domain for factor V. The FVIII protein evolved to interact very specifically with factors IX and X in the factor X activation or "tenase" complex. The FV protein evolved to interact very specifically with factors X and II in the prothrombin-activating or "prothrombinase" complex. Presumably, these coagulation factors continue to evolve. The structure and even the function of factors VIII and V hundreds of thousands of years in the future is unknown, but evolutionary pressure will drive the process!

In a similar manner, factors VII, IX, X, and protein C, the vitamin K–dependent coagulation factors, characterized now by their serine-histidine-aspartic acid charge relay catalytic domain, the duplicated epidermal growth factor domains which are involved in protein–protein interactions, and the membrane-binding, amino-terminal γ-carboxyglutamic acid-containing domain, evolved through domain duplication and structural evolution. Prothrombin differs from the other vitamin K–dependent proteins by having two kringle domains in place of the EGF (epidermal growth factor) domains; protein Z differs by lacking the histidine and serine residues necessary

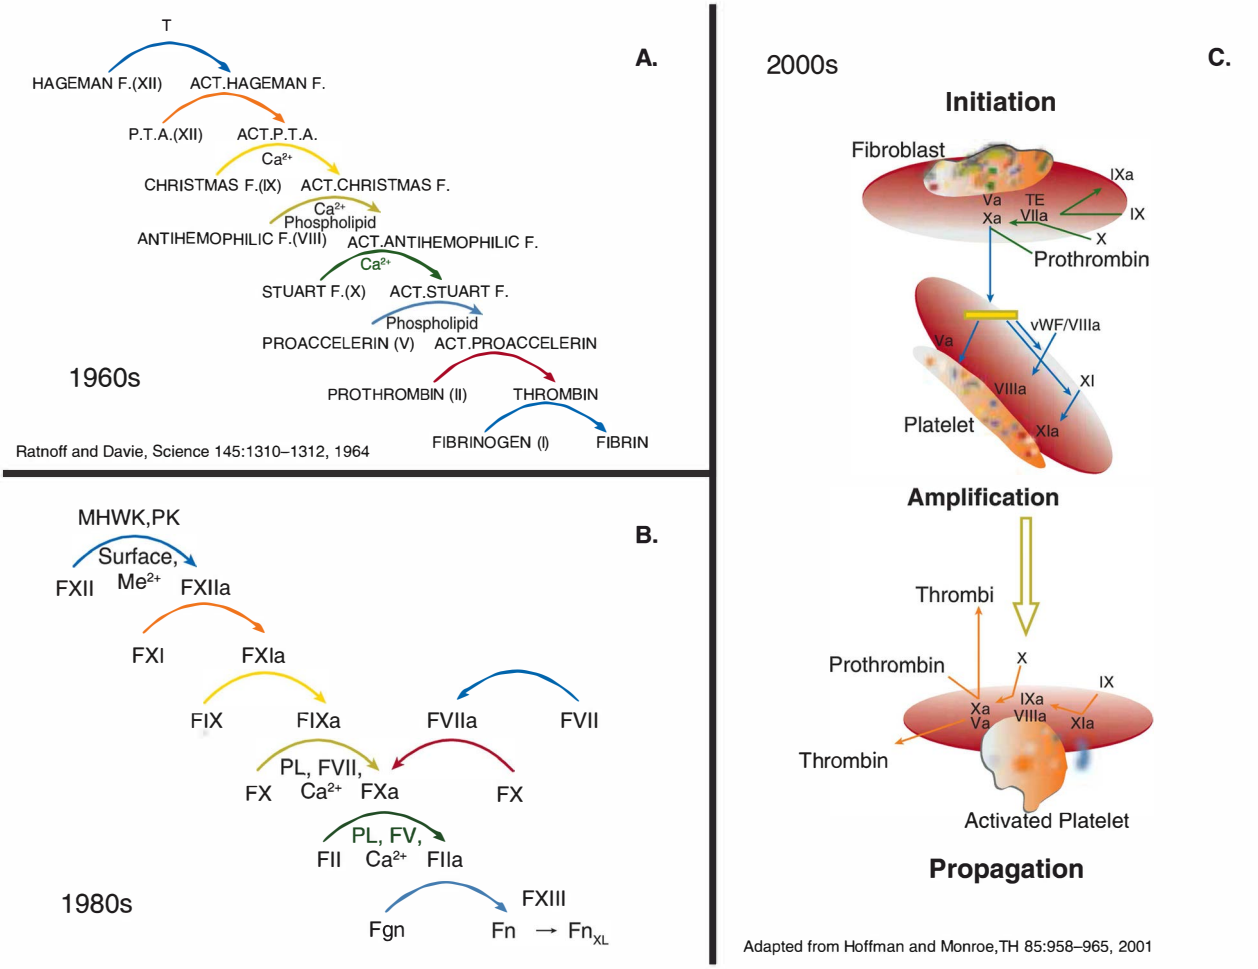

FIGURE 8.1 The human coagulation cascade through the years. **A:** The original coagulation cascade or waterfall postulated by MacFarlane[1] and by Ratnoff and Davie.[2] The development of a fibrin clot is seen as a series of sequential enzymatic reactions, starting with factor XII and ending with the conversion of fibrinogen to fibrin. **B:** Modified coagulation cascade used in the 1970s through the 1990s. This modified cascade began to separate the coagulation process into an intrinsic and extrinsic system, each assessed separately by a PT and a PTT. It also reflected the understanding that factors VIII and V were enzymatic cofactors not proteolytically active enzymes. **C:** Current concepts of coagulation, which indicate the cell-based nature of coagulation.

for catalysis in the catalytic domain. Because some of these genes are on separate chromosomes, there is speculation[9] that the duplication of the vitamin K–dependent factors came about through two rounds of total genome duplication that occurred in early vertebrate evolution some 500 million years ago.[10] Each vitamin K–dependent protein now plays a unique role in the coagulation process. Their evolution as separate clotting factors with separate functions adds to the complexity of the system, its control, and its specificity.

COAGULATION TESTING

Early on, clotting assays that were sensitive to components of the coagulation system were developed and were used to define the enzymatic pathways leading to clot formation. The two most important of these, the prothrombin time (PT) developed by Quick[11] and the partial thromboplastin time (PTT) developed by Langdell et al.[12] and later modified by Rapaport,[13] continue to be used by coagulation laboratories throughout the world, The PT measures the factors in the extrinsic pathway (FIGURE 8.1B) and is sensitive to plasma levels of factors VII, X, V, prothrombin, and fibrinogen. The PTT, which measures the intrinsic pathway (FIGURE 8.1B), is sensitive to plasma levels of the contact factors, factors IX, VIII, X, V, prothrombin, and fibrinogen. The factors common to both pathways, factors X, V, prothrombin, and fibrinogen, constitute what is called the final common pathway. It is important to emphasize that this arbitrary division into extrinsic, intrinsic, and final common pathways does not represent what occurs *in vivo* and is used simply to understand and interpret the clotting assays that are used to measure coagulation (see Chapter 50). These divisions into arbitrary pathways also do not reflect important connections that exist between the various pathways. An example is the ability of tissue factor–factor VIIa complex to activate both factor

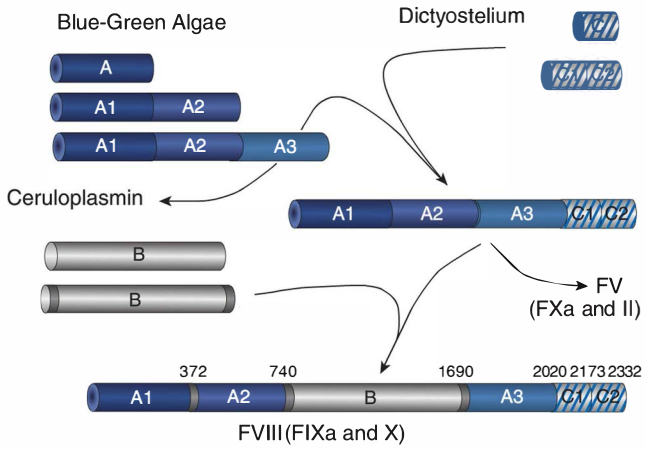

FIGURE 8.2 Evolutionary aspects of coagulation. The figure shows the evolution of coagulation factors V and VIII over an estimated 450 million years. Modern factor VIII, at the bottom, (and V, not shown) consist of triplicated A domain repeats and duplicated C domain repeats with divergent B domains interposed between the A2 and A3 domains. The A domains are derived from sequences in blue-green algae which duplicated and then triplicated. The C domains are derived from *Dictyostelium* and duplicated over time. The insertion of the B domain into factor VIII is a relatively recent event. Factor VIII has evolved (and continues to evolve) to be a cofactor in the activation of factor X by factor IXa, while factor V has evolved to be a cofactor in the activation of prothrombin by factor Xa. In similar manner, the vitamin K–dependent coagulation factors have evolved through domain building and sequence divergence. Indeed, not only have individual proteins developed by domain duplication and divergence, but the whole coagulation cascade has evolved through protein duplication and divergence. (copyright G. C. White).

IX in the intrinsic pathway as well as factor X in the common pathway. Nevertheless, the tests are useful in screening for various deficiencies in the coagulation system and as a basis for assays for the functional measurement of clotting factor activities. Tests that measure fibrinolytic activity are also available. The euglobulin clot lysis time is sensitive to proteins leading to and regulating clot lysis.

THE ROLE OF SURFACES IN COAGULATION

Functionally, the relationship between clotting and surfaces is striking.[14,15,16,17] For a process that is typically termed humoral, most of the coagulation reactions take place on biologic surfaces (see FIGURE 8.3). For example, the assembly of the prothrombinase complex, where factors Xa and thrombin-activated factor V form a complex with prothrombin, occurs on acidic phospholipids on the surface of cells. The presence of a phospholipid surface increases the rate of activation of prothrombin by several orders of magnitude (see Chapter 4). It also localizes the reaction to the site of injury and may protect the reaction from inhibitors. Likewise, the assembly of the tenase complex, where factors IXa and thrombin-activated factor VIII form a complex with factor X, occurs on acidic phospholipids. These reactions on acidic phospholipids are mediated in part by γ-carboxyglutamic acid (Gla) residues present in the amino-terminal Gla domain of the vitamin K–dependent coagulation factors.[18,19] The γ-carboxylation of glutamic acid occurs posttranslationally and confers an extra negative charge on glutamic acid that is thought to mediate calcium binding, which in turn induces a change in conformation that enables the protein to interact with acidic phospholipids on cellular surfaces.[20,21] FIGURE 8.4 shows the insertion of a Gla domain into a phospholipid surface.[21] The activation of protein C by thrombin is another reaction that occurs on a cellular surface, in this case the surface of the endothelial cell, by virtue of thrombomodulin, an endothelial-specific integral membrane protein that functions as a cofactor in the reaction, along with protein S.[22,23,24] Both protein C and protein S are vitamin K–dependent and thus interact with the membrane in the same way as factors II, VII, IX, and X. Activated protein C (APC) can thereafter interact with the endothelial protein C receptor (EPCR) to mediate the cellular effects of APC, another reaction that occurs on the cell surface by virtue of the membrane integration of EPCR.[25,26] The contact activation complex in which prekallikrein and high molecular weight kininogen form a complex with factor XII is also assembled on a surface, in this case, negatively charged surfaces like glass and kaolin, materials used to initiate coagulation *in vitro* via the intrinsic pathway.[27–30] *In vivo*, these negatively charged surfaces might be bacteria or other inflammatory generated surfaces. Thus, the assembly of cofactor, enzyme, and substrate on surfaces is a recurring theme in blood coagulation, resulting in optimal efficiency and rate of the molecular reactions, especially as a phospholipid or cell membrane provides the surface for efficient positioning of interacting enzyme complexes with proenzyme substrates.

Coagulation inhibitors such as antithrombin and heparin cofactor II are also more efficient when the reactions occur on surfaces (see Chapter 18). The typical surface in these reactions is glycosaminoglycans like heparin, heparan sulfate, and dermatan sulfate.[31,32] At least in part, heparin and the other glycosaminoglycans act as a template for the formation of a ternary complex that brings antithrombin together with its target protease, facilitating the interaction of the two reactants and thereby increasing the rate of this interaction by up to several 1,000-fold through a combination of bridging mechanisms and heparin-dependent conformational changes. A unique sequence-specific pentasaccharide in the heparin molecule contains the binding sites for both antithrombin and protease.[33] Heparin cofactor II is another serpin (serine protease inhibitor) that selectively inactivates thrombin (not factor Xa) in the presence of a heparin or dermatan sulfate template.[34] Finally, fibrin itself is an important coagulant surface. Once thrombin is bound to fibrin, it is resistant to antithrombin and even more so to antithrombin–heparin complexes.[35–37]

AMPLIFICATION AND REGULATION OF COAGULATION

An important feature of the coagulation system is the presence of amplification and regulatory influences. These are key to getting the coagulation reaction started, generating the large burst of thrombin that is needed to form a stable clot but also turning the process off so that excessive clotting does not occur. Thus, the initial formation of tissue factor–VIIa complexes can generate small amounts of thrombin that, in turn, can feed back to activate factors XI, IX, and X, as well as factors V and VIII

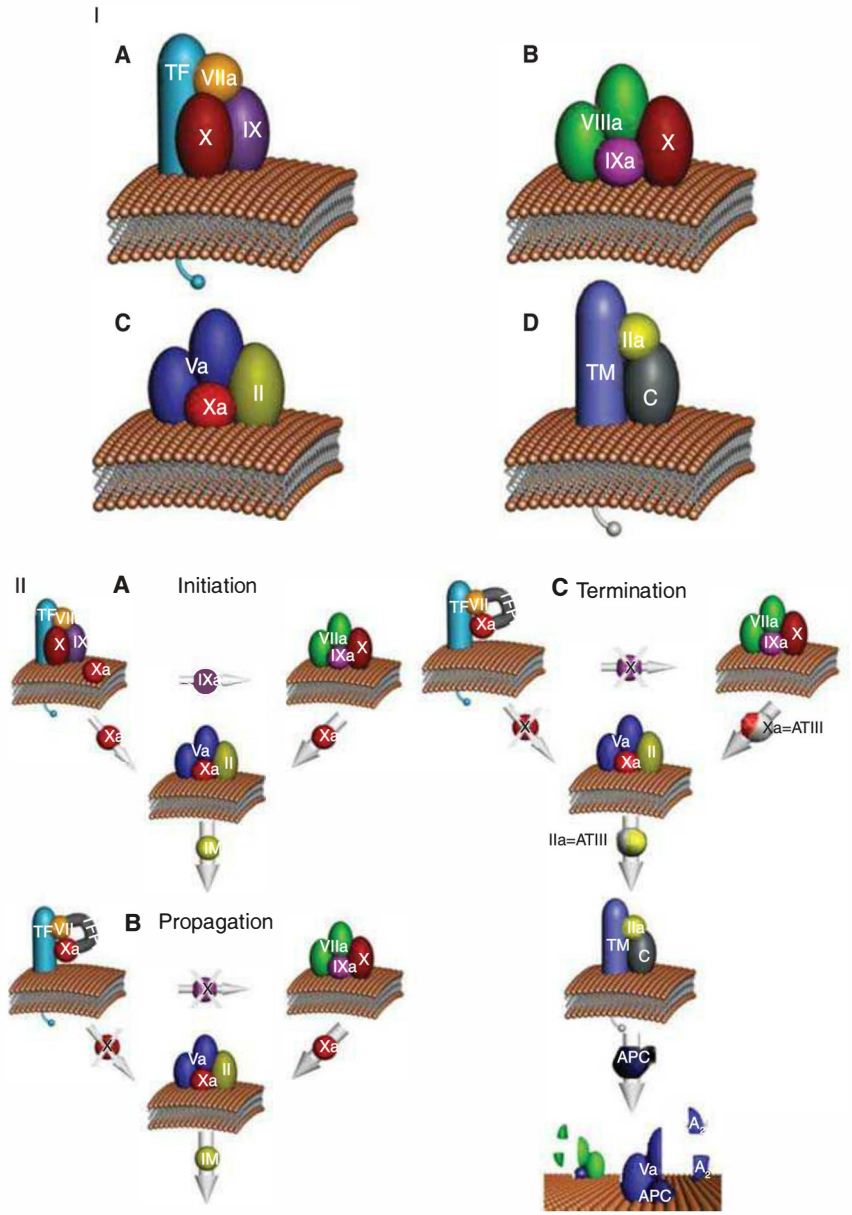

FIGURE 8.3 Surface reactions in coagulation. Coagulation reactions occur on surfaces that localize the factors and bring them together. **Part I: A:** The *tissue factor–factor VIIa complex* composed of tissue factor, which is an integral membrane protein; factor VIIa, which interacts with acidic phospholipids through its γ-carboxyglutamic acid (Gla) domain; and factors IX and X, which interact with acidic phospholipids through their Gla domains; **B:** The *tenase complex* composed of factor IXa, which interacts with acidic phospholipid surfaces through its Gla domain; factor VIII, which interacts with phospholipids through the C2 domain; and factor X, which interacts with acidic phospholipids through its Gla domain; **C:** The *prothrombinase complex* composed of factor Xa, which interacts with acidic phospholipids through the Gla domain; factor V, which interacts with phospholipids through the C2 domain; and prothrombin, which interacts with acidic phospholipids through its Gla domain; and **D:** The *protein C activation complex* composed of thrombomodulin, an endothelial integral membrane protein; protein C, which interacts with acidic phospholipids through its Gla domain; and thrombin. Other coagulation reactions such as the contact system interact with other biologic membranes, but the function remains assembly of complexes to improve enzymatic efficiency. **Part II:** The various surface reactions in the coagulation process, which are shown as isolated reactions but are in reality occurring all on the same membranes and next to each other. **A:** During *initiation*, the tissue factor–VIIa complex initiates coagulation, leading to formation of small amounts of factors IXa and Xa, which generate small amounts of thrombin. **B:** In the *propagation* phase, increased thrombin generation comes about through primarily feedback activation from factor IXa and the tenase complex. **C:** At the same time, in what is termed the *termination* phase, thrombin that is generated begins to exert an anticoagulant effect by activating protein C, which cleaves and inactivates factors V and VIII. (Figure provided by K. Mann.)

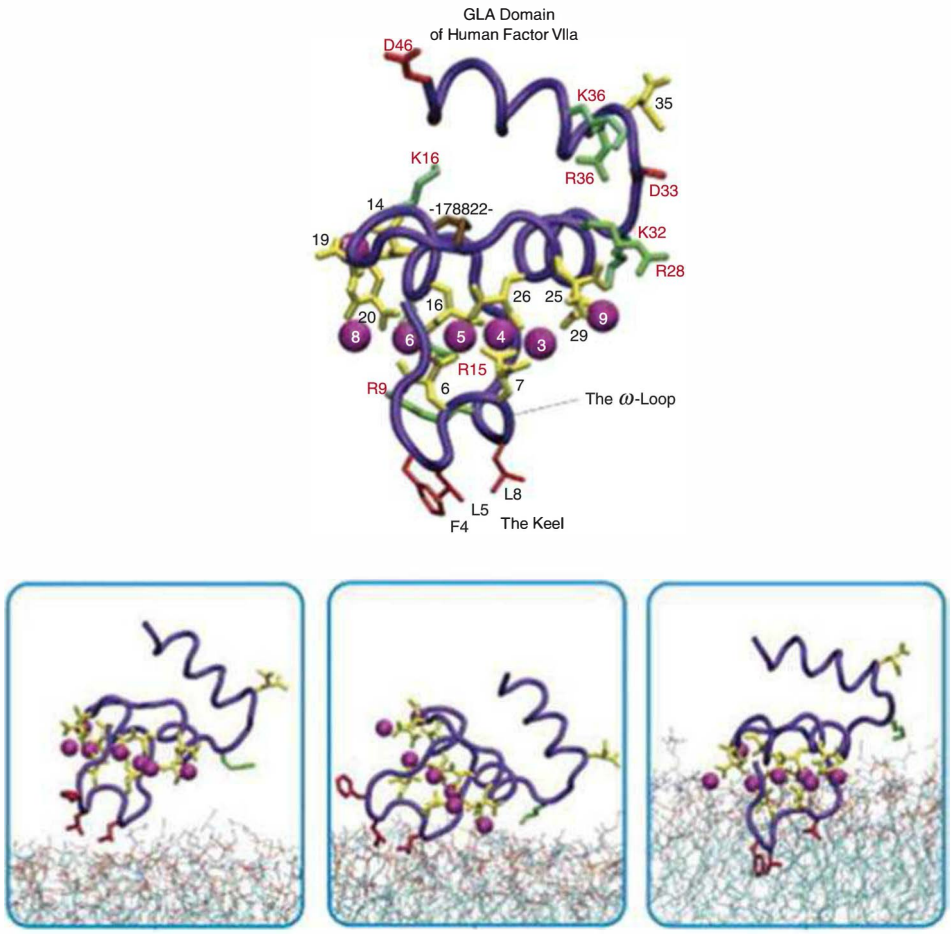

FIGURE 8.4 Insertion of a Gla domain into a phospholipid membrane. The Gla domain of human factor VIIa is depicted in the top of the figure. The backbone is shown in *purple* as a tube. Calcium ions are shown as *purple spheres* with their PDB numbering. The side chains of the hydrophobic residues of the "keel" are shown in *red*. The bottom part of the figure shows the insertion of the Gla domain into an anionic membranous bilayer of DOPS (1,2-dioleoyl-*sn*-glycero-3-[phospho-L-serine]). (Adapted from Figs 1 and 5 in Ohkubo YZ, Tajkhorshid E. Distinct structural and adhesive roles of Ca2+ in membrane binding of blood coagulation factors. *Structure* 2008;16:72–81.)

and platelets, amplifying the process and leading to generation of progressively larger amounts of thrombin. The activation of factor IX by the tissue factor–VIIa complex also serves to further activate factor X through the intrinsic pathway, further contributing to thrombin generation. There is evidence from *in vitro* work that the "burst" of thrombin is an important driver of hemostasis.[38] The greater the concentration of thrombin generated, the stronger the clot. At the same time, the generation of thrombin is strongly regulated to prevent more generalized clot formation. One mechanism of regulation relates to how thrombin is generated. For example, the generation of thrombin tends to be localized, in part, by where the tissue damage occurs and, in part, by the occurrence of clotting on cellular surfaces. Because activated platelets and inflammatory cells localize to the site of vascular damage, the generation of thrombin on the surface of these cells is also localized to the site of vascular damage. This localization promotes hemostasis without leading to more generalized thrombosis in distant parts of the circulation, although, with massive trauma and more extensive tissue damage, thrombin generation may be less localized, regulatory pathways may be overwhelmed, and disseminated intravascular coagulation may occur. Another mechanism for controlling thrombin generation is through negative feedback reactions in the coagulation system. For example, thrombin activates protein C to APC, which leads to the destruction of factors Va and VIIIa, reducing their ability to catalyze the activation of factor X and prothrombin and thereby limiting the amount of thrombin generated. Thrombin also activates plasminogen, converting it to plasmin which degrades fibrin(ogen). Plasmin, itself, also exerts positive feedback by cleavage of an activation peptide from plasminogen (connecting Glu-plasminogen to Lys-plasminogen), rendering it more susceptible to surface binding and subsequent activation by plasminogen activators. Finally, inhibitors of activated coagulation factors, such as antithrombin and tissue factor pathway inhibitor (TFPI), work to dampen thrombin generation by inhibition of activated coagulation factors or coagulation factor complexes.

The finely tuned nature of the coagulation system is underscored by the ability of even subtle genetic alterations to perturb the balance. A prevalent mutation in factor V at a site of cleavage by APC, called factor V Leiden (R506Q), results in a sevenfold increase risk of venous thrombosis in the heterozygous state and an 80-fold increase in the homozygous state.[39] This is the result of an inability of APC to induce "feedback inhibition" of factor Va in the coagulation process, leading to increased thrombin formation. Similarly, a polymorphism (G20210A) in the 3'-untranslated region of the prothrombin gene induces a mild but reproducible hypercoagulable state by virtue of increasing the transcription of prothrombin and therefore the plasma concentration of prothrombin.[40] This 25% to 35% increase in prothrombin concentration is enough to change the hemostatic–thrombotic balance. More severe alterations, including deficiency or abnormalities of antithrombin, have more prevalent effects on thrombosis. These hypercoagulable conditions are discussed in Part IV, Chapter 81 of this text.

CENTRAL ROLE OF THROMBIN AND ITS ROLE AS PROCOAGULANT AND ANTICOAGULANT

In many regards, thrombin is the central enzyme in the coagulation cascade.[41,42] Cofactors V and VIII (which are both activated and inactivated by thrombin), prothrombin (activated), factor XI (activated), factor IX (activated), factor XIII (activated), and fibrinogen ("activated") are all cleaved by thrombin. At the same time, thrombin activates the anticoagulant pathway through its effects on protein C (activated) and protein S (inactivated). As described above, thrombin is active in the fibrinolytic pathway, generating plasmin, and also activating thrombin-activated fibrinolysis inhibitor. In addition, thrombin is a strong activator of platelets, stimulating shape change, secretion, and aggregation. This effect on platelets depends on the interaction of thrombin with protease-activated receptors (PARs) on the surface of platelets. During thrombin-induced platelet activation, changes occur in the platelet membrane with the exposure of acidic phospholipids on the outer membrane leaflet. These promote coagulation by providing a procoagulant surface.[43]

Thrombin also affects the anticoagulant and procoagulant properties of the vessel wall.[44,45,46,47] Normally, the endothelial cell presents a thromboresistant surface to blood, one that is unreceptive to coagulation factors and only weakly reactive with platelets and other vascular cells. These weak interactions with platelets and leukocytes are mediated by integrins and promote rolling along the surface, but these are transient interactions and essentially serve to help localize platelets and leukocytes to the area where they might be needed in case of vascular injury. This thromboresistance is related to various properties of endothelium, from charge to heparin-like glycosaminoglycans that coat the endothelium to inhibitory molecules such as prostacyclin (PGI_2), thrombomodulin, TFPI, nitric oxide, plasminogen activators, and CD39 (ecto-NTP diphosphohydrolase). However, with the generation of thrombin, the relationship between the endothelium and blood changes. Thrombin activates endothelial cells through PARs to effect a variety of biologic responses, including contraction, relaxation of interendothelial junctions leading to increased vascular permeability, reduction in thrombomodulin expression, secretion of von Willebrand factor, downregulation of CD39, upregulation of transforming growth factor β, and secretion of endothelin which contributes to vasoconstriction; thrombin also increases the generation of nitric oxide and prostacyclin. Thus, although generating a somewhat mixed response, the overall effect of thrombin on the vessel wall would be predicted to reduce the natural thromboresistance of the vessel wall and increase the potential to participate in thrombus formation. Thrombin also plays a role in atherogenesis, partly through its ability, along with platelet-derived growth factor and fibroblast growth factor, to stimulate smooth muscle cell proliferation.

More recently, thrombin has been shown to play an important role outside its traditional role in coagulation. For example, thrombin has been linked to cancer metastasis and tumor angiogenesis.[48,49] Thrombin also is important in normal angiogenesis. Thrombin plays a key role linking coagulation and inflammation.[50,51] Thrombin upregulates proinflammatory molecules that increase endothelial permeability, in part leading to leukocyte diapedesis and transmigration of cytokines. Thrombin also affects the immune system, stimulating the release of inflammatory cytokines such as IL-6 from cells such as monocytes and acting directly on cells of the innate immune system. This capacity of thrombin to bring both the coagulation and inflammatory pathways together is a key to host defense mechanisms in man.

All of these underscore the fundamental importance of thrombin in a variety of biologic processes, from hemostasis and thrombosis to processes not initially thought to be related to coagulation such as cancer, inflammation, and the immune response.

In conclusion, the focus in this section is on the humoral coagulation system, the proteins and reactions leading to both clot formation and clot dissolution and the proteins that control or regulate those reactions. The topics are the structure of the proteins, their genetics, the role of tissue factor and its inhibitor, the cofactors V and VIII and their role in coagulation, the biology of von Willebrand factor, the vitamin K–dependent factors, the contact factors, fibrinogen, factor XIII, the inhibitors antithrombin, protein C and protein S, and the fibrinolysis system. The reader is also referred to the chapters in the initial section of the book, which describe some of the basic processes involved in thrombosis and hemostasis, including the principles of molecular biology, enzymology, cell biology, and immunology. These basic chapters are intended to provide companion reading for each of the initial Sections of the book. For example, Chapter 3 by Everett, et al., entitled Molecular Biology, is relevant to all of the Chapters in this section. Molecular biology has been an important key to understanding the biology of the coagulation system, starting with the initial cloning of the cDNAs for each protein. For most, this provided the first insight into structure and the initial correlation with function. Structure has been essential for understanding the enzymatic specificity of the proteins, their interactions with membranes, the formation of enzymatic complexes, and the interaction with inhibitory proteins. Mouse models, crystal structures, and gene transfer vectors all derive from the molecular biology of the proteins. Structure will be critically important to understand how antibodies form in response to treatment as well as for inhibiting the immune response after gene transfer. The genomic structure is important for understanding the control of protein production and the evolution of the coagulation system. Chapter 4 by Krishnaswamy provides important enzymology background for this section. The coagulation system is largely an enzymatic cascade and understanding the basic principles of enzyme biochemistry and kinetics is key to understanding the control of coagulation. Finally, Kaufman and Popolo describe the cell biology of protein production in Chapter 5. Knowing how proteins are synthesized

and the nature of their posttranslational modifications, such as γ-carboxylation of the vitamin K–dependent proteins, is important to understanding how they function. In turn, the chapters in this section provide important background for later sections on disorders of the blood coagulation system.

The Blood Coagulation Factors and Inhibitors: Their Primary Structure, Complementary DNAs, Genes, and Expression

DOMINIC W. CHUNG, WENFENG XU, AND EARL W. DAVIE

A BRIEF INTRODUCTION TO THE BLOOD COAGULATION CASCADE

When tissue damage occurs, platelets become activated, aggregate, and adhere to the site of vascular injury where they form a thrombus. During this process, the blood coagulation cascade is initiated when the tissue factor (TF) comes in contact with factor VII (or factor VIIa) in the flowing blood and forms a potent enzyme complex at the site of injury (FIGURE 9.1). This complex initiates a series of reactions involving coagulation proteins circulating in blood in a precursor or inactive form.[1] The complex of factor VIIa and TF catalyzes the conversion of factor X to factor Xa. Factor Xa, in turn, converts prothrombin to thrombin in the presence of factor Va, phospholipid, and calcium. Thrombin then converts fibrinogen to fibrin, leading to an insoluble clot of activated platelets and fibrin polymers. Thrombin also activates the intrinsic pathway of blood coagulation by converting factor XI to factor XIa by a mechanism that is poorly understood. Factor XIa, in turn, converts factor IX to factor IXa in a reaction requiring calcium. Factor IXa then converts factor X to factor Xa in the presence of factor VIIIa, phospholipid, and calcium. This reaction provides a second mechanism for the activation of factor X in blood. Thrombin plays a critical role in blood coagulation in that it converts fibrinogen to fibrin, factor V and factor VIII to active cofactors, factor XI and protein C to serine proteases, factor XIII to a transglutaminase, and finally, it activates platelets (FIGURE 9.1). All these activation reactions involve minor proteolysis at arginine peptide bonds. The phospholipid participating in several of these steps is provided by the activated platelets and cell membranes. Divalent calcium is also required in several steps of the coagulation cascade, and the normal level ranges from about 3.5 to 5 mM in blood.

FACTOR VII

Factor VII is highly homologous in its amino acid sequence and gene organization with the other vitamin K–dependent proteins, including factor IX, factor X, and protein C (Table 9.1). In the presence of TF, factor VII initiates the extrinsic pathway. Factor VII is a single-chain glycoprotein (Mr 50,000) that is synthesized in the liver and secreted into the blood as a zymogen composed of 406 amino acids (FIGURE 9.2).[2–5] It contains 10 γ-carboxyglutamic acid residues that are localized in the Gla domain of the protein (amino acids 1 to 35). The Gla region is followed by two epidermal growth factor (EGF)-like domains and a serine protease domain (FIGURE 9.2). The γ-carboxyglutamic residues require vitamin K for their biosynthesis.[6] Factor VII also contains a residue of β-hydroxyaspartic acid (amino acid 63), located in the first of the two EGF-like domains.[7] The first EGF-like domain stabilizes the factor VIIa–TF complex and participates in calcium binding.[8–10] The β-hydroxylation of the Asn63 is not essential for the coagulant activity of factor VIIa since recombinant factor VII is not β-hydroxylated, and functions as well as the plasma-derived counterpart.[11] The first EGF-like domain contains novel *O*-linked carbohydrates at residues Ser52 and Ser60.[12–14] The Ser52 is *O*-glycosylated, being linked to either a disaccharide (Xyl-Glc) or a trisaccharide (Xyl2-Glc) in approximately equal amounts. The Ser60 contains one residue that is conjugated to fucose by *O*-glycosylation. Recombinant factor VII/VIIa missing either one or both *O*-linked Ser residues exhibits decreased TF binding but has similar calcium binding relative to the wild-type.[9] Factor VIIa has another potential carbohydrate attachment site located at Asn322. Factors VII and VIIa contain two high-affinity calcium-binding sites located in the protease domain and the first EGF1 domain as well as six to seven low-affinity calcium-binding sites in the Gla domain.[15]

Factor VII is converted to a serine protease (factor VIIa) by minor proteolysis. Factor VIIa, however, has little if any physiologic activity until it combines with TF. The factor VIIa–TF complex then converts factor X to factor Xa in the presence of phospholipids and calcium ions.[1] Factor VIIa also converts factor IX to factor IXa in the presence of TF and calcium ions.[9] The physiological importance of the latter pathway is unclear. *In vitro* experiments evaluating the initiation phase of blood coagulation with ultrasensitive fluorescent markers indicate that factor Xa is generated almost exclusively by the factor VIIa–TF complex during the initiation phase of coagulation.[16] The conversion of human factor VII to factor VIIa is catalyzed by thrombin and factor Xa as well as factor IXa, and factor XIIa.[3,5,17–20]

The activation of factor VII is due to the cleavage of a single peptide bond (Arg152-Ile) (FIGURE 9.2). This leads to the formation of a salt bridge between the α-ammonium group of Ile153 and the carboxylate group of Asp343 and a reregistration of a β-strand in the protein,[21] resulting in a conformational change and formation of an active charge-relay system. Factor VIIa may also be formed by an autocatalytic mechanism,[22,23] but this pathway is very slow and may have

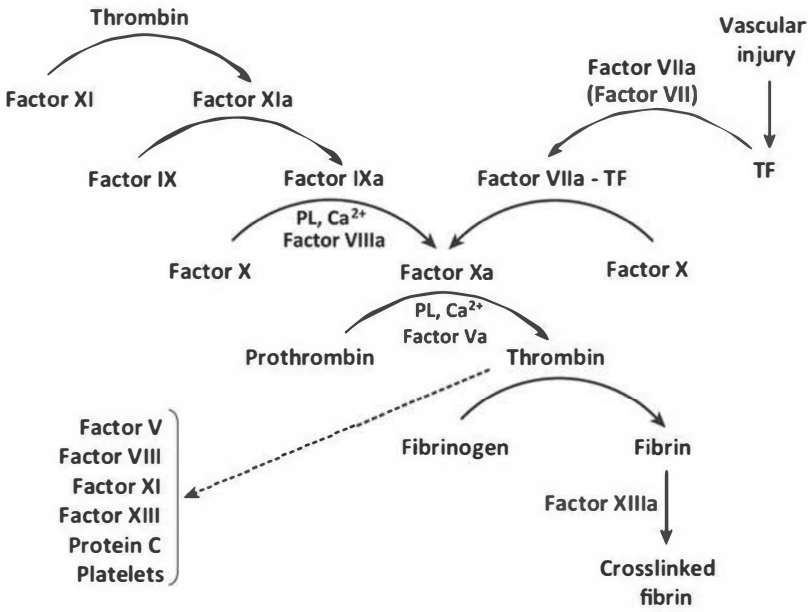

FIGURE 9.1 An abbreviated blood coagulation cascade. (Modified from Davie EW, Fujikawa K, Kisiel W. The coagulation cascade: initiation, maintenance, and regulation. *Biochemistry* 1991;30:10363.)

little physiological importance.[24] Factor VIIa is a serine protease composed of a light chain (152 amino acids) and a heavy chain (254 amino acids) held together by a single disulfide bond between Cys135 and Cys262. The light chain contains the Gla domain followed by the two EGF domains, whereas the heavy chain contains the catalytic domain with the active site residues of His193, Asp242, and Ser344. The active site Ser344 is located in the same sequence of Gly-Asp-Ser-Gly-Gly-Pro that is present in all the other serine protease clotting factors, including thrombin, factor IX, factor X, factor XI, and activated protein C (APC).

The crystal structure of human factor VIIa lacking the *N*-terminal γ-carboxyglutamic acid domain is shown in FIGURE 9.3.[25] Factor VIIa has an elongated shape similar to that of a tulip, in which the Gla and EGF-like domains form the stem while the catalytic domain forms the blossom.

The cDNA and gene for factor VII have been isolated, and their sequence determined.[26,27] The sequence of the mRNA coding for human factor VII contains approximately 2,450 nucleotides (nts) that code for a prepro leader sequence of 38 amino acids and 406 amino acids present in the mature protein circulating in blood (FIGURE 9.2). A noncoding region of 1,026 nts plus a poly(A) tail follows the stop codon of TAG. The noncoding region also contains the polyadenylation recognition sequence of AATAAA, which are located 40 nts upstream from the poly(A) tail.[28]

A second clone has been identified for human factor VII, containing a prepro leader sequence of 60 amino acids.[26] This leader sequence contains an additional 22 amino acids inserted between Val at –17 and Ala at –18 in the 38–amino acid prepro leader sequence encoded by an additional exon in intron A, suggesting that the two mRNA species result from alternative splicing.[27] The removal of the prepro leader sequence requires signal peptidase in addition to a second processing protease that cleaves the peptide bond following the arginine at position –1.[29]

The gene for factor VII (F7) spans approximately 12.8 kb and consists of eight exons interrupted by seven introns. The positions of the introns with respect to the amino acid sequence and the types of intron–exon boundaries are almost exactly the same as the genes coding for the other vitamin K–dependent proteins (FIGURE 9.1 and Table 9.1). The gene coding for factor VII also contains five regions of tandem repetitive sequences, and more than a quarter of the intron sequences consist of minisatellite DNA sequences, which vary in the number of copies among individuals.[30]

The absence of a CCAAT box in the factor VII promoter contrasts with the promoter structures of factor IX, which has a functional CCAAT box, and factor X, which contains a putative CCAAT box that binds the ubiquitous transcription factor NF-Y.[31–33] The major transcription start site for factor VII is located approximately 50-bp upstream from the first initiation Met and is close to the binding sites for a Sp1-like transcription factor and HNF-4.[34,35] The G-C rich Sp1-like site is located at –100 to –94, whereas the HNF-4 site is located at –63 to –58. The factor VII HNF-4 recognition sequence, ACTTTG, is also present in the promoters of factor X and factor IX. A naturally occurring mutation in the factor IX HNF-4 site causes the hemophilia B Leiden phenotype, whereas a similar mutation in the factor VII promoter causes lifelong bleeding and virtually no detectable factor VII.[33,36]

Genetic defects leading to an abnormal factor VII include a replacement of Arg304 or Arg353 with Gln, resulting in reduced clotting activity,[37–39] presumably by a conformational change near the catalytic site. A substitution of Phe38 to Ser (factor VII central)[40] and factor VII variant Gln100 to Arg[41] result in reduced TF binding and impaired activation of factors IX and X.[40] A polymorphism originating from a decanucleotide (CCTATATCCT) inserted at position –323 relative to the first Met-initiating codon[42] and a substitution of G for T at nt –81 disrupts an HNF-4–binding site in the factor VII promoter,[36] resulting in a modest reduction in factor VII levels.[42]

Pharmaceutical preparations of recombinant factor VIIa have been very helpful in the treatment of patients with factor VIII deficiency and inhibitors as well as in patients with other coagulopathies.[43,44]

Table 9.1

Comparison of intron location and splice junction type and size for human factors VII, IX, X, protein C, and prothrombin

Intron	Protein	Location (Amino Acid)	Splice Type	Size (bp)
A	Prothrombin	–17	1	386
	Factor VII	–17	1	2,574
	Factor IX	–17	1	6,206
	Factor X	–17	1	6,542

TISSUE FACTOR

Human TF (Mr 44,000) is a transmembrane glycoprotein synthesized in adventitial fibroblasts. When blood comes into contact with the subendothelium following vascular injury,[45–48] factor VII binds to TF to form a bimolecular complex in the presence of calcium ions,[1,49–54] initiating coagulation. TF is a single-chain protein containing 263 amino acids and is synthesized with a signal peptide of 32 amino acids (FIGURE 9.4).[55,56,57] The extracellular or cellular surface domain of TF is 219 residues and contains three repeating sequences of Trp-Lys-Ser. It also contains two disulfide bonds linking Cys49 with Cys57, and Cys186 with Cys209.[58] The membrane-spanning region of TF is 23 amino acids (residues 220 to 242), whereas the cytoplasmic portion of the protein at the carboxyl end of the molecule is 21 residues in length. The cytoplasmic portion also contains a half-Cys residue (Cys245) that is acylated by palmitic or stearic acid.[58] Three potential glycosylation sites with a sequence of Asn-X-Thr/Ser (Asn11, Asn124 and Asn137) are also present in the molecule.[55,56,57]

The crystal structure of TF,[59] and factor VIIa–TF complex has been determined in several different laboratories.[8,60] The extracellular region of TF (TF-219) consists of two immunoglobulin-like domains that are formed by two antiparallel β-sheets (FIGURE 9.5). The crystal structure of factor VIIa in a complex with a mutant of bovine pancreatic trypsin inhibitor (BPTI) lacks about two-thirds of the amino-terminal Gla domain of factor VIIa (FIGURE 9.6, **left**). The complex of TF (TF-219) and the factor VIIa-BPTI mutant (FIGURE 9.6, **right**),[60] enhanced by calcium about 150,000 fold,[15] is >100 Å long and 40 to 60 Å wide. In the absence of the inhibitor, the catalytic domain of factor VIIa, bound to the BPTI mutant at the top of the complex, is readily available to bind factor X and convert it to factor Xa.

The mRNA for human TF is 2.3 kb,[55,56,57] including a 5′ noncoding region of 75 bp, 885 bp of coding sequence, a stop codon, and a 3′ noncoding region of 1,141 bp, followed by a poly(A) tail. The gene for human TF (F3) spans 12.4 kb on chromosome 1,[56,61] contains six exons separated by five introns (A to E, Fig. 9.4), three full Alu sequences, one partial Alu sequence, and a typical TATA promoter element present 26-bp upstream from the cap site. TF in vascular endothelium and monocytes can be induced with several agents, such as phytohemagglutinin and endotoxin, interleukin 1, TNF, phorbol esters, and thrombin.[62–68] Functional studies indicate that basal TF transcription is controlled by the transcription factor Sp1. A distal enhancer (–227 to –172 bp) containing two AP1 sites and an NFκB site mediates the induction of the TF transcription in monocytic and endothelial cells.[69]

FACTOR X

Factor X (Mr 58,800) is a vitamin K–dependent glycoprotein (15% carbohydrate) that is synthesized in the liver and secreted into the plasma. Human factor X is composed of a light chain of 191 amino acids (Mr 16,200) and a heavy chain of 254 amino acids (Mr 42,000) held together by a single disulfide bond (FIGURE 9.7).[70,71,72,73] The light chain of human factor X contains 11 residues of γ-carboxyglutamic acid, one residue of β-hydroxyaspartic acid (residue 63),[71] and two EGF-like domains,[73–75] the first of which contains one high-affinity calcium-binding site.[76]

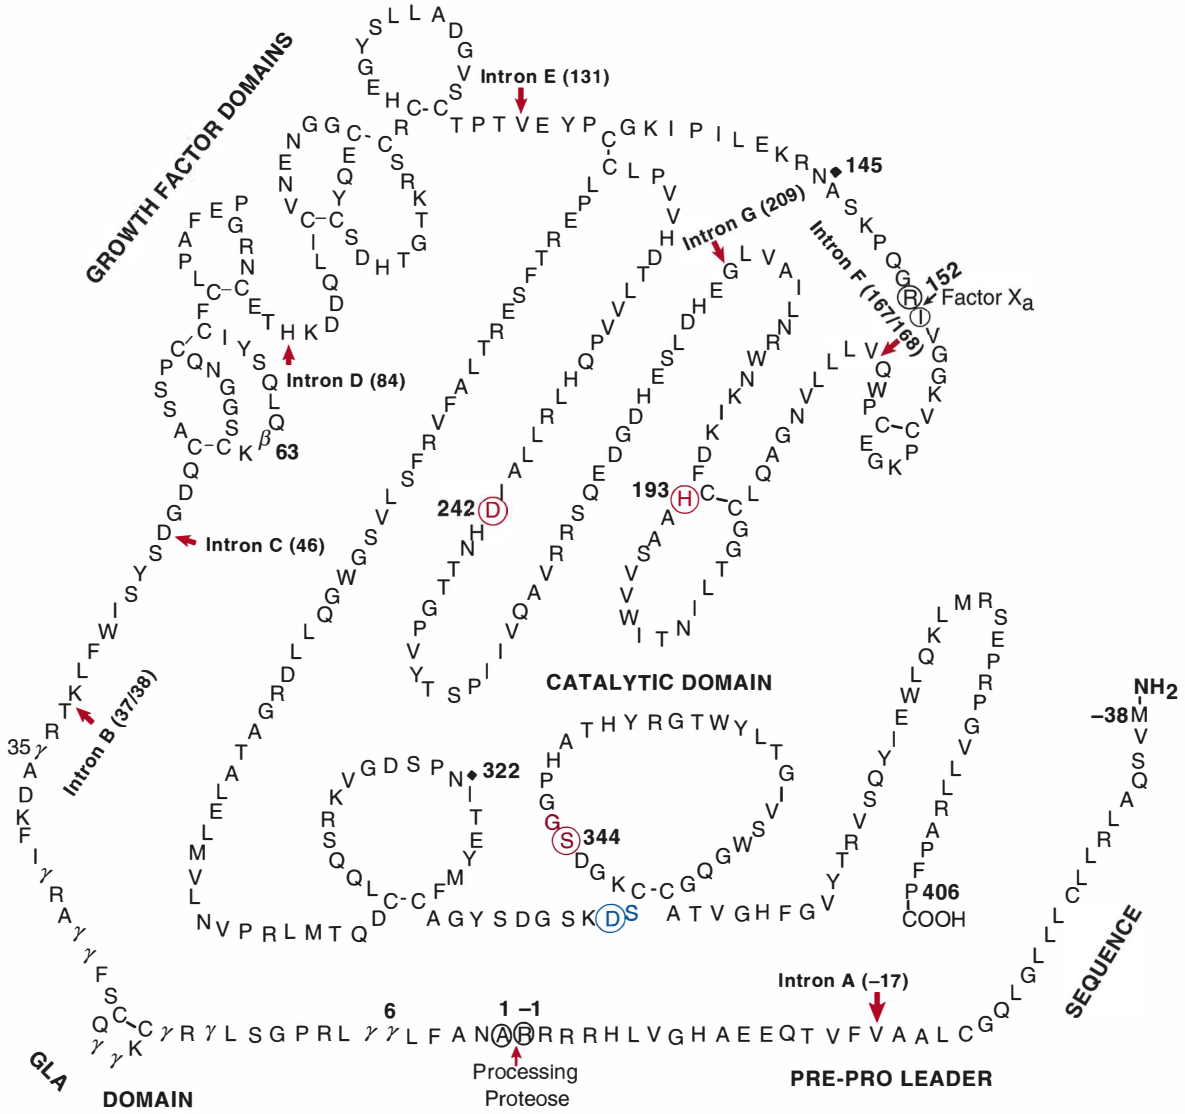

FIGURE 9.2 Amino acid sequence for human prepro factor VII. The prepro leader sequence (–38 to –1) is removed during biosynthesis by signal peptidase and a processing protease that hydrolyze the Arg(–1)-Ala bond. The single cleavage site by factor Xa is shown by a *solid arrow*. The Gla domain and potential growth factor domains are located within residues 1 to 152, which constitute the light chain of factor VIIa. The heavy chain or catalytic domain contains 254 residues, including the three principal amino acids participating in catalysis. The amino acids (His193, Asp242, and Ser344) are *circled*. Two potential carbohydrate attachment sites are shown by *solid diamonds*. The proposed disulfide bonds have been placed by analogy to those established in bovine prothrombin and epidermal growth factor. The single-letter code for amino acids is as follows: A, Ala; R, Arg; N, Asn; D, Asp; C, Cys; Q, Gln; E, Glu; G, Gly; H, His; I, Ile; L, Leu; K, Lys; M, Met; F, Phe; P, Pro; S, Ser; T, Thr; W, Trp; Y, Tyr; V, Val; γ, γ-carboxyglutamic acid; β, β-hydroxyaspartic acid.

The heavy chain of factor X contains the activation peptide and the catalytic domain.[77] The activation peptide also contains two potential *N*-linked carbohydrate-binding sites, including an Asn39-Gln-Thr sequence and an Asn49-Leu-Ser sequence. In bovine factor X, there is an *N*-linked (Asn36) as well as an *O*-linked (Thr300) carbohydrate chain.[77]

Factor X is synthesized with a prepro leader sequence that requires two processing steps for its removal (FIGURE 9.8). These reactions are catalyzed by a signal peptidase as well as by a furin-like enzyme that cleaves the Arg residue on the carboxyl end of the propiece. Additional processing in the single-chain precursor occurs between Arg139 and Ser143, which is the *N*-terminal residue in the activation peptide. This protease activity results in the removal of a basic tripeptide of Arg-Lys-Arg and the formation of the two-chain circulating molecule that is held together by a single disulfide bond (FIGURE 9.7).

The crystal structure of factor Xa lacking the Gla domain is very similar to that of factor VIIa and factor IXa (FIGURE 9.9), an elongated molecule of 100 Å in length.[78] In the intact molecule,

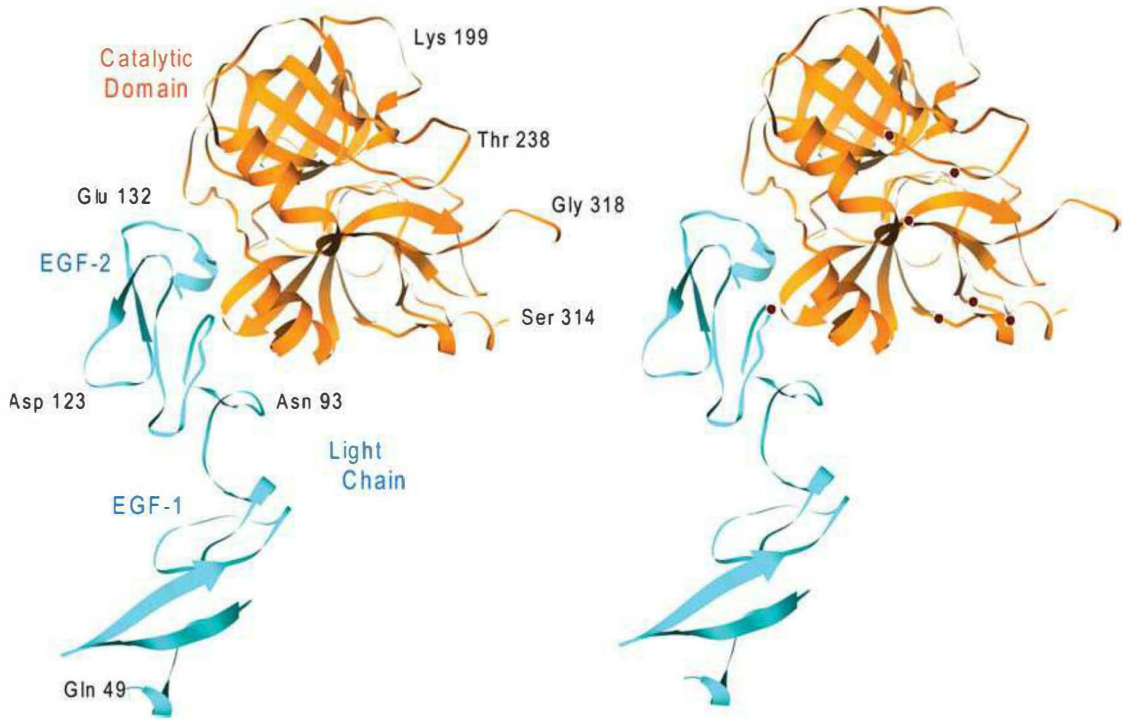

FIGURE 9.3 Ribbon structure of Gla domainless factor VIIa starting with Gln 49. The protein takes the shape of a tulip with the EGF1 and EGF2 domains (*colored cyan*) forming the stem, while the catalytic domain (*colored orange*) is the flower. The structure on the right shows the location of seven known mutations (*black dots*) in the human protein. (Modified from Pike AC, Brzozowski AM, Roberts SM, et al. Structure of human factor VIIa and its implications for the triggering of blood coagulation. *Proc Natl Acad Sci U S A* 1999;96:8925.)

the Gla region of factor X is partially buried in the phospholipid surface, which is about 61 to 69 Å from the active site.[79]

Activation of factor X involves the cleavage of an Arg-Ile1 peptide bond in the amino-terminal end of the heavy chain, liberating a small activation peptide of 52 amino acids (FIGURE 9.7).[70] During the activation reaction, the new amino-terminal Ile1 residue turns and flips into the interior of the catalytic domain. The new α-ammonium group of Ile1 then forms a salt bridge with the carboxylate group of Asp184 (*circled in green*, FIGURE 9.9),[80] generating a serine protease with an active catalytic site involving His42, Asp88, and Ser185 (*circled in blue*, FIGURE 9.9).

The gene for human factor X (F10) contains eight exons and seven introns on chromosome 13 at q32-qter in approximately 27 kb of DNA,[72,81] only 2.8 kb downstream from the gene coding for factor VII.[32] The introns are located between amino acid residues –17 (intron A), 37, and 38 (B), at residue 46 (C), and at residue 84 (D) between the two potential growth factor domains (FIGURE 9.7 and Table 9.1). Intron E is located at residue 128 following the second growth factor domain and just before the disulfide bond connecting the light and heavy chains. The last two introns (F and G) are located in the heavy chain or catalytic domain of the molecule and are present between residues 15 and 16 and at residue 55. The rest of the catalytic chain is free of introns.

The first patient identified with factor X deficiency[82–84] had a single-nucleotide change of G to A (GTG to ATG) resulting in a Val148Met change in the catalytic domain of the protein (*red arrow*, FIGURE 9.8) (Asakai, Roberts, Davie, unpublished data). Other molecular aberrations include partial deletions of exons VII and VIII, and amino acid substitutions of Arg for Gly(–20), Lys for Gla14, Ser for Pro343, and Cys for Arg366.[85–90] Amino acid changes that result in a loss of biological activity have been found throughout the catalytic domain as well as the EGF domains (FIGURE 9.10, *right panel*).

The mRNA for human factor X includes 1,475 nts that code for a prepro leader sequence of 40 amino acids, a light chain of 139 amino acids, a connecting tripeptide, and 303 amino acids that constitute the heavy chain.[73,75] The processing or polyadenylation sequence of ATTAAA is unusual in that it is located in the coding sequence and precedes the stop codon by one nucleotide.[28]

Two transcription start sites, a major one at –16-bp and a minor one at –10-bp upstream from the initiation Met codon, are present in the human factor X 5′-flanking region.[91] Full liver-specific promoter activity is contained within a 457-bp region upstream from the translation start site.[32] An apparent CCAAT sequence, present at –120 to –116 bp, binds the ubiquitous transcription factor NF-Y.[34] An HNF-4 functional element has been localized between –63 and –42 bp, and HNF-4 binding is required for liver-specific expression. Two additional positive regulatory regions have been identified at –215 to –149 bp and at –457 to –351 bp.[32]

FACTOR V

Factor V (Mr 330,000) is a glycoprotein that is synthesized as a single-chain molecule of 2,196 amino acids in liver and megakaryocytes and circulates in blood as an inactive cofactor

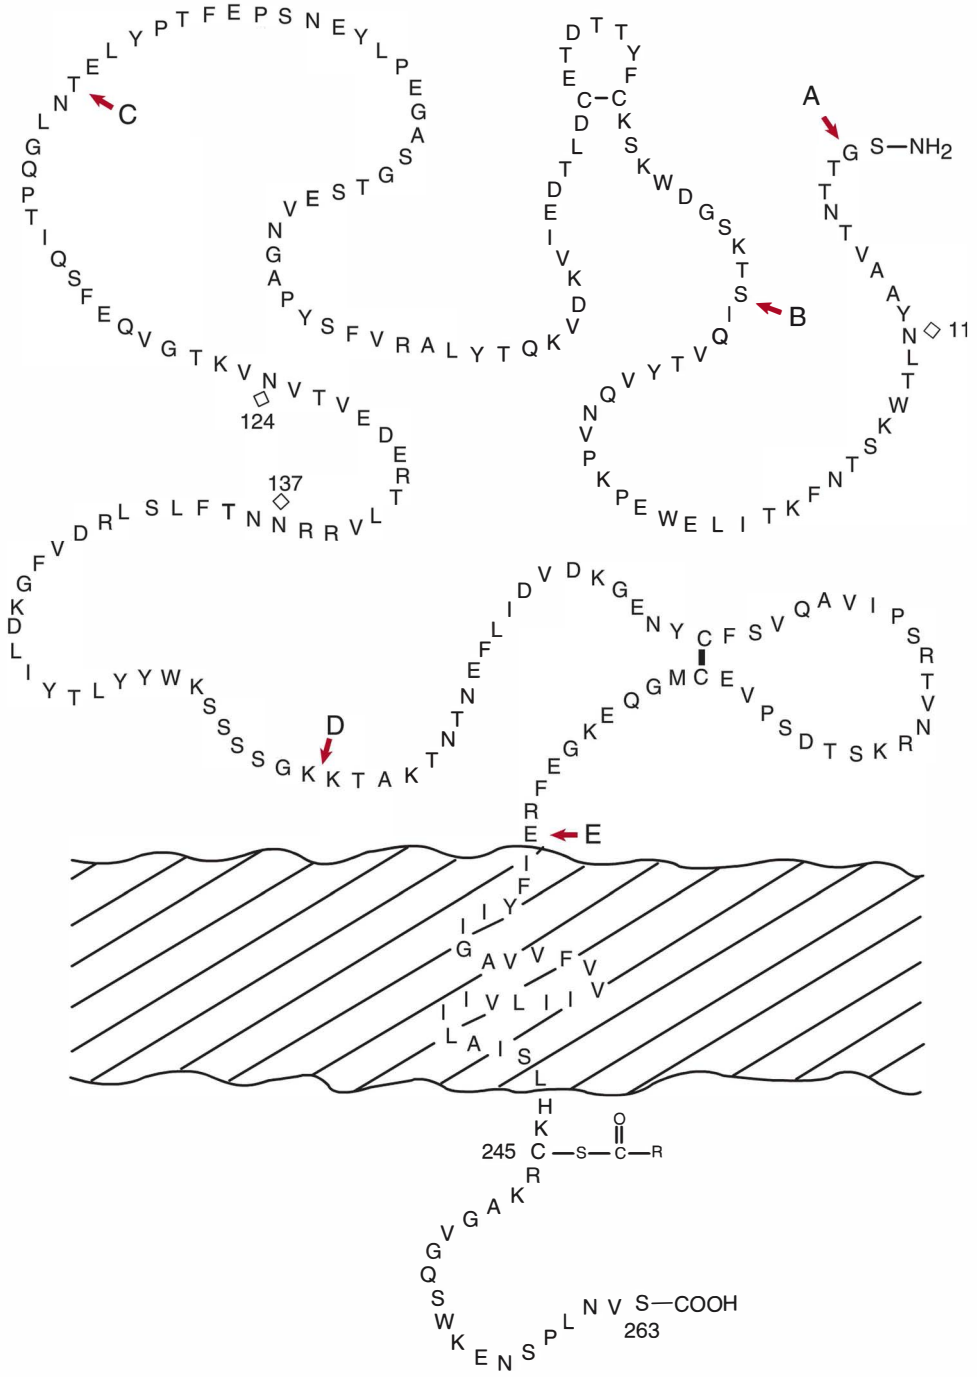

FIGURE 9.4 Amino acid sequence of human TF. The *solid arrows* indicate the position of the five introns (A to E). The three potential carbohydrate-binding sites are indicated by *open diamonds*. Cys 245 is acylated by palmitic or stearic acid.

at 7 μg/mL.[92] Approximately 20% of the factor V in blood is present in the α-granules of platelets.[93] Factor V is comprised of six domains (A1-A2-B-A3-C1-C2) that are highly homologous to those in factor VIII and ceruloplasmin (FIGURE 9.11).[94–97] The second and third A domains of factor V and factor VIII are separated by a large connecting B domain. In factor V, this domain is 836 amino acids in length, is located between amino acids 710 and 1,545, and has two tandem repeats of 17 amino acids and 31 tandem repeats of nine amino acids with a consensus sequence of [TNP]LSPDLSQT (FIGURE 9.12). The B domain in factor V shows no similarity in amino acid sequence to that present in factor VIII. Interestingly, chimeric cDNA expression constructs in which the connecting regions of factor V and factor VIII were exchanged show that sequences within the factor V connecting region increase the expression of the factor VIII chimera and its corresponding mRNA by twofold in COS1 cells.[98] In another

FIGURE 9.5 Ribbon structure of the extracellular domain (219 *N*-terminal residues) of TF. The two immunoglobulin-like domains TF-1 and TF-2 (*magenta*) are formed by two antiparallel β-sheets. The *N*-terminal Ser is located in TF-1. (Modified from Harlos K, Martin DM, O'Brien DP, et al. Crystal structure of the extracellular region of human tissue factor. *Nature* 1994;370:662.)

study, the connecting region or B domain of factor V did not require the chaperone proteins calnexin or calreticulin for efficient secretion, whereas the connecting region or B domain of factor VIII was required for both chaperone protein binding and proper secretion of factor VIII in a Chinese hamster ovary (CHO) cell line.[99] The third A domain in factor V, as well as factor VIII, is followed by two C domains. Each of the C domains is approximately 150 amino acids in length, with sequence identity of 35% to 50%.

The membrane-binding C2 domain of factor Va contains a β-barrel motif composed of eight antiparallel strands (FIGURE 9.13),[100] which form two tightly packed β-sheets of five and three strands. The bottom portion of the β-barrel is rich in basic amino acids and consists of three β-hairpin loops that form the calcium-independent membrane-binding site of factor Va.

Before participation in the coagulation cascade, the single-chain factor V undergoes minor proteolysis[95] by thrombin at Arg709, Arg1018, and Arg1545. Factor V can be activated by factor Xa, but the physiological importance of this activation pathway has not been established.[101]

Factor Va is composed of a heavy chain (A1-A2 domains, Mr 110,000) derived from the amino-terminus of the protein and a light chain (A3-C1-C2 domains, Mr 78,000) derived from the carboxyl-terminus of the molecule (FIGURE 9.11). The fragments corresponding to the central connecting B region are released from factor V during its conversion to factor Va by thrombin. The newly generated heavy and light chains associate and are held together by calcium that is bound to a high-affinity site

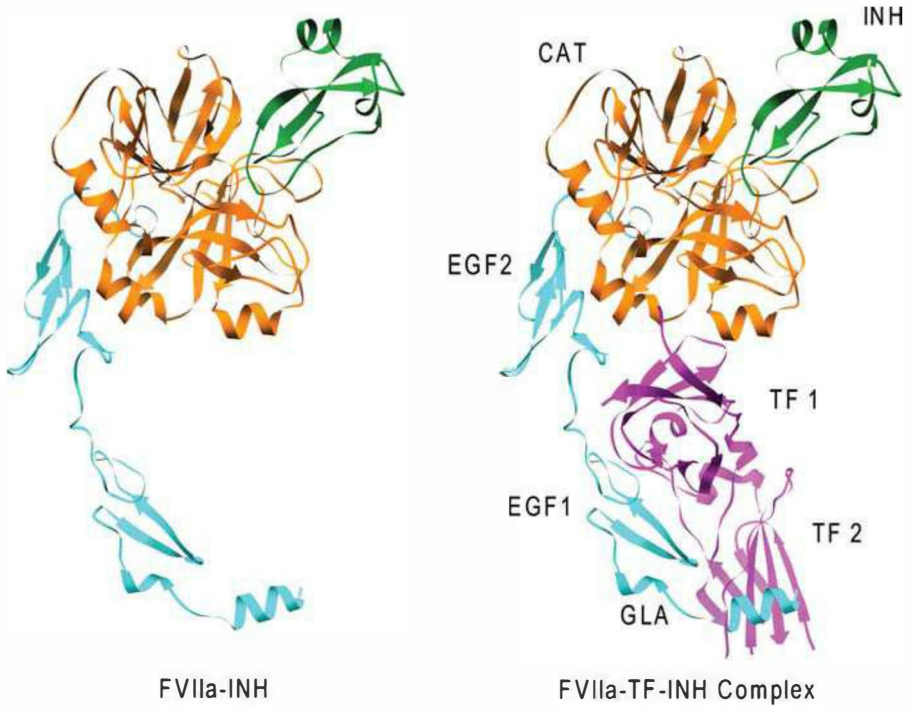

FIGURE 9.6 Ribbon structure of factor VIIa–inhibitor and factor VIIa–inhibitor–TF complex (Zhang E, St Charles R, Tulinsky A. Structure of extracellular tissue factor complexed with factor VIIa inhibited with a BPTI mutant. *J Mol Biol* 1999;285:2089). Factor VIIa (*cyan* and *orange*) complexed with pancreatic trypsin inhibitor (*green*) is shown in the left panel. The factor VIIa–inhibitor complex bound to TF (*magenta*) is shown in the panel on the right.

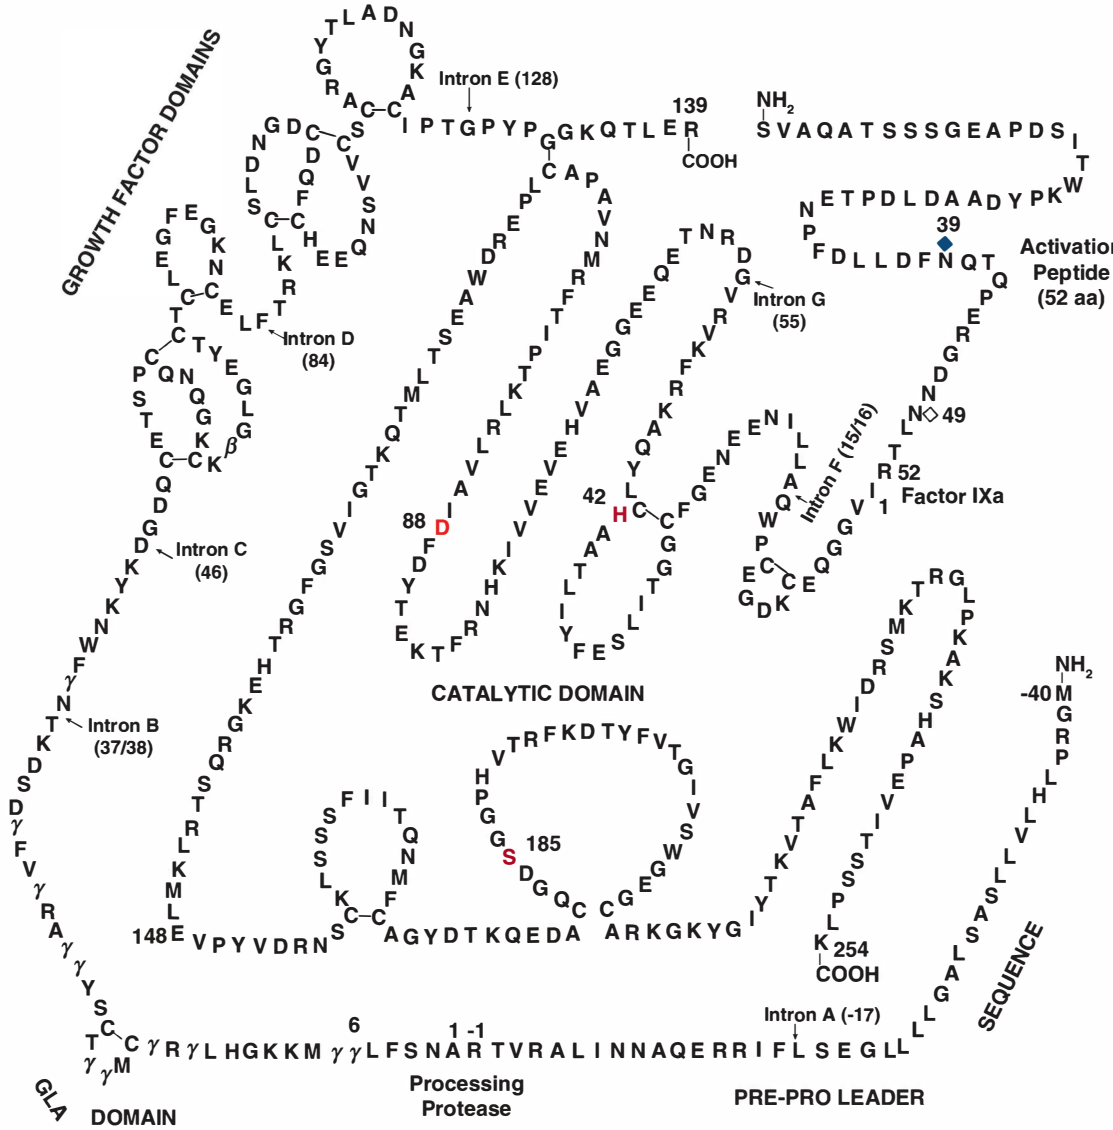

FIGURE 9.7 Amino acid sequence of human prepro factor X and the location of the seven introns (A to G). The tripeptide of Arg-Lys-Arg that connects the light chain to the heavy chain is not shown. The prepro leader sequence (–40 to –1) is removed during biosynthesis by signal peptidase and a processing protease that cleaves the Arg(–1)-Ala bond. The Gla domain and potential growth factor domains are located in the light chain within residues 1 to 139. The activation peptide of 52 amino acids is released from factor X during its conversion to factor Xa. The serine protease or catalytic domain of factor X contains 254 residues, including the catalytic triad of His42, Asp88, and Ser185, which are *circled*. Two *N*-linked carbohydrate attachment sites in the activation peptide are shown by *solid diamonds*. The proposed disulfide bonds in factor IX have been placed by analogy to those in bovine prothrombin and epidermal growth factor. The single-letter code for amino acids is given in FIGURE 9.2.

formed when the two chains combine. During the activation of prothrombin by factor Xa, the C1 and C2 domains of the light chain of factor Va are bound to phosphatidylserine in the membranes.[102] Important amino acid residues in the C2 domain of factor Va involved in the phospholipid binding include Trp2063 and Trp2064.[103] Modeling experiments and peptide inhibition studies suggest that the factor Xa binding to factor Va occurs via the A2 domain.

The cDNA for factor V is approximately 7 kb in size and codes for a leader peptide of 28 amino acids and a mature protein of 2,196 amino acids. The 3′ noncoding sequence also contains the typical sequence of AATAAA that functions as a polyadenylation signal.[28]

The gene coding for human factor V (F5) is located on chromosome 1q21-35 within 300 kb of the genes for the selectin family of leukocyte adhesive molecules.[104,105] The factor V gene spans more than 80 kb of DNA and consists of 25 exons[106] (72 to 2,820 bp) and 24 introns (400 bp to >11 kb) of DNA.

The organization of the gene for human factor V shows remarkable similarity to that of human factor VIII. The factor VIII gene, however, contains one additional exon (i.e., 26 rather

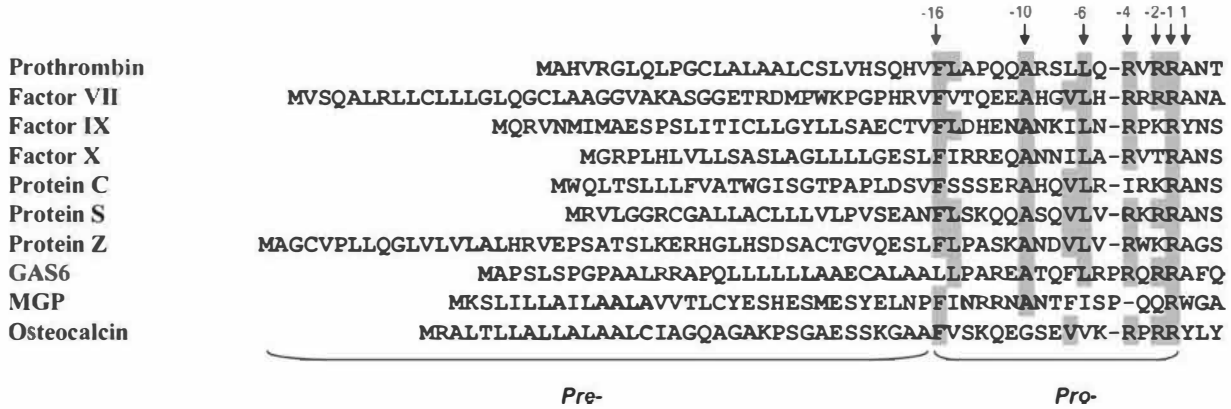

FIGURE 9.8 Prepro leader sequence of the vitamin K–dependent human plasma proteins. The putative hydrophobic core of each signal sequence is *shaded*. Identical and conserved amino acid residues within the propeptide region are also *shaded*. Numbering is relative to the mature amino-termini of the proteins.

than 25). The gene for factor VIII is also much larger than the gene for factor V, being approximately 180 kb in size. A comparison of the genomic DNA sequences for factor V and factor VIII indicated that 21 of the intron–exon boundaries occur at exactly the same location in the amino acid sequences coded by the two genes.[106] Of particular interest, the connecting B region factors V and VIII are both coded by a single very large exon. In the factor V gene, this exon is located between the 12th and 13th introns, whereas in factor VIII, it is between the 13th and 14th introns.

Recently, a homozygous factor V Leiden mutation (A for G at nt 1,691) has been shown to cause APC resistance and is the major known cause of hereditary thrombophilia.[107,108] This mutation results in the replacement of Gln for Arg at ammo acid residue 506, and this change disrupts the cleavage site for the inactivation of factor Va by APC,[12] and confers a lifelong risk of thrombosis.[109]

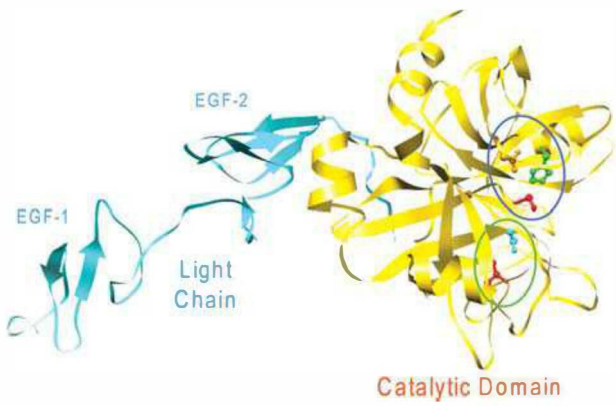

FIGURE 9.9 Ribbon structure of Gla domainless factor Xa starting with Asp 46. The catalytic triad of His 42, Asp88, and Ser185 is *circled* in blue, while the salt bridge formed between the carboxylate group of Asp184 and the α-ammonium group of Ile1 is *circled* in *green*. PROTHROMBIN

Prothrombin (Mr 71,600) is a glycoprotein containing 8.2% carbohydrate that is synthesized in the liver and secreted into the blood, where it circulates as a precursor to a serine protease at a plasma concentration of 100 μg/mL.[1] The amino acid sequence of human prothrombin is 579 amino acid residues (FIGURE 9.14).[110,111,112,113–116] The sequence of human prothrombin[117,118] is identical with about 46% within the heavy chain and has a similarity of about 75% with that of other vertebrates. Prothrombin contains an amino-terminal Gla domain of about 40 amino acids followed by two kringle domains, each containing approximately 80 amino acids and a carboxyl-terminal region with a typical serine protease domain homologous to pancreatic trypsin (FIGURE 9.14).[114,119,120]

During biosynthesis in the rough endoplasmic reticulum, prothrombin undergoes removal of a signal peptide sequence by signal peptidase, carboxylation of amino-terminal glutamic acid residues, cleavage of the propiece by a furin-like proprotein convertase, and the addition of three carbohydrate chains (FIGURE 9.14). The carboxylation of 10 glutamic acid residues located within the first 40 amino-terminal residues in prothrombin is catalyzed by γ-glutamyl carboxylase, which recognizes the propeptide sequence and is responsible for the vitamin K–dependent conversion of the amino-terminal glutamic acid residues to γ-carboxyglutamate. The γ-carboxyglutamyl residues coordinate Ca^{2+} ions, leading to the binding of the Gla region to an anionic phospholipid surface. The addition of the three *N*-linked carbohydrate chains occurs at Asn78 and Asn100 in the first kringle domain while the third carbohydrate chain is added to the serine protease domain at Asn53 in the catalytic chain.[111]

During the final stages of blood coagulation, prothrombin is converted to thrombin. Thrombin is a serine protease composed of a light chain of 49 amino acids (Thr272 to Arg320) and a catalytic heavy chain of 259 residues (Ile1 to Glu259)

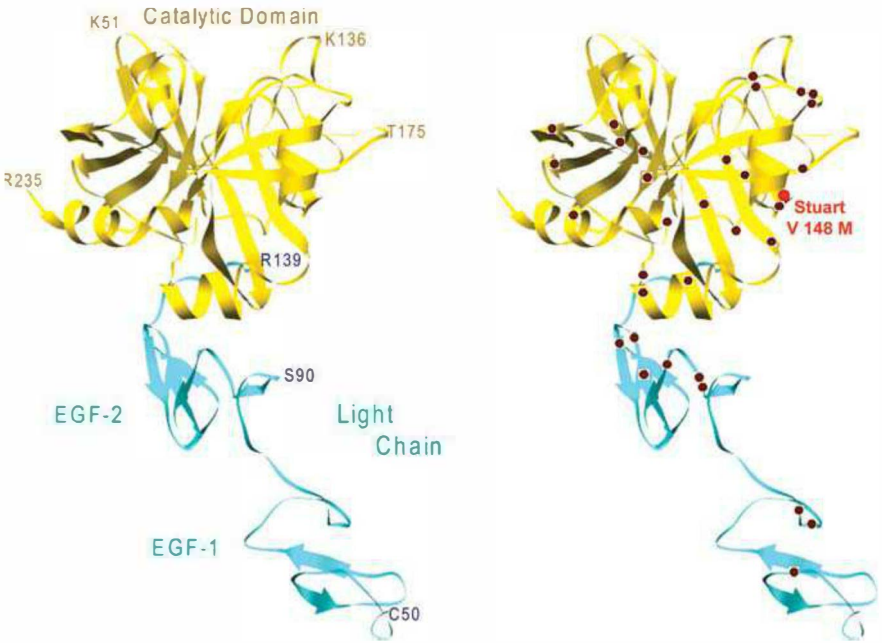

FIGURE 9.10 Ribbon structure of Gla domainless factor Xa starting with Asp46 and the Gla domainless factor Xa showing the location of missense mutations in 34 patients with factor X deficiency. The protein has a shape of a tulip with the EGF1 and EGF2 domains (*colored cyan*) forming the stem while the catalytic domain (*colored yellow*) contributes the flower. (Modified from Padmanabhan K, Padmanabhan KP, Tulinsky A, et al. Structure of human des(1-45) factor Xa at 2.2 A resolution. *J Mol Biol* 1993;232:947; Mutations are mainly from Peyvandi F, Menegatti M, Santagostino E, et al. Gene mutations and three-dimensional structural analysis in 13 families with severe factor deficiency. *Br J Haematol* 2002;117:685.)

(FIGURE 9.14), held together by a single disulfide bond. Human thrombin undergoes some additional autolysis at the Arg13Thr bond in the light chain, resulting in the removal of a 13–amino acid fragment, reducing the light chain of α-thrombin to 36 residues.

Thrombin generation is due to the cleavage of two internal peptide bonds in prothrombin catalyzed by factor Xa present in the prothrombinase complex.[121] The first cleavage at the Arg320-Ile bond generates a protease called meizothrombin (FIGURE 9.15), followed by cleavage of the Arg 271-Thr bond forming thrombin and fragment 1.2, a polypeptide containing the Gla domain and two tandem kringle domains. The replacement of the Arg271 by Cys results in a defective molecule (prothrombin Barcelona), demonstrating the importance of this cleavage site.[122]

In the absence of factor Va, the first cleavage of prothrombin by factor Xa occurs at the Arg271-Thr peptide bond generating fragment 1.2 and prethrombin-2. In a second step, prethrombin-2 is cleaved at Arg320. The catalytic efficiency of the prothrombin-2 pathway, however, is slow and insufficient for physiological clot formation.[121]

Thus far, there is no crystal structure available for prothrombin. In 1989, Bode et al.[123,124] published the first detailed crystallographic structures of thrombin and compared its structure with pancreatic trypsin, with which it shares considerable structural similarity. The amino acid sequence of thrombin including the catalytic residues of His43, Asp99, and Ser205 is shown in FIGURE 9.16. These residues correspond to His57, Asp102, and Ser195 as described in the charge-relay system present in chymotrypsinogen.[125] These three important amino acids (His43, Asp99, and Ser205) are enclosed by a red-dashed oval in thrombin (FIGURE 9.16A). The His, Asp, and Ser in the catalytic site of thrombin are also located in the middle of an equatorial cleft that separates the adjacent upper and lower β-barrels or hemispheres of a roughly spherical thrombin molecule (FIGURE 9.16, A,B).[123] The upper lip of the substrate-binding cleft contains the 60 loop

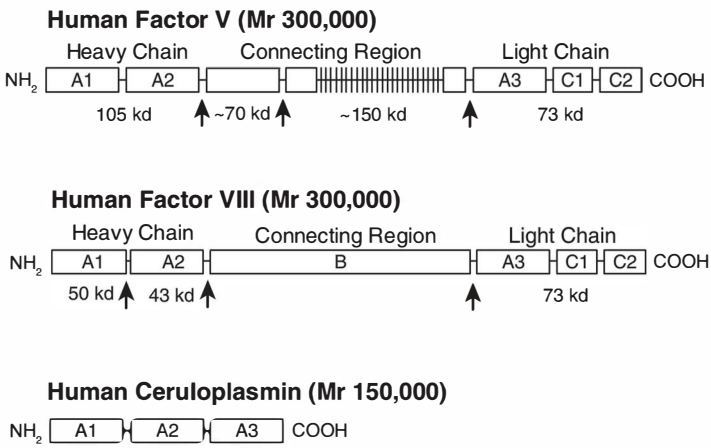

FIGURE 9.11 Structural domains in factor V, factor VIII, and ceruloplasmin. Thrombin cleavage sites are indicated by *solid arrows*. The identity of the domains is indicated by letters A, B, and C inside *boxes*. The 31 tandem repeats in the connecting region of factor V are indicated by *vertical bars*. The A domains in factor V correspond approximately to amino acids 1 through 331, 337 through 711, and 1,649 through 2,196. The C domains in factor VIII correspond approximately to amino acids 2,020 through 2,172 and 2,173 through 2,332. The A domains in ceruloplasmin correspond approximately to amino acids 1 through 338, 348 through 699, and 711 through 1,047.

(*magenta shading*, FIGURE 9.16), which is primarily hydrophobic and makes contact with hydrophobic residues present amino-terminal to the scissile bond of the substrate. The lower lip or γ-loop in the substrate-binding cleft (*green shading*, FIGURE 9.16) is more hydrophilic than the 60 loop and plays a role in determining the substrate specificity at the carboxyl side of the scissile bond in the substrate.

Thrombin cleaves peptide bonds immediately following Arg, a specificity that is due to a conserved Asp201 present six amino acids prior to Ser205 and located in the bottom of the

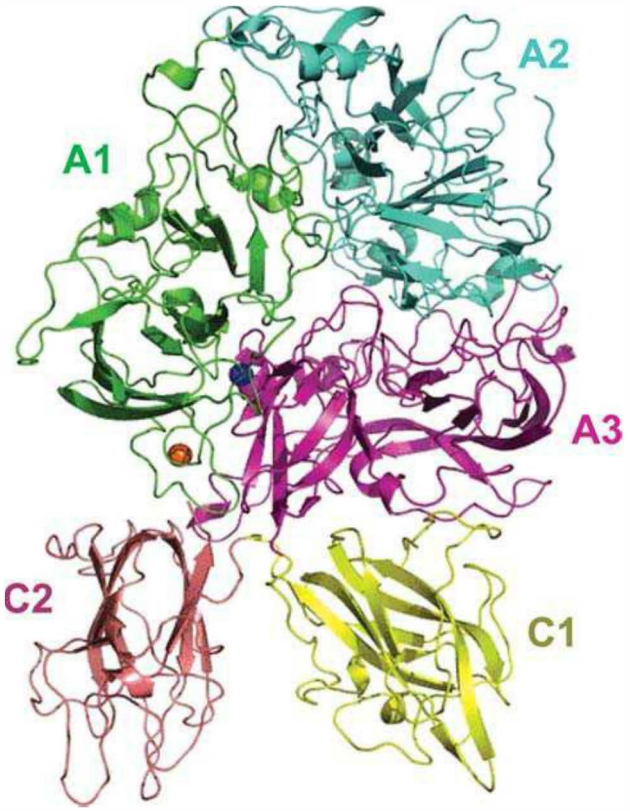

FIGURE 9.13 Model of human factor Va obtained by molecular dynamics simulations (Macedo-Ribeiro S, Bode W, Huber R, et al. Crystal structures of the membrane-binding C2 domain of human coagulation factor V. *Nature* 1999;402:434). The A1 domain is represented in *green*, A2 in *cyan*, A3 in *magenta*, C1 in *yellow*, C2 in *pink*. Ca^{2+} and Cu^{2+} are in *orange* and *blue*, respectively.

S1 primary specificity pocket. This specificity of thrombin is particularly evident for macromolecular substrates and inhibitors and is largely due to two surface regions that are distinct from the catalytic triad of Ser, His, and Asp.[126] These two surface regions are located on opposite ends of the substrate-binding groove in thrombin and have been called the anion-binding exosite I and exosite II (FIGURE 9.16C–E). Exosite I contains mainly basic amino acids including Lys21, 106, and 107 and Arg62, 68, 70, and 73 (FIGURE 9.16C–E).

Exosite II (heparin-binding site) consists mainly of the basic amino acids Arg89, 98, and 245 and Lys248 and 252. The sulfated glycosoaminoglycans present in heparin bind to thrombin by an electrostatic interaction and accelerates the rate of thrombin inhibition by antithrombin III.

The cleavage of the Arg320-Ile peptide bond in prothrombin catalyzed by factor Xa results in a new free amino-terminal Ile1 in the catalytic chain of the activated enzyme. The newly generated Ile1 turns and flips into the activation pocket of thrombin where its α-ammonium group forms a salt bridge with the carboxylate group of Asp204 (*dashed blue oval*, FIGURE 9.16A). This Asp is located just prior to the catalytic Ser205. The salt bridge induces a conformational rearrangement in the protein, leading to an active charge-relay system in the serine protease (*dashed red oval*, FIGURE 9.16A), essentially identical to that occurring in

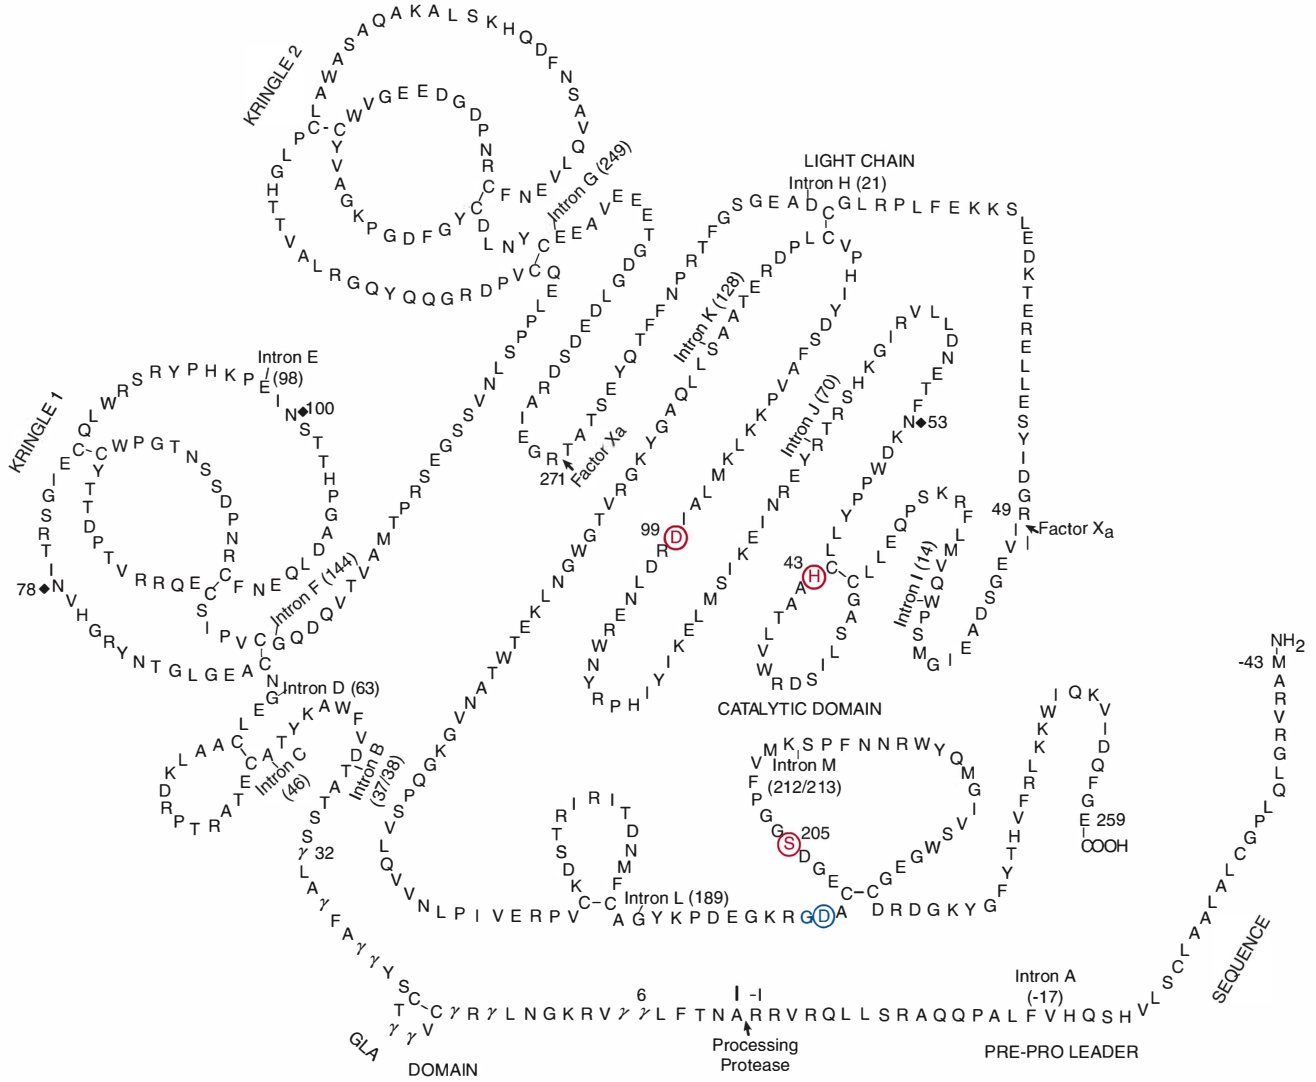

FIGURE 9.14 Amino acid sequence for human prepro prothrombin and the location of the 14 introns (A to M) (Degen SJ, Davie EW. Nucleotide sequence of the gene for human prothrombin. *Biochemistry* 1987;26:6165). The prepro leader sequence (−43 to −1) is removed during biosynthesis by signal peptidase and a processing protease that hydrolyzes the Arg(−1)-Ala bond. The Gla domain and the kringle domains are located within residues 1 through 271, which constitute fragment 1. This fragment is released from prothrombin during its conversion to thrombin by factor Xa. The light chain in thrombin is generated by the cleavage of the Arg319-Ile bond by factor Xa, and this chain is attached to the catalytic domain by a single disulfide bond. The serine protease or catalytic domain of thrombin contains 259 residues, including the three principal amino acids participating in catalysis. These three amino acids (His363, Asp419, and Ser525) are *circled*. Three potential carbohydrate attachment sites are shown by *solid diamonds*. The proposed disulfide bonds in human prothrombin have been placed by analogy to those in the bovine molecule.

the activation of pancreatic trypsin and all the other coagulation factors that form serine proteases.

The gene for human prothrombin (F2) is present in approximately 21 kb of DNA,[111,112,127,128] and it contains 13 introns (A through M) (FIGURE 9.14) (84 to 9,447 bp) and 14 exons (25 to 315 bp) located in the coding and 3′ noncoding portions of the gene (Table 9.2). The first intron (A) is in the prepro leader sequence at residue −17 while the second intron (B) follows the Gla domain between residues 37 and 38 in the mature protein. The third intron (C) is nine residues later at residue 46. These three introns are located in positions analogous to the first three introns in the coding regions of the genes for factor VII, factor IX, factor X, and protein C (Table 9.1).[27,72,129,130,131] The fourth intron (D) is just before the first kringle, whereas the next intron (E) is present within the first kringle. The fifth intron (F) is located immediately following kringle 1 (residue 144) and the sixth (G) immediately after kringle 2 (residue 249). The seventh intron (H) occurs in the region of prothrombin that becomes the light chain and the remaining five introns (I through M) are located in the catalytic domain at positions 14, 70, 128,

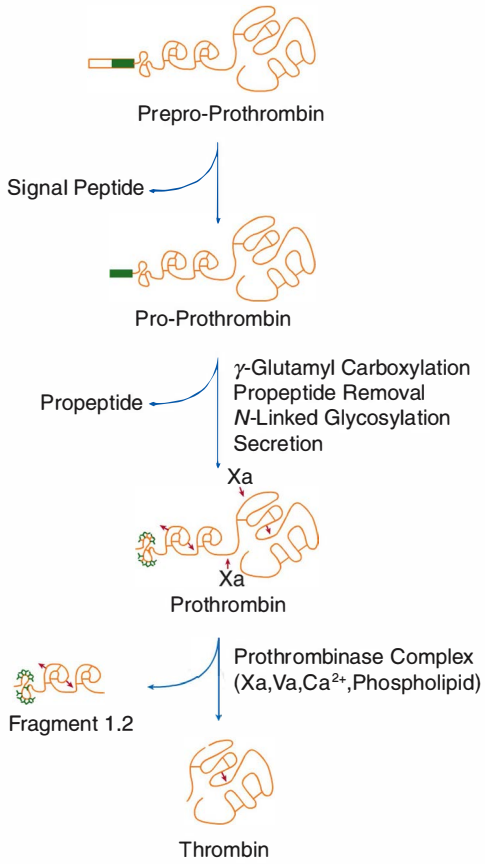

FIGURE 9.15 The processing and biosynthesis of prothrombin and the generation of thrombin. (Reprinted from Davie EW, Kulman JD. An overview of the structure and function of thrombin. *Semin Thromb hemost* 2006;32(Suppl 1):3, with permission.)

189, and between residues 212 and 213. The sequences at the splice junctions agree with the GT-AG rule of Breathnach and Chambon[132,133] and the consensus sequence of Mount,[133] except for one splice site at the 5′ end of intervening sequence L.[112]

The gene for prothrombin also contains 30 copies of Alu repetitive sequences, which make up 39% of the gene.[112] This family of DNA sequences is composed of approximately 300 nts, and the human haploid genome contains roughly 350,000 copies of Alu repetitive sequences.[134] In the prothrombin gene, many Alu sequences are tightly clustered and include five sets of tandem repeats. Intervening sequence L (9.5 kb) contains 20 Alu repeats, five of which occur in head-to-tail orientation with no additional DNA between them. The prothrombin gene also contains two copies of partial KpnI repeats (170 bp and 326 bp) located in intervening sequence L.

The mRNA for human prothrombin includes 1,866 nts that code for a prepro leader sequence of 43 amino acids and a mature polypeptide chain of 579 amino acids (FIGURE 9.14).[111,112] The prepro leader sequence includes a hydrophobic stretch of amino acids (residues –37 to –26) and ends with an arginine residue just before the amino-terminal alanine that is present in the circulating protein. The Arg-Ala peptide bond, however, is not cleaved by signal peptidase.[135] This enzyme cleaves the prepro polypeptide chain near the middle of the prepro leader sequence at one of the small amino acid residues such as alanine cysteine, or serine, leaving a propiece (18 to 24 amino acids) still attached to the polypeptide; the propiece is then cleaved by a second processing protease with a substrate preference for a basic residue at –4, –2, and –1.[29]

A prepro leader sequence, typical of the vitamin K–dependent coagulation factors (FIGURE 9.8), plays a role in the carboxylation reaction that occurs on the lumen side of the rough endoplasmic reticulum.[136,137] The conserved Phe and Ala residues at positions –16 and –10 appear to play an important role in the recognition sequence for this carboxylase.[138,139]

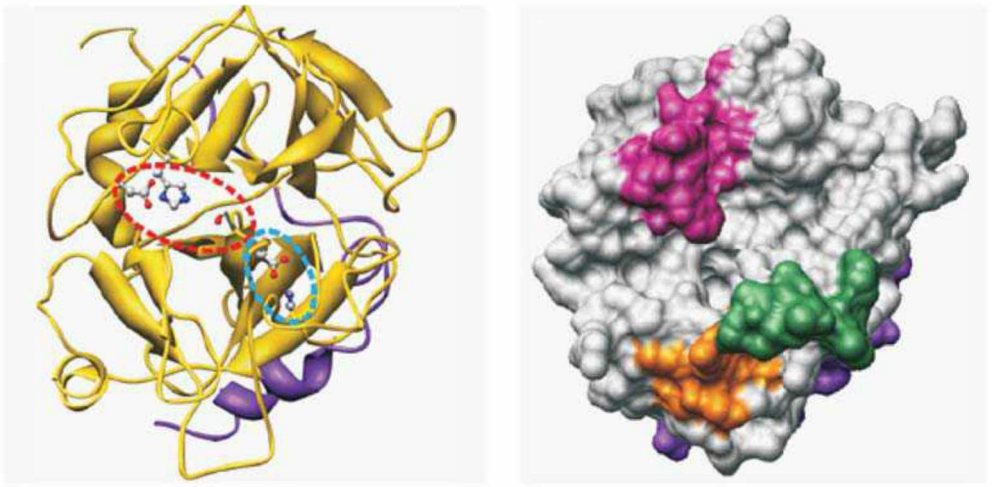

FIGURE 9.16 The catalytic and anion-binding exosites I and II in thrombin. The ribbon structure of thrombin **(A)** shows the catalytic triad of His43, Asp99, and Ser205 (enclosed in a *red-dashed circle*) and the salt bridge formed between Ile1 and Asp204 (enclosed in a *blue dashed circle*). The surface representations of thrombin are shown in the left **(C)**, standard **(B** and **D)**, and right **(E)** orientations. Like the other vitamin K–dependent coagulation factors, the liver-specific expression of prothrombin is transcriptionally regulated. The immediate 5′-flanking sequence does not contain TATA or CCAAT boxes, and the two major transcription start sites are located at –36- and –23-bp upstream of the initiator codon.[140] Full tissue-specific promoter activity is located within 1,000 bp of the transcription start sites.[140–142] A weak positive element lies in the region 400-bp upstream of the mRNA coding sequence, accounting for approximately 5% of the total promoter activity in HepG2 cells. A liver-specific enhancer element is located in the region between –940 and –860 bp. DNA protein–binding studies and functional reporter gene analysis with mutant promoter constructs have demonstrated that this 80-bp enhancer contains an HNF-1–binding site flanked by a G-C–rich motif that binds a ubiquitous Sp1-like transacting factor.[140,141,143] All together, six different transcription factors bind to the prothrombin enhancer region and at least three (HNF-4-alpha, HNF-3-beta, and Sp1/Sp3) are important in the regulation of prothrombin expression.[143]

A common G to A substitution at nucleotide position 20,210 in the 3′-untranslated end of the prothrombin gene results in an elevated level of circulating prothrombin and a 2.8-fold increased risk for venous thrombosis.[144,145]

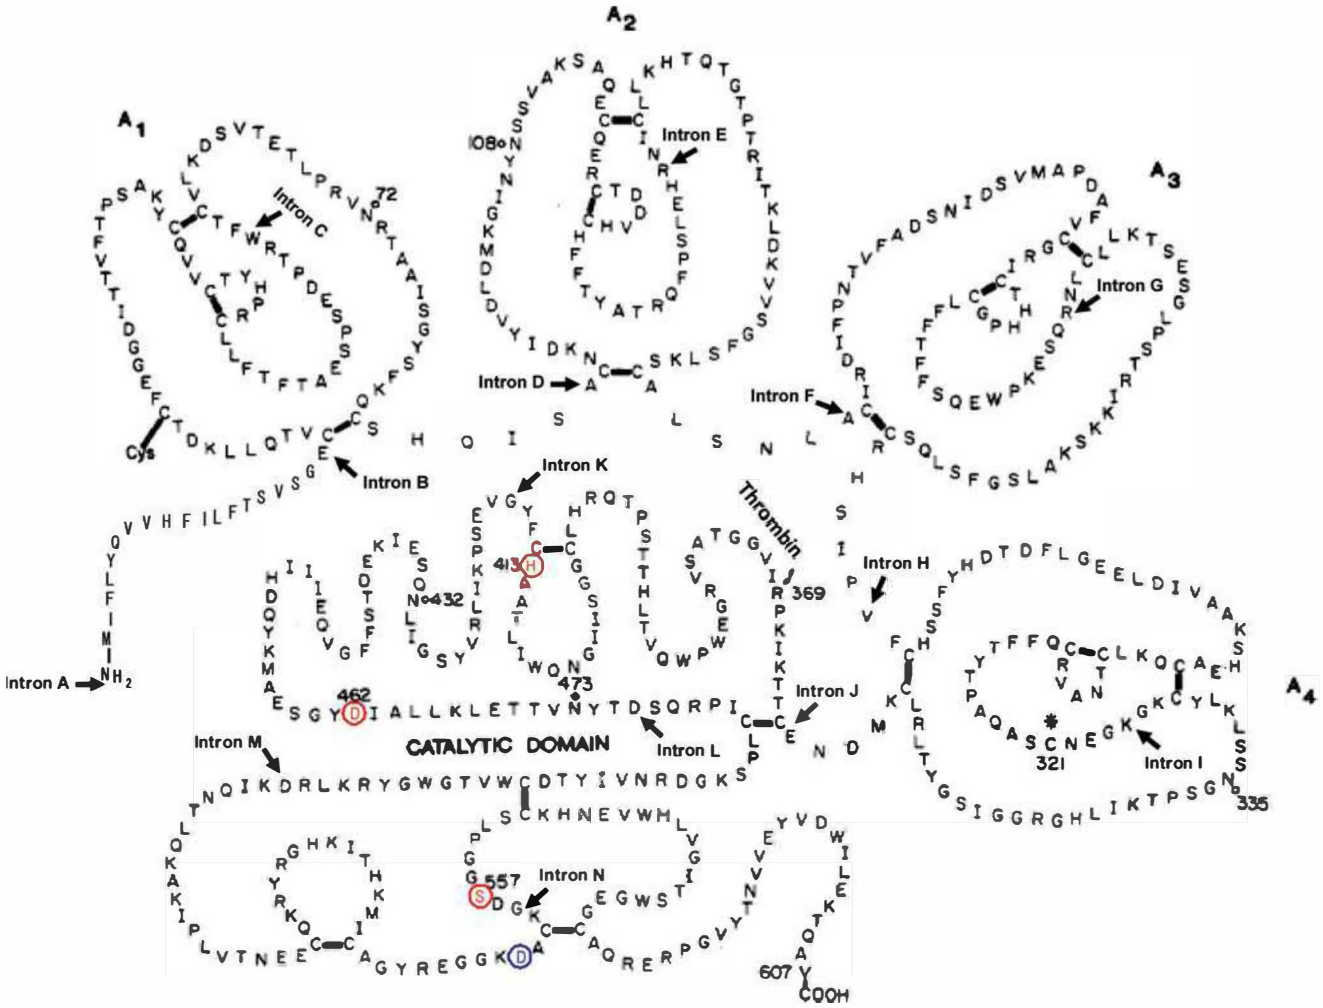

FIGURE 9.17 Amino acid sequence of human prepro factor XI. The signal sequence (−18 to −1) is removed during biosynthesis by signal peptidase by cleavage of the Gly(−1)-Glu bond. Factor XI circulates in plasma as a homodimer connected by a single disulfide bond linking Cys321 in the fourth apple domains of both subunits. The location of the 14 introns (A to N) is shown by *solid arrows*. The four apple domains (of 90 or 91 amino acids) are labeled A1, A2, A3, and A4. The site of cleavage (Arg369-Ile) catalyzed by thrombin during the conversion of factor XI to factor XIa is shown with a *small arrow*. The three members of the catalytic triad (His413, Asp462, and Ser557) are *circled*. The four *N*-linked carbohydrate attachment sites (Asn72, 108, 432, and 473) are shown by *solid diamonds*.

FACTOR XI

Factor XI (Mr 143,000) is a plasma glycoprotein (5% carbohydrate) composed of 1,214 amino acids synthesized in the liver and secreted into the plasma as a zymogen that circulates as a complex with high molecular weight kininogen (HMWK).[146] Factor XI is an unusual zymogen to a serine protease in that it contains two identical polypeptide chains, each with a catalytic site,[147] linked by a single disulfide bond in the fourth apple domain (Cys321) (FIGURE 9.17).[148,149] Each of these chains contains four tandem repeats of 90 (or 91) amino acids ("apple" domains) that range in identity from 23% to 34% (FIGURE 9.17)[150] and are linked by disulfide bonds between the first and sixth, second and fifth, and third and fourth half-Cys.[148] An extra half-Cys (Cys11) present in apple 1 forms a disulfide bond with another half-Cys residue, whereas Cys321 in each fourth apple domain links the two identical polypeptide chains of the protein together by a disulfide bond. The four apple domains in factor XI are also highly homologous to the four tandem repeats present in plasma prekallikrein but have not been identified in any other protein.[151,152] Present evidence indicates that factor XI is bound to HMWK through apple 1, whereas apple 2 is involved in the interaction of factor XI with factor IX.[153–156] The two catalytic domains in factor XI contain amino acid sequences typical of the pancreatic trypsin family of serine proteases and are located in the carboxyl end of the protein (FIGURE 9.17). The four apple domains and the catalytic domains in the dimer of factor XI are readily observed in the crystal structure of the protein (FIGURE 9.18A,B).[157] Each apple domain (60 × 60 × 20 Å) consists of a single α-helix surrounded by seven antiparallel β-strands. The four tandem apple domains form a shape that resembles a flat saucer. In the dimer, the two saucers are located between the two catalytic domains where they form an inverted V shape.

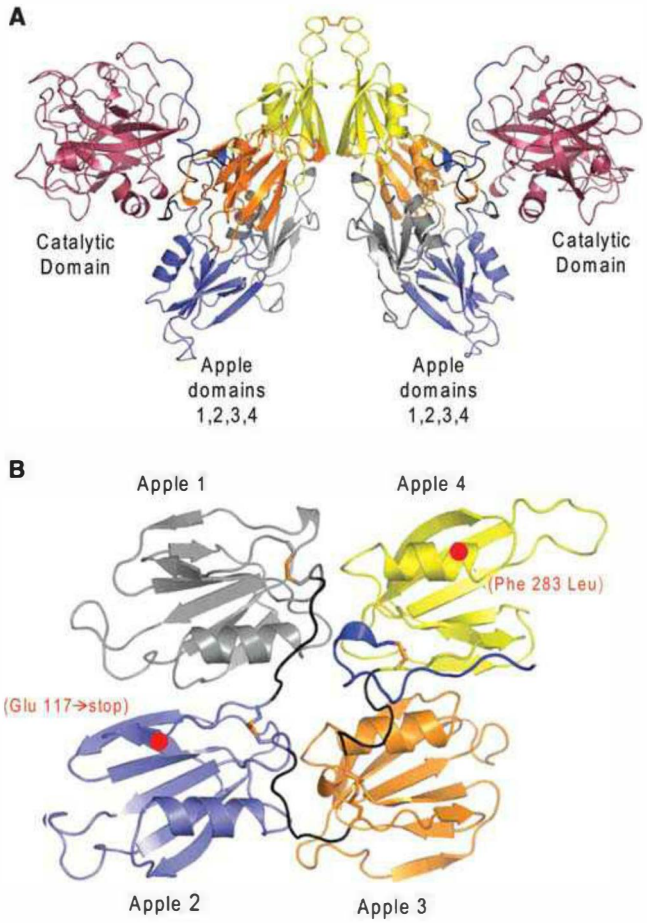

FIGURE 9.18 Ribbon structures of the factor XI dimer **(A)** and the four apple domains of factor IX **(B)**. The two catalytic sites are on the outside of the catalytic domains (colored *magenta*), while the two sets of four apple domains are in the middle where they are linked by a single disulfide bond between Cys321 from each of the apple four domains **(A)**. Apple 1 is colored *gray*, apple 2 is *blue*, apple 3 is *orange*, and apple 4 is *yellow*. (Reprinted from Papagrigoriou E, McEwan PA, Walsh PN, et al. Crystal structure of the factor XI zymogen reveals a pathway for transactivation. *Nat Struct Mol Biol* 2006;13:557, with permission.)

Factor XIa is a glycoprotein with five potential *N*-glycosylation sites in each chain. There are four carbohydrate chains, including two on the heavy chain (Asn72 and Asn108) and two on the catalytic or light chain (Asn432 and Asn473), but none on Asn335 of the heavy chain.

The conversion of factor XI to factor XIa catalyzed by thrombin readily occurs in the presence of a negatively charged material such as dextran sulfate, sulfatide, or heparin.[158,159] Factor XI can also be activated *in vitro* by factor XIIa in the presence of HMWK and a negatively charged surface.[160] Both of these activation reactions are due to the cleavage of an internal Arg369-Ile peptide bond in each of the two polypeptide chains,[150] resulting in the formation of factor XIa, a serine protease composed of two heavy chains (each 369 amino acids) and two light chains (each 238 amino acids) held together by three disulfide bonds. Each of the two light chains contains a serine protease domain that starts with Ile370. During the activation of factor XI, the newly generated Ile370 turns and flips into the activation pocket where its α-ammonium group forms a salt bridge with the carboxylate group of Asp556. This generates an active serine protease that includes the catalytic triad of His413, Asp462, and Ser557 in the light chain of each factor XIa subunit.

The cDNA for human factor XI has been isolated from a λgt11 expression library prepared from human liver. This mRNA was approximately 2,100 nts long.[150] These data also indicated that factor XI is synthesized as a single polypeptide chain with a typical leader sequence of 18 amino acids (FIGURE 9.17). Each of the two chains present in the mature molecule contains 607 amino acids. Also, the cDNA for factor XI contains a potential polyadenylation or processing sequence of AACAAA rather than the typical AATAAA.[28] This sequence is located 21 nts upstream from the poly(A) tail and is present in the 166 nts that constitute the 3′ noncoding sequence of the mRNA.

The gene for human factor XI (F11) is approximately 23 kb, located on the distal end of the long arm of chromosome 4 (4q35)[161,162] and contains 15 exons interrupted by 14 introns (FIGURE 9.17). The first exon codes for the 5′-untranslated region, whereas exon II codes for the signal peptide. The four apple domains are coded by the next eight exons. Each apple domain is coded by two exons interrupted by a single intron, and these introns are located in essentially the same position within each of the four apple domains. The carboxyl-terminal region of factor XIa containing the catalytic chain is coded by five exons, four of which are located in the same positions as those in the genes for human tissue plasminogen activator and human urokinase.

Factor XI deficiency is an unusually mild bleeding tendency that occurs in either sex.[163] Factor XI deficiency is found primarily in the Ashkenazi Jewish population,[164] and mutations occurring almost entirely in two regions of the gene coding for apple 2 and apple 4. The first mutation (type II) results in a stop codon at residue 117 in apple 2, where GAA coding for Gln117 is replaced by a stop codon of TAA (FIGURE 9.18B), leading to the synthesis of a truncated polypeptide and loss of biological activity. The second principal mutation (type III) results in an amino acid substitution at Phe283 in the fourth apple domain by Leu,[165] resulting in reduced dimerization of the molecule and a lowered secretion.[166] The third, far less common mutation (type I), disrupts normal mRNA splicing and changes a nucleotide sequence of GTAAC to ATAAC at the last intron–exon boundary.[165]

In a study of 43 patients with severe factor XI deficiency, 49% were due to the type II mutation and 47% to type III.[167,168] More than 152 different mutations have been published that occur in all four apple domains as well as in the catalytic domain.[169]

FACTOR IX

The gene for factor IX (F9), like factor VIII, is located in the distal region of the long arm of the X chromosome. No link, however, exists between the genes for these two proteins.[170,171,172] The factor IX gene is in region Xq27 and is closely linked to the fragile X site.[173]

Factor IX (Mr 57,000) is a single-chain glycoprotein (17% carbohydrate) composed of 415 amino acids (FIGURE 9.19).[170,171,172] Like prothrombin and factor VII, it is a vitamin K–dependent protein and contains 12 residues of γ-carboxyglutamic acid

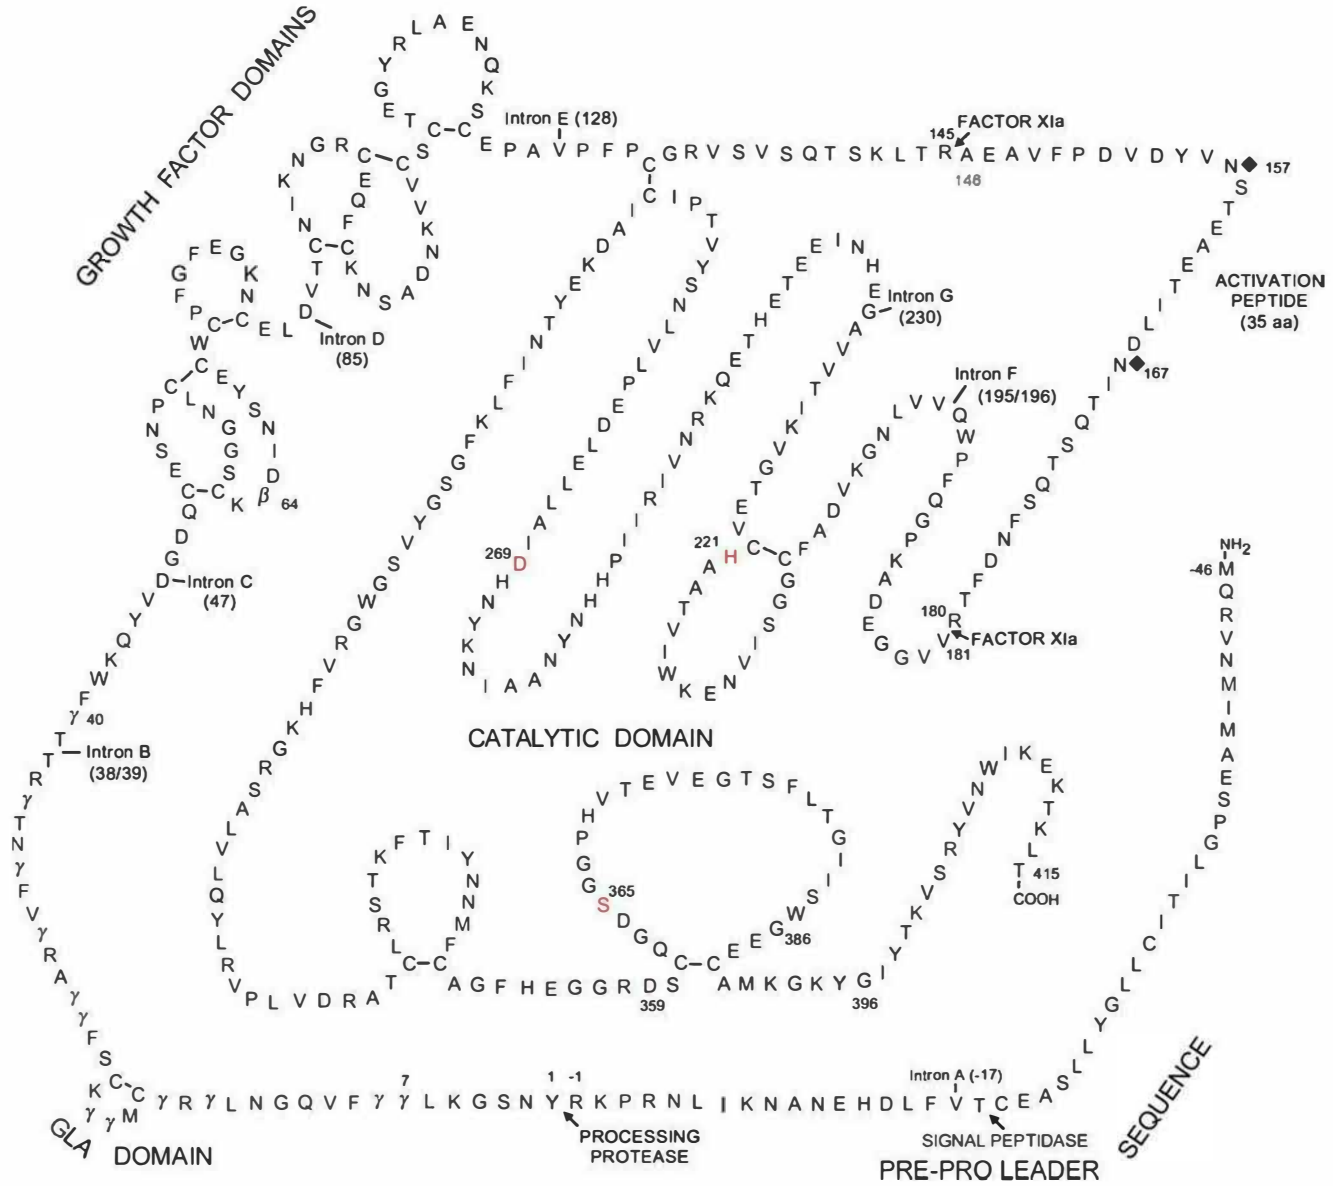

FIGURE 9.19 Amino acid sequence of human prepro factor IX and the location of the seven introns (A to G). The prepro leader sequence (–46 to –1) is removed during biosynthesis by signal peptidase and a processing protease that hydrolyzes the Arg(–1)-Tyr bond. The Gla domain and epidermal growth factor domains are located within residues 1 through 145, which constitute the light chain of factor IXa. The activation peptide of 35 residues is released from factor IX during its conversion to factor IXa by factor XIa. The amino acids at which this cleavage occurs (Arg145-Ala and Arg180-Val) are *circled*. The serine protease or catalytic domain of factor IX contains 235 residues, including the three principal amino acids participating in catalysis. These three amino acids (His221, Asp269, and Ser365) are also *circled*. Two potential carbohydrate attachment sites in the activation peptide are shown by *solid diamonds*. The proposed disulfide bond in factor IX have been placed by analogy to those in bovine prothrombin and epidermal growth factor.

(Gla domain) located in the amino-terminal region of the protein. The Gla domain is followed by two EGF-like domains, which show considerable homology with the corresponding regions of factor VII, factor X, protein C, and protein S.[73–75,174] The two EGF domains in factor IX are followed by an activation glycopeptide and a catalytic domain of 235 amino acids (FIGURE 9.19). The individual domains are readily identified in tulip-shaped crystal structure (FIGURE 9.20),[175] which has a stem composed of the amino-terminal Gla domain and two EGF domains attached to the catalytic domain that forms the blossom (FIGURE 9.20).

Factor IX is cleaved at two internal arginine peptide bonds (Arg145-A1a and Arg180-Val, FIGURE 9.19) by factor XIa or the factor VIIa–TF complex, generating factor IXa, a serine protease composed of a light chain and a heavy chain held together by a disulfide bond.[1,176] During the activation reaction, a glycopeptide of 35 amino acids is released, generating

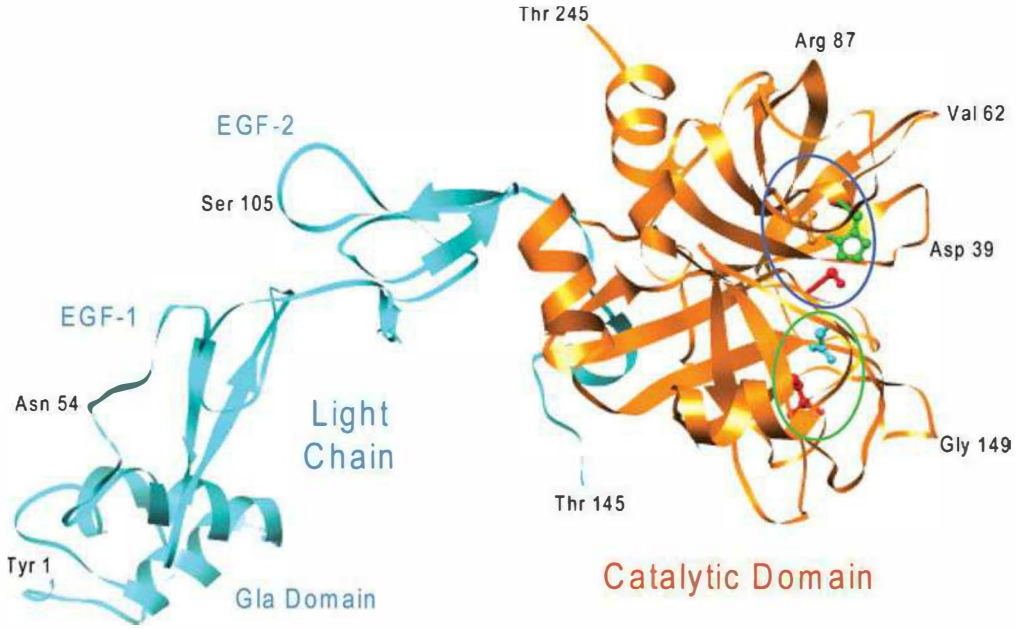

FIGURE 9.20 A ribbon structure of human factor IXa. The salt bridge formed between Val181 and Asp364 during the activation of factor IX is *encircled* in *green*, while the catalytic triad of His221, Asp269, and Ser365 are *encircled* in *blue*. The light chain of factor IXa, including the Gla domain and the two epidermal growth factor domains are *colored cyan*, while the catalytic domain is *colored orange*. (Modified from Davie EW, Kulman JD. An overview of the structure and function of thrombin. *Semin Thromb hemost* 2006;32(Suppl 1):3.)

a new amino-terminal Val181 in the heavy chain. The Val181 is then inserted into the activation pocket of the enzyme where its α-ammonium group forms a salt bridge with the carboxylate group of Asp364, a residue located next to the active site Ser365 (*encircled in green*, FIGURE 9.21), generating a serine protease with an active catalytic triad of His221, Asp269, and Ser365 (*encircled in blue*, FIGURE 9.20).

A model of the 1:1 factor IXa complex with factor VIIIa in the presence of phospholipid and calcium based on the lowest energy structure is shown in FIGURE 9.21.[177] The A2 and A3

The tertiary structure and domain organization of coagulation factor VIII. *Blood* 2000;96:979). The factor VIIIa A1, A2, and A3 domains are colored *dark gray*, while the C1 and C2 domains of factor VIIIa are colored *light gray*. The factor IXa light chain is colored *yellow*, while the catalytic domain is colored *orange*. Phospholipid-binding regions are colored *blue*. (From Ngo JC, Huang M, Roth DA, et al. Crystal structure of human factor VIII: implications for the formation of the factor IXa–factor VIIIa complex. *Structure* 2008;16:597.)

Table 9.3

Location and size of exons and introns in the human factor IX gene (F9)

Exon	Nucleotide Positions[a]	Length (bp)	Amino Acids[b]	Intron	Nucleotide Positions	Length (bp)
I	1–117	117	–46 to –17	A	118–6,325	6,206[c]
II	6,326–6,489	164	–17 to 37	B	6,490–6,677	188
III	6,678–6,702	25	38–47	C	6,703–10,391	3,689
IV	10,392–10,505	114	47–85	D	10,506–17,668	7,163
V	17,669–17,797	129	85–128	E	17,798–20,362	2,565
VI	20,363–20,565	203	128–195	F	20,566–30,038	9,473
VII	30,039–30,153	115	196–234	G	30,154–30,821	668
VIII	30,882–32,757	1,935	234–415	—	—	—

bp, base pair.
[a]Includes 30 nts of the 5′ end and 1,390 nts of the 3′ noncoding sequences.
[b]Amino acids encoded in each exon; negative numbers refer to amino acids in the prepro leader sequence.
[c]Includes the 50 extra nucleotides in the polymorphic DNA.

domains of factor VIIIa interact with multiple domains in factor IXa to form the complex.[178,179] The C1 and C2 domains in factor VIIIa and the Gla domain on factor IXa (*colored dark blue*) are at the bottom of the complex bound to the membrane surface. The catalytic site in factor IXa is at the top of the complex about 75 to 80 Å above the membrane surface and is readily available to bind and cleave factor X.

The gene for human factor IX (F9)[129,131] contains approximately 34 kb of DNA, including eight exons (I to VIII) and seven introns (A to G) located within the coding and 3′ noncoding region of the gene (FIGURE 9.19). The eight exons range in size from 25 bp (exon III) to 1,935 bp (exon VIII). Exons I and II code for a prepro leader sequence and a Gla domain, whereas exons IV and V each codes for EGF domains. The last three exons code for the activation peptide and the catalytic domain. The seven introns range in size from 188 nts (intron B) to 9,473 nts (Intron F) (Table 9.3). The introns are located in positions essentially identical to those in factor VII, factor X, and protein C (Table 9.1).

Originally, it was suggested that the initiation site for mRNA synthesis starts at an A 29 nt upstream from the initiation methionine, but other studies indicate three major transcription sites, including +1, +4, and +30 as well as a minor site at +8.[180] Therefore, there may be considerable heterogeneity of transcription initiation, reflecting the absence of a well-defined or typical TATA-like promoter element in the 5′ end of the gene. The 5′ end of the gene also contains three Met codons (at –46, –41, and –39) for polypeptide initiation, but the Met(–39) is the only one conserved in the human, monkey, dog, and murine factor IX genes.[181,182] This suggests that the Met(–39) is the most probable initiation site for human factor IX biosynthesis under physiologic conditions.

The transcriptional regulation of the factor IX gene has been the most extensively studied of all the vitamin K–dependent coagulation factors. This is due to the Leiden phenotype, a rare form of hemophilia B that is characterized by spontaneous correction of severe childhood hemophilia B with the onset of puberty.[183] The genetic defects that confer the factor IX Leiden phenotype have been found to be single-nucleotide substitutions within a 54-bp region of the factor IX transcriptional promoter.[33,184–188] The developmental timing of the expression of the factor IX gene characterized by these mutations suggests that the transcription of the factor IX gene is, in part, hormonally mediated. A consensus androgen response element (ARE) has been identified between nts –36 and –17 of the factor IX promoter.[189,190] This sequence overlaps a functional HNF-4–binding site. Interestingly, a substitution of C for G at –26 bp causes lifelong hemophilia B, presumably by disruption of the ARE, whereas substitutions at –21 and –20 bp (A, G, or C for T in the sequence ACTTTG) result in disruption of the HNF-4–binding site and the Leiden phenotype.[33,187,190] These data suggest that androgen binding can partially overcome the negative effect of impaired HNF-4 binding to the promoter. Other Leiden mutations include nucleotide substitutions at positions –6, –5, + 8, and +13 relative to the transcription start site.[191] These mutations correspond to a disruption in the proximal C/EBP-binding site (+1 to +18 bp) and a disruption in the binding site of an uncharacterized transactivating regulatory factor (–15 to –1 bp).[184,192] Experiments investigating the molecular mechanisms explaining Leiden-specific mutations outside the putative ARE have identified interactions between C/EBP and the hormonally regulated transcription factors D-site–binding protein and hepatic leukemia factor.[193–196] Accordingly, the hormonal sensitivity of the factor IX promoter may be mediated by both direct androgen receptor binding to the promoter and the indirect regulatory effects of androgen receptor on the expression of developmentally regulated transcription factors. The factor IX promoter is complex and includes a negative regulatory or silencer activity in the region spanning –1,700 to –1,400 bp.[197] This region contains the short sequence ATCCTCTCC, which has been associated

with the silencer activity in several genes expressed primarily in the liver.[198]

Kurachi et al.[199,200] have found that the factor IX gene contains two age-related stability elements (ASE): a short sequence from –797 to –776 bp with an enhancer-like ASE-5′-element and the other ASE element, which confers an increased mRNA stability, in the middle of the 3′-untranslated region in an extensive stretch of dinucleotide repeating structures.

The gene for factor IX contains four Alu sequences.[131] The first is located in intron A, with the next three in intron F. A fifth Alu sequence is present in the 3′-flanking region of the gene, located approximately 230 nts downstream from the poly(A) adenylation site. Each of the five Alu sequences contains short direct flanking repeats ranging from 7 to 14 nts long. The gene for factor IX contains other repetitive sequences, including two KpnI repetitive elements, in the 5′ end of the gene and within intron D.

A major polymorphic site involving a deletion of 50 nts is present within intron A[201]; a second is a TaqI site after the fourth exon in the gene; and[173,202], a third site is in exon VI that codes for the activation peptide[203] results in the conversion of Ala3 (GCT) to Thr (ACT). The threonine appears to be more prevalent in the general population, with a frequency perhaps as high as 0.8.A fourth polymorphism in intron C, in which a G has been changed to a C, results in a loss of a recognition site for endonuclease XmnI.[201] These polymorphic sites have made it possible to establish methods for carrier detection of factor IX deficiency.

At present, hundreds of factor IX abnormalities have been defined at the protein and gene level. Factor IX Chapel Hill is due to a change of a G (in CGT) to an A (in CAT) in exon VI, causing a substitution of a His for Arg145.[204] Accordingly, the cleavage of a critical Arg-Ala bond by factor XIa during the coagulation process is blocked, reducing the activity of factor IX Chapel Hill to approximately 8% of normal.

One of the most interesting cases of hemophilia also known as the "royal disease" was associated with Queen Victoria of England (1819 to 1901), who was a carrier of hemophilia (factor VIII or factor IX deficiency). One of her granddaughters was Empress Alexandra (1872 to 1918),[205] the mother of Crown Prince Alexis (1904 to 1918), who inherited severe hemophilia from his mother (FIGURE 9.22A).[206] In July 2007, a grave was discovered near Ekaterinburg, which contained bone fragments identified by DNA sequencing to belong to Prince Alexis and his sister Anastasia, who were the two youngest children of Nicholas II and Alexandra.[207–209] Sequence analysis of DNA from members of the Tsar's family showed no missense or small insertion or deletion mutations in the coding regions of genes for factor VIII or factor IX, but an A to G mutation (nt 10,389) was found in intron C located three base pairs upstream of exon IV in the splice acceptor site of the factor IX gene.[210,211] This resulted in a change of the wildtype sequence of AAAG/ATGGA to

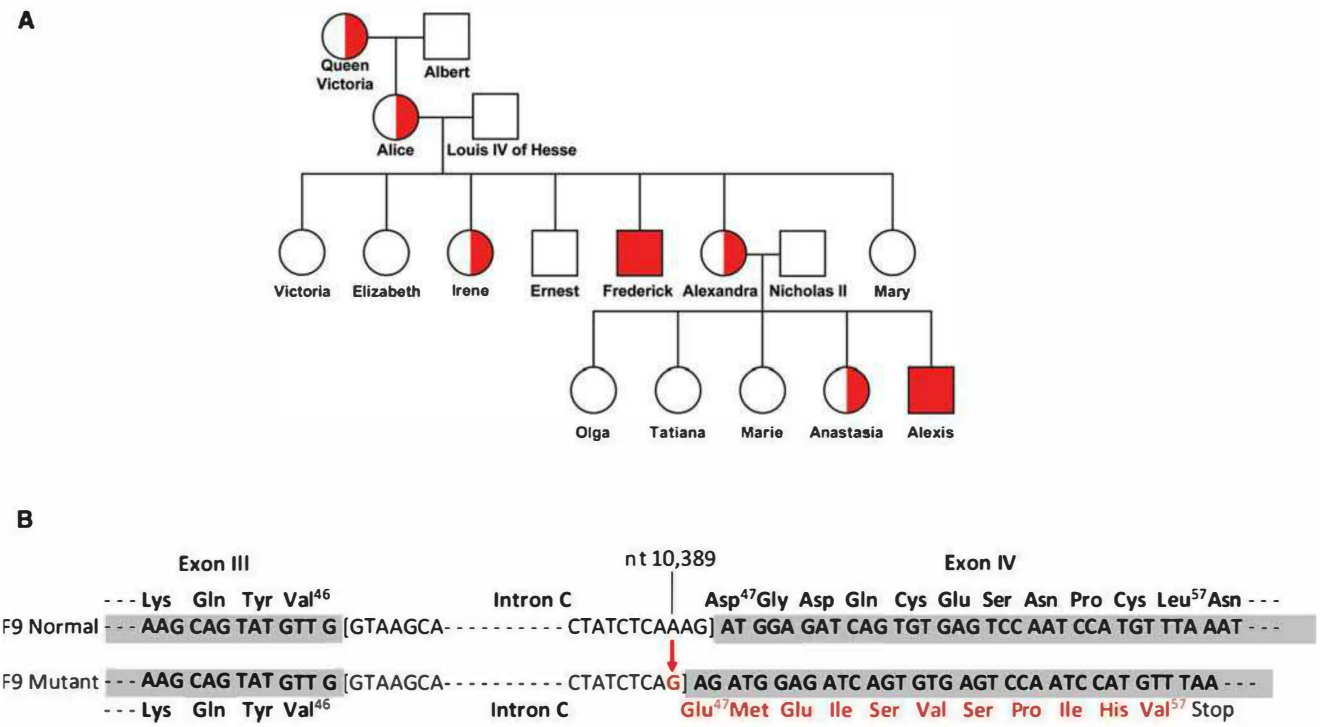

FIGURE 9.22 **A:** A partial family tree of Empress Alexandra. The female carriers of factor IX deficiency are shown with half-red circles, while males with factor IX deficiency are shown with red squares. **B:** The DNA sequence in intron C of the normal and mutated factor IX gene. The A to G mutation (nt 10,389 in the factor IX gene) occurred three base pairs upstream of exon IV in the splice acceptor site. (Modified from Lannoy N, Hermans C. The 'royal disease'—haemophilia A or B? A haematological mystery is finally solved. *Haemophilia* 2010;16:843 and Rogaev EI, Grigorenko AP, Faskhutdinova G, et al. Genotype analysis identifies the cause of the "royal disease". *Science* 2009;326:817.)

AG/AGATGGA and a different nucleotide sequence in the mRNA coding for factor IX. In addition, a premature downstream stop codon is formed and the amino acid sequence of exon IV ends with an abnormal 11–amino acid sequence (FIGURE 9.22B). As expected, an analysis of the DNA from Alexandra, a heterozygous carrier, indicated the presence of both wild and mutant alleles, while the DNA from Alexis had only the mutant allele. One of Alexis's sisters presumed to be Anastasia was also a heterozygous carrier of the mutation (FIGURE 9.22A). This splice junction mutation in the factor IX gene has been found in three unrelated patients with severe hemophilia B.[212–214]

Another factor IX abnormality is due to a point mutation that changes an essential G in a splice junction site to a T[215] at the 5′ end of intron F, changing the exon–intron junction from GAG/GTACT to GAG/TTACT. A similar mutation in the GT donor splice sequence in the β-globin gene results in β-thalassemia.[216] Gene deletions have been reported in four out of five patients with antibodies to factor IX.[217] Two patients had deletions of more than 18 kb of DNA coding for factor IX, a third patient had a deletion of more than 9 kb, and in a fourth patient, who had <0.2% circulating factor IX antigen (factor IX Seattle 2), a deletion of a single adenine in exon V resulted in a frameshift that converted Asp85 to a Val, a stop codon at position 86, and a polypeptide of only 85 amino acids that terminated after the first EGF domain.[218] The location of the amino acid changes in factor IX from patients from 91 unrelated families with factor IX deficiency due to missense mutations is shown in FIGURE 9.23 (Xu W, Thompson AR, Davie EW. Unpublished data). The mRNA for human factor IX is approximately 2,800 nts long and includes 138 nts that code for a prepro leader sequence of 46 amino acids and 1,245 nts that code for 415 amino acids present in the circulating protein (FIGURE 9.20).[129,131,172] The prepro leader sequence of 46 amino acids includes two additional methionines that could also generate a prepro leader sequence of 41 or 39 amino acids. It is unknown which of these start sites is used under physiologic conditions. The stop codon of TAA in the mRNA is followed by a rather long 3′ noncoding sequence of 1,387 nts and a poly(A) tail. The polyadenylation sequence of AATAAA is located 16 nts upstream from the poly(A) tail.

The isolation of a cDNA coding for human factor IX has made it possible to express this protein in rat hepatoma cells, chick embryo fibroblasts, and BHK cells.[219–221] The full-length cDNA for human factor IX is coexpressed with the processing enzyme furin in CHO cells.[222] Recombinant factor IX has procoagulant function that is indistinguishable from plasma-derived factor IX[223] and is produced for therapeutic use in patients with hemophilia B.

Although most gene therapy delivery systems target the liver, other targets include myoblasts, primary fibroblasts, keratinocytes, capillary endothelial cells, and hematopoietic stem cells have been employed,[224–228] using viral vectors derived from retroviruses, adenoviruses, and herpes simplex viruses, as well as nonviral vectors such as naked DNA, DNA protein complexes, and liposome-encapsulated DNA.[229] One successful preclinical study of gene transfer for hemophilia B was accomplished by infusion of an amphotropic retroviral vector encoding canine factor IX cDNA into the Chapel Hill inbred strain of hemophilia B dogs after partial hepatectomy.[230,231]

FACTOR VIII

Factor VIII (Mr 330,000) is a large glycoprotein that is synthesized as a single-chain multidomain protein of 2,332 amino acids with a domain organization of A1-A2-B-A3-C1-C2. An internal homology (30%) of the A domain consists of a triplicated sequence at residues 1 to 329, 380 to 711, and 1,649 to 2,019 (FIGURES 9.11 and 9.24). A second duplication (40% homology) of 150 amino acids (C1 and C2 domains) is located in the carboxyl terminus of the molecule (residues 2,020 to 2,174 and 2,175 to 2,332). Copper is bound to the processed and secreted factor VIII,[232,233] but it is unclear if this ligand binding stabilizes or is necessary for the interaction between the heavy and light chains.

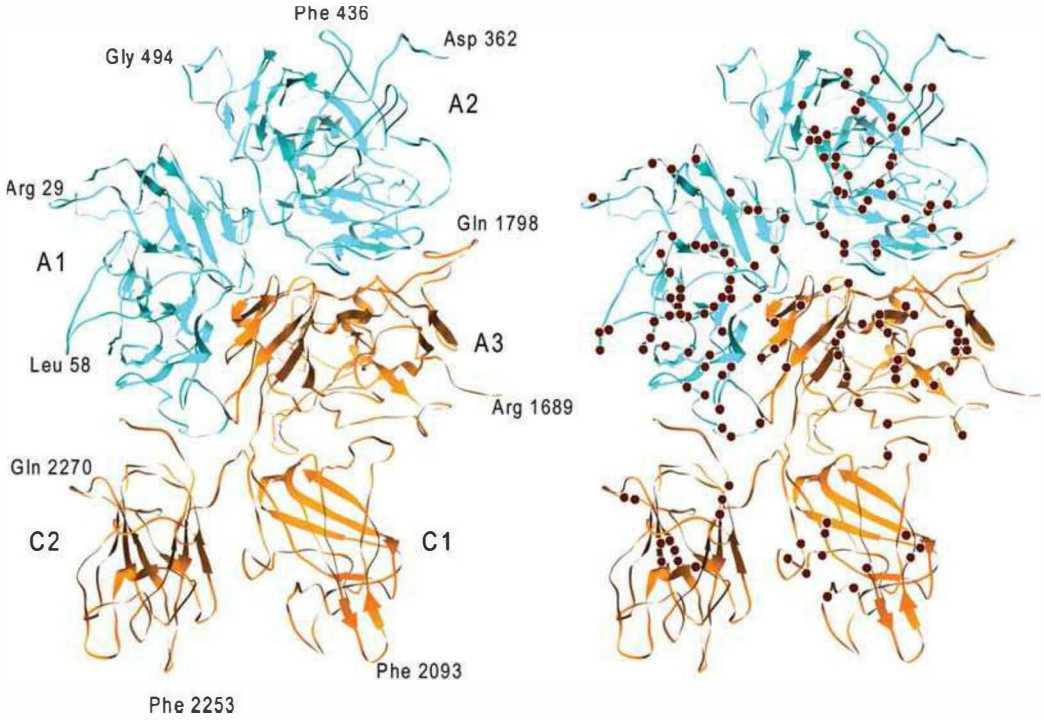

FIGURE 9.24 The ribbon structure of human factor VIII with a deleted B domain. The two structures shown in the left and right panels have their A1 and A2 domains colored *magenta*, while the A2, C1, and C2 domains are colored *orange*. The location of missense mutations resulting in severe hemophilia are shown in black dots in the A1, A2, A3, C1, and C2 domains in the right panel. (Modified from Liu ML, Shen BW, Nakaya S, et al. Hemophilic factor VIII C1- and C2-domain missense mutations and their modeling to the 1.5-angstrom human C2-domain crystal structure. *Blood* 2000;96:979.)

The heavily glycosylated B domain (connecting region) has little if any role in factor VIII coagulant activity. Factor VIII is synthesized primarily in the liver as a single-chain protein (2,332 residues) and processed into heterodimeric light and heavy chains that circulate in complex with von Willebrand factor (vWF).[234] The amino-terminal heavy chain (Mr 90,000 to 200,000) contains the A1-A2 domains and portions of the B domain, while the light chain (Mr 80,000) contains the carboxyl terminal A3-C1-C2 domains, after cleavage at Arg1648 in the B-A3 junction and other B domain sites. The binding of factor VIII to vWF as well as to membrane phosphatidylserine involves the C1 and C2 domains.[235]

Unprocessed factor VIII contains 25 potential Asn-linked carbohydrate attachment sites, located mainly in the connecting B region of the molecule between the heavy and light chains that are generated by thrombin (FIGURE 9.11). Six tyrosine sulfation sites are predicted in factor VIII, including Tyr346 in the 50-kDa fragment of the light chain; Tyr718, 719, and 723 in the 43-kDa fragment of the light chain; and Tyr1664 and 1680 in the heavy chain. Tyrosine residues in the light chain are partially sulfated in recombinant factor VIII expressed in CHO cells and fully sulfated in COS1 cells; sulfation of these residues does not influence coagulant activity but is essential for vWF binding.[236–238] Proteolytic cleavage by thrombin occurs primarily at Arg740 and Arg372 in the heavy chain and Arg1689 in the light chain. The three chains now contain the A1, the A2, and the A3-C1-C2 domains, held together by calcium, with the connecting B domain (amino acids 741 to 1,648) being split out by these proteolytic cleavages. Precisely which cleavage(s) is responsible for the activation and inactivation of factor VIII by thrombin or other proteases is unclear at present.

All five domains including the A1, A2, A3, C1, and C2 are readily identified in crystal structures[177,239,240] (FIGURE 9.24). One calcium is present in the A1 domain coordinated by Glu110 and Asp116, Asp125, and Asp126. The second calcium in the A2 domain is coordinated by Asp538 and Asp542. One copper ion was coordinated by two His and a single Cys residue in the A1 domain, while a second copper ion was coordinated by two His residues and a single Cys residue in the A3 domain. Glycosylation sites occur at Asn42 and Asn239 in the A1 domain as well as at Asn1810 in the A3 domain and Asn2118 in the C1 domain. The C1 and C2 domains are important for binding to platelets,[240] while the C2 is the binding site to vWF.[239,240]

The mRNA for human factor VIII is approximately 9,000 nts long and codes for a leader sequence of 19 amino acids and a mature protein of 2,302 amino acids.[241,242–244] The mature polypeptide chain ending in tyrosine is followed by a stop codon of TGA and 1,802 nts of noncoding sequence. A polyadenylation or processing site of AATAAA is present 19 nts upstream from the polyadenylation signal.[28]

The gene for factor VIII (F8) is located on the tip of the long arm of the X chromosome in region Xq28.[241] It contains approximately 186 kb of DNA and consists of 26 exons (69 to 3,106 nts)

and 25 introns (200 nts up to 32.4 kb).[241,242–244] Approximately 5% of the gene is present in the exons and the remaining 95% is noncoding DNA. A start site for initiation of mRNA synthesis[241] is likely at a G located 170 nts upstream from the initiating methionine.

Interestingly, intron 22 of the factor VIII gene contains an independent gene oriented in the opposite direction.[245] A transcript of 1.8 kb is present in many cells, and its cDNA isolated from a human liver library contains a long open reading frame. A comparison of the genome and cDNA sequence has revealed that this independent gene within intron 22 contains no introns.

Full promoter activity is located within the 300 bp from the initiation codon. The factor VIII regulatory region is complex in that DNA protein–binding studies show the presence of 19 binding sites distributed along the region from –1,175 to –9 bp, many of which are currently being investigated.[246–248]

The functional cis-acting elements within the fully active factor VIII promoter include HNF-1 (–64 to –35 bp), NFκB (–123 to –79 bp), C/EBPα (–203 to –149 bp), C/EBPβ (–275 to –252 bp), and HNF-4 (–312 to –279 bp).[246,247,249] Stimulation of cultured human hepatocytes with the cytokine IL6 results in a sixfold increase of factor VIII mRNA.[250] A vast number of genomic DNAs from patients with hemophilia A have been analyzed using a variety of methods.[251,252] Gross rearrangements of the gene for factor VIII, including deletions and insertions, have been found in 1% to 5% of hemophiliacs.[253,254] Accordingly, most of the defects in the gene for factor VIII are caused by point mutations. Most deletions and nonsense mutations, which create termination codons, lead to truncated molecules of factor VIII and cause severe hemophilia. Most deletions are the result of nonhomologous recombination between dissimilar sequences in which short-sequence homologies facilitate end-joining reactions.[255] Deletion breakpoints, however, are not clustered in particular regions of the factor VIII gene.[256] Deletions of the factor VIII gene are also associated with a fivefold increased risk of developing inhibitors compared with other severe hemophiliacs without gene deletion.[256]

Insertions of the transposable line 1 repetitive sequence into exon XIV have been found in two sporadic cases.[257] In each case, the inserted sequence contained most of the second open reading frame for a reverse transcriptase and poly(A) sequence; moreover, a target-site duplication at the 5′ and 3′ ends flanked the insertion.[258,259] Most cases of moderately and mildly severe hemophilia A are caused by single-point mutations that lead to impaired biosynthesis, secretion, and stability of the molecule.[260] Only a few mutations have proved to be causative for functional abnormalities of factor VIII protein, including substitutions of Arg372 and Arg1689 by Cys or His and of Tyr1680 by Phe.[261–263] The mutation at Arg372 results in a molecule that is resistant to the thrombin cleavage required for activation.[264,265] Tyr1680, as well as Arg1689, is included in a putative binding site of the light chain for vWF.[266] A number of point mutations occur at the CpG dinucleotides.[267,268] Because of the extreme heterogeneity of defects in the factor VIII molecule, intragenic DNA polymorphisms, such as the BclI site in intron 18, the XbaI site in intron 22, and a hypervariable dinucleotide repeat in intron 13, will continue to be useful in a pedigree analysis for genetic prediction.[261,269] The location of many of the amino acid changes in factor VIII due to missense mutations is shown in FIGURE 9.24.

The preparation of factor VIII by methods of recombinant DNA technology for the routine treatment of patients with classic hemophilia has been accomplished, including a recombinant factor VIII lacking the connecting B domain.[270]

FIBRINOGEN

Fibrinogen (Mr 340,000) is a dimeric plasma glycoprotein consisting of three pairs of polypeptide chains $(A\alpha,B\beta,\gamma)_2$, with apparent molecular weights of 67,600, 52,300, and 48,900, respectively, held together by disulfide bonds and folded in a trinodular structure.[271–273] The Aα chain is composed of 610 amino acids, while the Bβ chain has 461, and the γ chain has 411.[274–276]

The cDNA for the Aα chain of human fibrinogen is about 2,100 nts in length and includes a region that encodes a nascent Aα polypeptide of 644 amino acids,[277] which contains an *N*-terminal signal peptide of 19 amino acids, and a *C*-terminal extension of 15 amino acids (residues 611 to 625), which is removed from the nascent Aα chain in the hepatocyte or after secretion into the circulation. The mature Aα chain is free of carbohydrate.[278] Residues 1 to 16 of the mature Aα chain is fibrinopeptide A, which is cleaved and released by thrombin during the conversion of fibrinogen into monomeric fibrin. The remaining polypeptide chain, containing residues 17 to 610, becomes the α chain of fibrin. The Aα chain contains eight tandem repeats of approximately 13 amino acids (residues 270 to 372) of unknown function. Residues 472 to 552 of the Aα chain, least conserved among vertebrate fibrinogens, are characterized as a hypervariable region. The Aα chain contains two RGD sequences, including residues 95 to 97 in a region of the molecule that forms coiled coils with the Bβ and γ chains and a second including residues 572 to 574 that are close to the *C*-terminus of the molecule. While the RGD sequence at residues 572 to 574 does not play a significant role in platelet adhesion,[279] this sequence binds to $\alpha_v\beta_3$ and mediates adhesion to endothelial cells.[280] Three nonsynonymous polymorphic sites in the Aα chain have been identified[281]: Ile(–14)Val in the signal peptide, Thr312Ala, and Thr437Ala in the mature polypeptide. An alternatively spliced, extended variant of the Aα chain, known as the αE chain, contains 847 amino acids[282,283] and amounts to 1% of the Aα chain population. Alternative splicing of a downstream exon (sixth exon) results in the replacement of residues 611 to 625 in the prevalent Aα chain by a sequence of 236 amino acids (residues 611 to 847). Since residues 611 to 625 are proteolytically removed from the Aα chain, the overall effect of alternative splicing is to extend its length by 236 amino acids. The extended sequence is homologous to the *C*-terminal globular domains of the Bβ and γ chains: it contains two *N*-glycosylation sites,[282] binds calcium,[284] and interacts with integrins $\alpha_M\beta_2$ and $\alpha_X\beta_2$ on leukocytes.[285] Typically two αE chains are incorporated into fibrinogen, thus giving rise to a homotypic variant form of fibrinogen called fib-420 $(\alpha E,B\beta,\gamma)_2$ with a molecular weight of 420,000.[286] The level of fib-420 is threefold higher in newborns (3%) than in adults (1%). Conversion of fib-420 to fibrin-420 by thrombin is accompanied by a reduced rate of polymerization, suggesting the additional *C*-terminal globular domain in the αE chain delays lateral protofibril aggregation, and promotes a greater degree of fibril branching.[287] Posttranslational modifications also contribute to Aα chain heterogeneity. Twenty-five percent of Ser3 and Ser345

in the Aα chain are phosphorylated.[288,289] The first amino acid residue of the Aα chain, Ala1, is removed by an aminopeptidase in 10% of the nonphosphorylated chains.[290] The *C*-terminal half of the Aα chain is very sensitive to proteases, and 25% of the Aα chains have been cleaved at Lys583 by plasmin,[291] while cleavage at Asn269, Gly297, and Pro309 has been observed.[292]

The cDNA for the Bβ chain of human fibrinogen is about 1,890 nts in length and contains a sequence that encodes a nascent Bβ chain of 483 amino acids.[293] After removal of the signal peptide of 22 amino acids, the mature Bβ chain (461 amino acids) is incorporated into the six-chain fibrinogen. The first residue Gln is cyclized into pyroglutamic acid, which protects the *N*-terminus of the Bβ chain from degradation by aminopeptidases.[290] Residues 1 to 14 of the mature Bβ chain form fibrinopeptide B, which is removed by thrombin during the conversion of fibrinogen into fibrin. Pro31 of the Bβ chain is partially hydroxylated (20%),[294] and Asn364 is the site for an *N*-linked carbohydrate attachment.[295] At least three polyadenylation sites, resulting in varying lengths of 3′ noncoding regions, have been identified in the cDNAs for the Bβ chain. Two nonsynonymous polymorphisms have been identified in the Bβ chain including Pro77Ser and Arg448Lys.[281] The *C*-terminal region of the Bβ chain, residues 198 to 461, folds into a globular structure called the β-nodule, which contains the "b" polymerization site that plays a role in lateral aggregation of fibrils.[296]

The cDNA for the γ chain of human fibrinogen is about 1,590 nts in length,[297] and contains a region that encodes the nascent γ chain of 437 amino acids and additional amino-terminal 26 residues that are the signal peptides. The mature γ chain of 411 amino acids contains a single *N*-linked glycosylation site at Asn52.[298] Two nonsynonymous polymorphisms have been identified including Tyr114His and Gly165Arg.[281] The region encompassing Val143 to Val411 folds into a globular γ nodule that contains the "a" polymerization site.[299,300] The *C*-terminal 12 amino acids of the γ chain (residues 400 to 411) bind to integrin $\alpha_{IIb}\beta_3$, and this sequence is essential for platelet aggregation.[201] Alternative polyadenylation and truncation of the precursor mRNA in the ninth intron leads to truncation of the mRNA and translation read-through of the ninth exon into the ninth intron. Translation of this form of mRNA gives rise to the variant γ' chain, in which the *C*-terminal four amino acids in the γ chain (residues 408 to 411) are replaced by an alternative sequence of 20 amino acids (residues 408 to 427).[301,302] The γ' chain, which amounts to approximately 10% of the total γ chain content, is usually present in the form of a heterodimeric fibrinogen $(A\alpha B\beta)_2\gamma\gamma'$. The unique alternative *C*-terminal extended sequence of the γ' chain contains two sulfated tyrosine residues,[303] and this anionic region binds factor XIII[304] and thrombin.[305,306] The γ' variant exhibits a number of unique functional properties. It binds poorly to platelets and inhibits platelet aggregation,[307] delays lateral fibril aggregation,[308] alters the structure of fibrin,[309] and delays fibrinolysis.[310] Elevated levels of γ' chain may be associated with increased risk of cardiovascular diseases,[311–313] ischemic stroke,[314] and thrombotic microangiopathies.[315]

The genes for the three chains of human fibrinogen, designated FGA (fibrinogen alpha chain), FGB (fibrinogen beta chain), FGG (fibrinogen gamma chain), respectively, are linked and are located in chromosome 4q28[316] in a cluster approximately 53 kb in length (FIGURE 9.25). The genes are arranged in the order of FGG-FGA-FGB, and the FGB gene is oriented in a direction opposite to that of the other two genes.[317] The FGG gene is approximately 8,617 nts in length and contains 10 exons.[318] Differential polyadenylation and translation read-through from the ninth exon into the ninth intron leads to expression of the γ' isoform. The ratio of the $\gamma'$to total fibrinogen is regulated by the differential utilization of two polyadenylation signals including one in the ninth intron (pA1) giving rise to the γ' chain and one in the 10th exon (pA2) giving rise to the γ chain. A single-nucleotide polymorphism in the pA2 polyadenylation site (C10034T) increases its affinity for the polyadenylation factor CstF. As a result, this polymorphism leads to a reduced expression of the γ' chain.[319]

The FGA gene, located 14 kb downstream of the FGG gene, is approximately 7,618 nts in length[318] and contains six exons. Exons I to V of the FGA gene encode the prevalent Aα chain, while alternative splicing appended the downstream exon VI to the mRNA to encode the αE isoform. Exons V and VI of the FGA gene are unusually large, encoding residues 153 to 625 of the Aα chain and residues 611 to 847 of the αE chain, respectively.

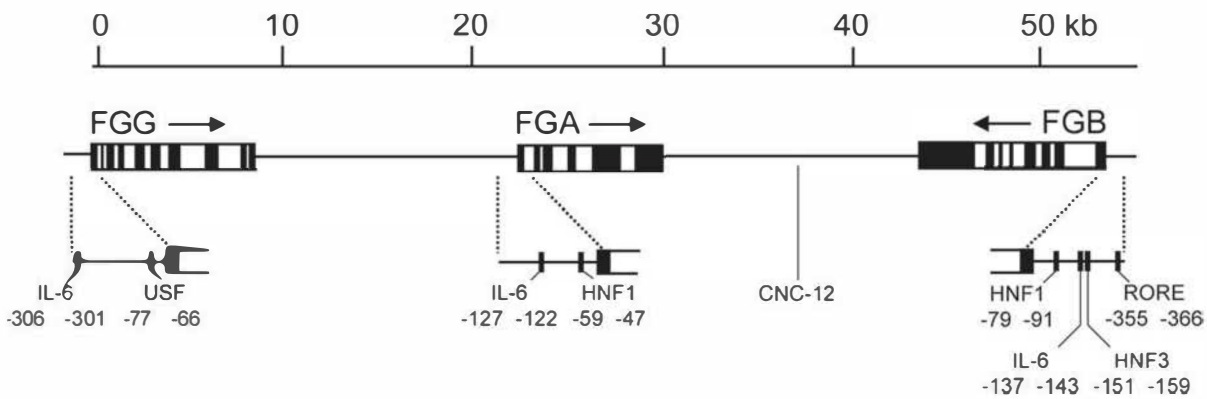

FIGURE 9.25 Arrangement of the fibrinogen genes on chromosome 4q28 and locations of regulatory elements. HNF-1, hepatocyte nuclear factor-1; HNF-3, hepatocyte nuclear factor-3; USF, upstream stimulatory factor; IL6, interleukin 6–responsive element; RORE, retinoic acid receptor-related orphan receptor alpha-binding element. CNC-12, intergenic noncoding sequence.

The FGB gene is approximately 9,784 nts in length[318] and is located 13 kb downstream of the FGA gene in an orientation opposite to that of the FGG and FGA genes. The FGB gene contains eight exons with no evidence of differential splicing. Two Alu repeat sequences including one in intron 5, and one in the 3′ flanking region, have been identified.

Fibrinogen is primarily synthesized in hepatic parenchymal cells, and liver-specific expression of the FGA and FGB genes has been attributed to a hepatocyte nuclear factor-1 (HNF-1)–dependent mechanism.[224,320] HNF-1–responsive elements are located –47 to –59 and –79 to –91 nts from the transcription initiation sites of the FGA and FGB genes, respectively (FIGURE 9.25). Liver-specific expression of the FGG gene is attributed to an upstream stimulatory factor (USF)-dependent mechanism, and a USF-responsive element is located –66 to –77 nt in the FGG gene. A 340-bp noncoding sequence named CNC-12, located in the intergenic region between the FGA and FGB genes, exhibits liver-specific enhancer activity. This activity suggests that this single conserved region within the fibrinogen gene cluster contributes to the coordinate expression of the fibrinogen genes in liver.[321]

Fibrinogen is an acute-phase protein and its level in plasma is increased four- to sevenfold during an acute-phase state induced by tissue damage, inflammation, or stress.[322] Functional IL6-responsive elements in the transcriptional regulatory regions of the three fibrinogen genes have been identified (FIGURE 9.25).[224,320,322–325] IL6 binds to IL6 receptors on hepatocytes and activates the transcription of NF-IL6, which in turn upregulates the expression of acute-phase proteins,[326] including the three chains of fibrinogen. A HNF-3–binding site in the promoter of the FGB gene (–151 to –159 nt), upstream of an IL6 element (–137 to –142 nt), is also essential for a full response to IL6 induction.[327] A binding site (RORE) for the retinoic acid receptor–related orphan receptor alpha has been identified in the promoter region (–355 to –366 nt) of the FGB gene.[328]

A single-nucleotide polymorphism in the 5′-flanking region of the FGB gene, –455G/A, has been proposed to be associated with elevated plasma fibrinogen and cardiovascular disease,[329] but this association was not confirmed.[145,330,331] Regions with small influence on fibrinogen expression may be present on chromosomes 2, 10, 17, and 20,[332] as well as the gene for HNF-1 on chromosome 12, and an unknown locus on chromosome 14.[333]

Disturbance of the circadian rhythm mediated by homozygous inactivation of the core circadian protein Bmal1 in mice is accompanied by a prothrombotic phenotype, in which circulating levels of several plasma proteins, including fibrinogen, are 40% elevated.[334] A screen of 470 microRNAs (miRNA) in HuH7 hepatoma cells shows that expression of 23 miRNAs causes significant reductions in fibrinogen synthesis, while four miRNAs causes increased synthesis.[335] Posttranslational modifications of fibrinogen may be prothrombotic or antithrombotic.[336,337]

FACTOR XIII

Factor XIII (Mr 320,000) (fibrin-stabilizing factor) is a proenzyme of plasma transglutaminase. In blood, it circulates as a heterotetramer composed of dimers of A and B subunits (A2B2), held together by noncovalent bonds. The A subunits contain the catalytic site with transglutaminase activity,[338,339] while the exact function of the B subunits remains unknown. The heterotetramer circulates in association with fibrinogen.[340]

In the presence of fibrin, thrombin converts factor XIII to factor XIIIa,[341,342] which catalyzes the formation of intermolecular epsilon-(γ-glutamyl)-lysine bonds with substrates such as fibrin monomers, α_2-plasmin inhibitor, fibronectin, and collagen.[343–345] The cross-linking in fibrin polymers occurs between Gln398 in the γchain of one fibrin molecule and Lys406 in the γ chain of an adjacent fibrin molecule. A deficiency of factor XIII can result in a lifelong bleeding tendency, delayed wound healing, and recurrent spontaneous abortion.

The A Subunit of Factor XIII

In blood, the A subunit (Mr 75,000) of factor XIII circulates as a heterotetramer with the B subunit,[346] while in various tissues and cells it exists as a dimer (A2). The exact site of the biosynthesis and mechanism of secretion of the A subunit into the blood has not been established. The concentration of the A subunit in plasma is 15 μg/mL, essentially all in complex with the B subunit,[346] but this may vary in disease states.[345,347]

The A subunit consists of 731 amino acids (FIGURE 9.26) with an amino-terminal sequence of Acetyl-Ser-Glu-Thr. There are two putative calcium-binding sites based on the homology to the EF hand.[348] The active-site Cys residue is located at position 314 within the sequence of Tyr-Gly-Gln-Cys-Trp and is identical to the active site of human and guinea pig tissue transglutaminase.[349] Eight more Cys residues are present in the A subunit, but none forms disulfide bridges. Although there are six potential Asn-linked glycosylation sites in the A subunits, little or no carbohydrate has been detected in the molecule.

In the conversion of factor XIII to factor XIIIa by thrombin, an activation peptide of 37 amino acids (Mr 4,000) is released from the amino-terminus[350,351] by cleavage between Arg37 and Gly38. In the presence of calcium ions, the modified A2B2 tetramer dissociates into an active A' dimer and two B subunits and unmasks the active sites, a process that is accelerated by fibrin.[352]

The crystal structure of the A subunit of factor XIII (FIGURE 9.27)[353] shows four distinct domains in the A subunit which follow the amino-terminal activation peptide of 37 residues. These include a beta sandwich (about 140 residues), a central core (about 330 residues), and two barrels (each about 100 residues). The central core contains Cys314 (shown by a *red star* in FIGURE 9.27) that is essential for catalytic activity of the enzyme, which may share a common ancestry with other cysteine proteases.[354]

The mRNA for the A subunit (~3.8 kb) lacks a sequence coding for a typical hydrophobic leader sequence that is usually required for protein secretion. The mRNA for the A subunit has a long 3′ noncoding region of approximately 1.5 kb.[350,355,356] The gene for the A subunit of human factor XIII (F13A1) is located on chromosome 6p24-25,[357,358] spanning more than 160 kb and including 15 exons interrupted by 14 introns.[356] The activation peptide is encoded by the second exon, the first putative calcium-binding site by the sixth, the active-site Cys by the seventh, the second putative calcium-binding site by the 11th, and a thrombin inactivation site by the 12th exons (FIGURE 9.26).

The homology of the A subunit of factor XIII to tissue keratinocyte transglutaminase and erythrocyte band 4.2 protein is 41%, 45%, and 27%, respectively.[349,359–361] However the active-site Cys residue in the band 4.2 protein is replaced by an Ala residue so that it lacks transglutaminase activity. A homologous transglutaminase has also been purified from hemocytes of horseshoe crab,[362] and

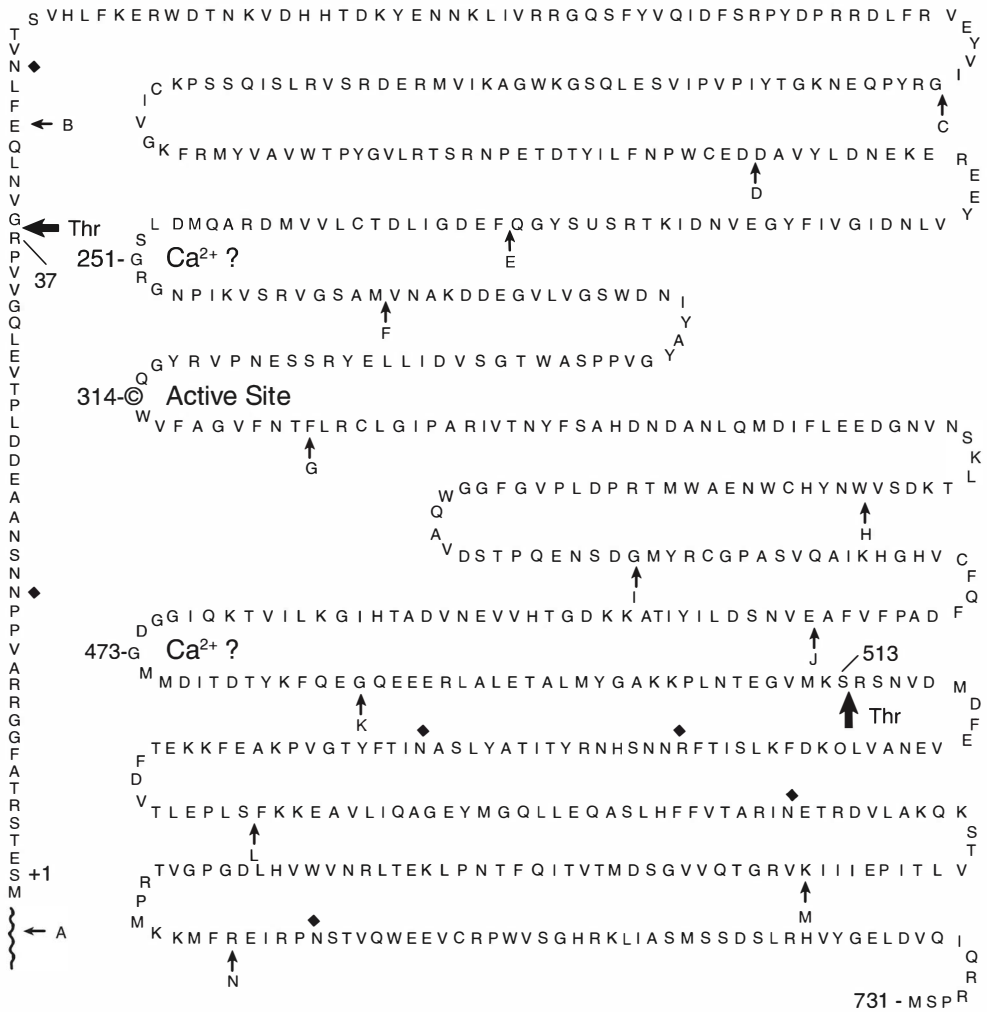

FIGURE 9.26 Amino acid sequence for the A subunit of human factor XIII and the location of the 14 introns (A to N). The thrombin cleavage site at Arg37-Gly, leading to the activation of the molecule, is shown with a *solid arrow*. The locations of the introns are shown with *small arrows*. Potential calcium-binding sites are shown with the active site Cys314. A thrombin inactivation site at Lys513-Ser is shown with an *open arrow*. Potential *N*-glycosylation sites are identified by *open diamonds*.

the gene for band 4.2 protein has the same structure as that of the A subunit of factor XIII.[363] The gene for keratinocyte transglutaminase has been localized on chromosome 14, which is different from that for the A subunit of factor XIII.[364] Thus far, 67 mutations have been observed in the F13A1 gene (FIGURE 9.27, *right panel*).[365]

The B Subunit of Factor XIII

The B subunit (Mr 80,000) of factor XIII is a plasma glycoprotein (8.5% carbohydrate) synthesized in the liver that circulates in blood both as a complex with the A dimer (XIII-A2B2) and as a free XIII-B2 dimer at a concentration of 21 μg/mL.[366] Administration of A subunits to patients with an A subunit deficiency causes an increase in the plasma level of the B subunit as well.[367,368] Three families with a bleeding tendency secondary to B subunit deficiency have been reported.[369–371]

The mRNA for the B subunit is approximately 2.3 kb long and codes for a hydrophobic leader sequence of 20 amino acids that is involved in secretion.[372,373] The mature protein starts with the unblocked amino-terminal sequence of Glu-Glu-Lys-Pro and consists of 641 amino acids (FIGURE 9.28). Almost the entire (98%) B subunit is composed of 10 tandem repeats, called sushi structures[374] or glycoprotein-1 structures, each consisting of 60 to 65 amino acids with highly conserved Cys, Pro, Gly, Tyr, Phe, and Trp residues. Sushi structures are found in at least 26 different proteins and two cDNAs from mammalian sources.[344,374] The B subunit contains 40 Cys residues (four in each of the 10 sushi structures). The first and third, and the second and fourth Cys residues in each sushi structure of the B subunit are most likely linked by disulfide bonds analogous to those determined in β_2-glycoprotein I and C4b-binding protein.[375,376] Three potential Asn-linked glycosylation sites are present in the B subunit. An Arg-Gly-Asp sequence exists in the last sushi structure of the B subunit, but its function is unclear.

The gene for the B subunit of factor XIII (F13B) is localized on chromosome 1 at bands 1q31-q32.1,[377] and other genes coding for proteins containing multiple sushi structures are also clustered on chromosome 1 at q32.[378] The gene for the B subunit

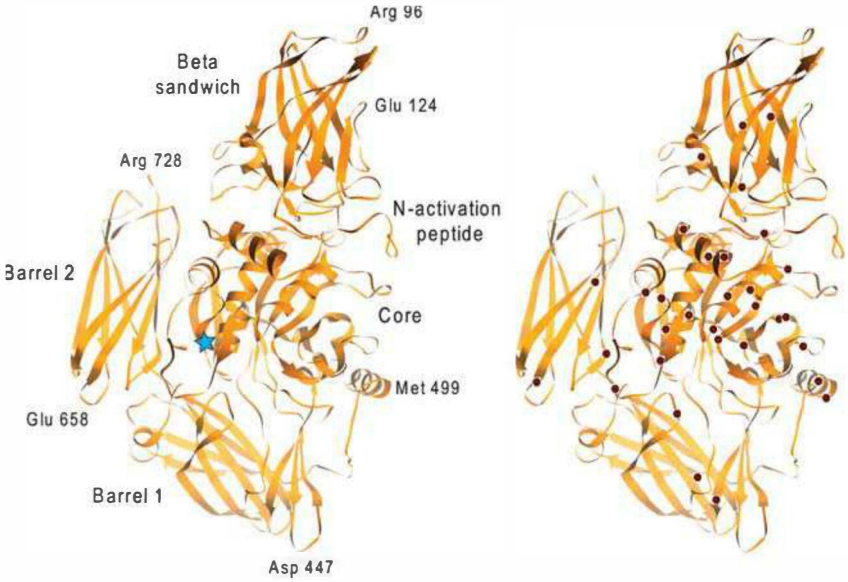

FIGURE 9.27 Ribbon structure of factor XIIIA. The protein contains our distinct domains including a beta sandwich, a central core, barrel 1, and barrel 2. Cys314 in the central core is shown by a *cyan* star and is part of the Cys-His-Asp triad of the catalytic site. Sixty-seven mutations that occur throughout the protein are shown by black dots in the structure in the right panel. (From Yee VC, Pedersen LC, Le Trong I, et al. Three-dimensional structure of a transglutaminase: human blood coagulation factor XIII. *Proc Natl Acad Sci U S A* 1994;91:7296; Hsieh L, Nugent D. Factor XIII deficiency. *Haemophilia* 2008;14:1190.)

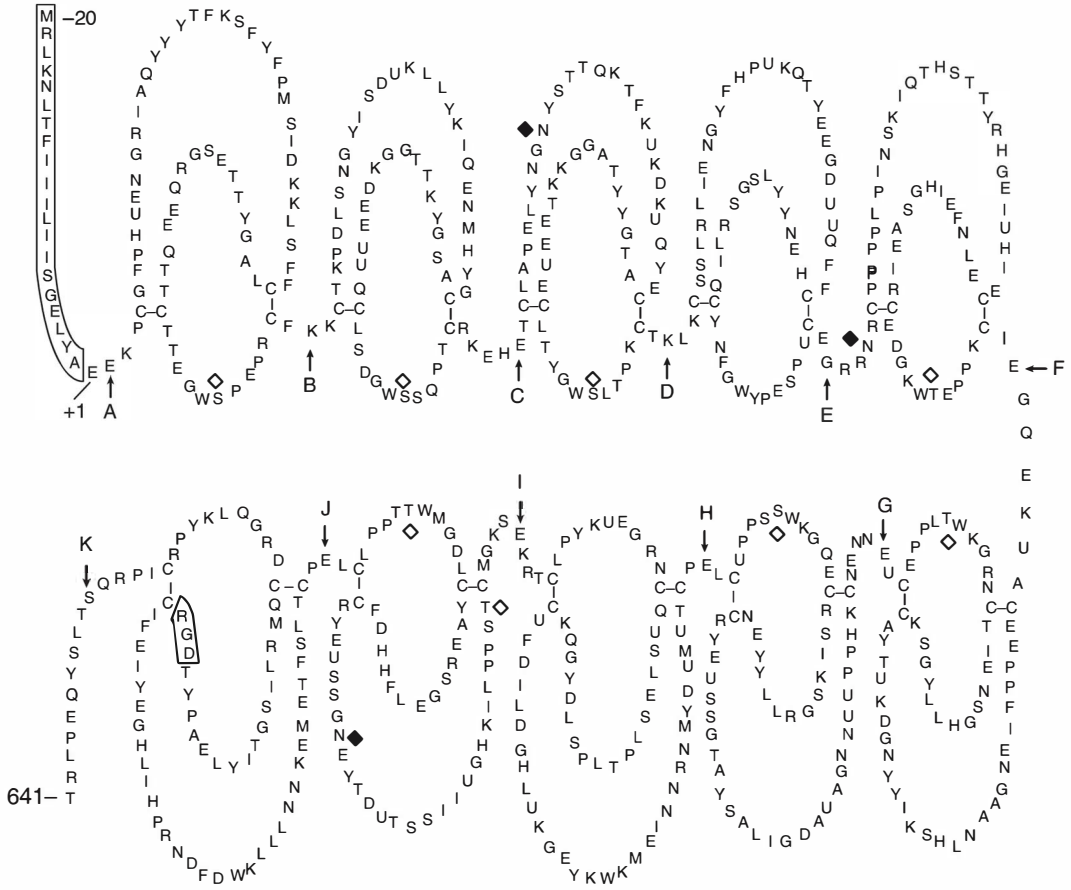

FIGURE 9.28 Amino acid sequence of the B subunit of human factor XIII and location of the 11 introns (A to K), indicated by *solid arrows*. Residues –20 to –1, enclosed in a *box*, constitute the signal sequence. The ten sushi domains are linked by disulfide bonds by analogy with those in β_2 glycoprotein and C4b-binding protein. (Naski MC, Lorand L, Shafer JA. Characterization of the kinetic pathway for fibrin promotion of alpha-thrombin-catalyzed activation of plasma factor XIII. *Biochemistry* 1991;30:934; Folk JE, Finlayson JS. The epsilon-(gamma-glutamyl)lysine crosslink and the catalytic role of transglutaminases. *Adv Protein Chem* 1977;31:1.)

spans approximately 28 kb and includes 12 exons interrupted by 11 introns.[372] All the intron–exon boundaries follow the GT-AG rule.[28] The leader sequence is encoded by the first exon, whereas the carboxyl-terminal region of the protein and the 3′ noncoding region are encoded by the 12th exon. Each of the 10 sushi structures is encoded by a single exon, and its 5′ and 3′ intron–exon boundaries are type I.[372] All sushi structures in the genes for other proteins are also encoded by single exons, with very few exceptions.[377]

Although the presence of polymorphisms in amino acid sequences has been suggested by isoelectric focusing technique, no mutations have been reported thus far. On the contrary, restriction fragment length polymorphisms are detected in the genomic DNAs.[378] Genetic defects of the complete B subunit deficiency indicate that a nucleotide deletion destroyed an intron–exon splice junction in one allele and replacement of a Cys residue with Phe diminished a disulfide bridge in another allele.[379]

PROTEIN C

Protein C (Mr 62,000) is a vitamin K–dependent glycoprotein that circulates in blood as a precursor to a serine protease.[380–383] Protein C is composed of a light chain of 155 amino acids (Mr 21,000) and a heavy chain of 262 amino acids (Mr 41,000), held together by a disulfide bond (FIGURE 9.29).[384,385] The light

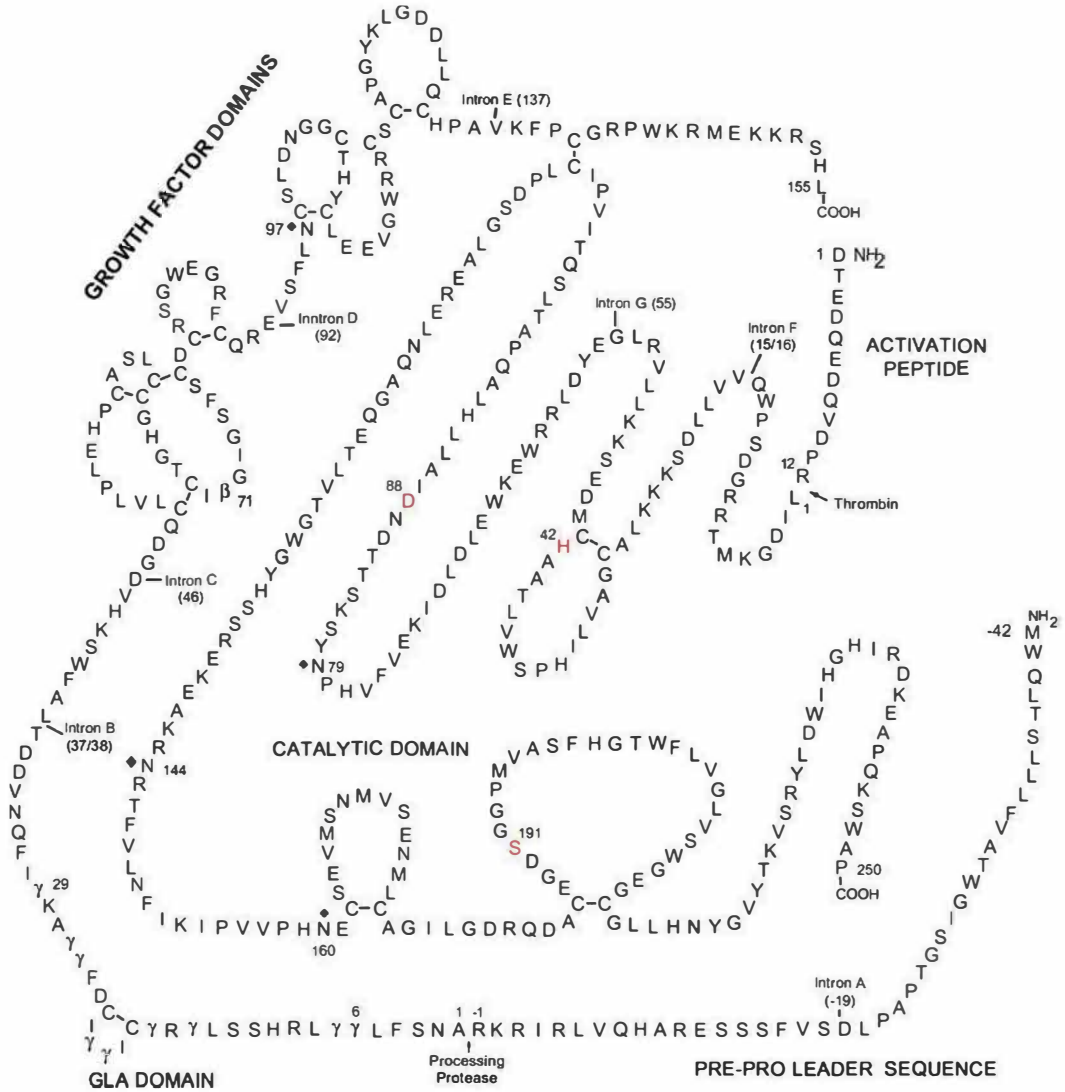

FIGURE 9.29 Amino acid sequence of human prepro protein C and location of the seven introns (A to G). The eighth intron in the 3′ noncoding sequence is not shown. The prepro leader sequence (–42 to –1) is removed during biosynthesis by signal peptidase and a processing protease that cleaves the Arg(–1)-Ala bond. The Gla domain and epidermal growth factor domains are located in the light chain within residues 1 to 155. The connecting peptide of Lys-Arg present between the light and heavy chains is not shown. The activation peptide of 12 residues is released from protein C by thrombin during its conversion to APC. The peptide bond (Arg-Leu) cleaved by thrombin is indicated by an arrow. The serine protease or catalytic domain of protein C contains 250 residues, including His42, Asp88, and Ser191, which participate in catalysis. Two potential carbohydrate attachment sites in the activation peptide are shown by *solid diamonds*. The proposed disulfide bonds in protein C have been placed by analogy to those established in bovine prothrombin and epidermal growth factor.

chain contains nine γ-carboxyglutamic acid residues followed by two EGF-like domains.[130,386–389] The light chain also has one β-hydroxyaspartic acid that has been reported to be involved in Ca^{2+} binding and anticoagulant activity.[10,390]. The heavy chain of protein C contains an activation peptide followed by a catalytic or serine protease domain. The protein also has four potential attachment sites for carbohydrate bound to asparagine, including residue 97 in the light chain and residues 79, 144, and 160 in the heavy chain.

Protein C activation by thrombin is greatly accelerated by thrombomodulin.[381,391–394] APC then inactivates factors Va and VIIIa by minor proteolysis in the presence of calcium and phospholipid.[381,395–398] Protein S functions in the latter reactions as a cofactor.[398–400] The conversion of protein C to a serine protease (APC) by thrombin is due to the cleavage of an Arg-Leu peptide bond at the amino-terminal region of the heavy chain, generating an activation peptide of 12 amino acids and a new amino-terminal Leu1 (FIGURE 9.29). The newly formed α-ammonium of Leu1 flips back into the catalytic domain where it forms a salt bridge with the carboxyl group of Asp190 and a serine protease with an active charge relay system involving His42, Asp88, and Ser191 (circled *in red*, FIGURE 9.29).

The mRNA for human protein C is approximately 1,700 nts in length and codes for a prepro leader sequence, a single-chain polypeptide of 419 amino acids, and a stop codon.[387] The 419 amino acids include a dipeptide located between the light chain and the heavy chain. The 3′ noncoding sequence consists of 68 nts and includes a processing or polyadenylation sequence of ATTAAA, which is located 16 nts upstream from the poly(A) tail. The prepro leader sequence in protein C is 42 amino acids in length (FIGURE 9.29). It is likely that the signal peptidase cleaves the prepro leader sequence following the serine residue located at –18 and removal of the propepetide by a furin-like protease that cleaves at Arg(–1). The light and heavy chains of circulating protein C are initially connected by a Lys-Arg dipeptide that is removed during processing.

The gene for human protein C (PROC) is present on chromosome 2 at q14-21, and in approximately 11 kb of DNA.[130,389,401] The gene contains nine exons and eight introns (FIGURE 9.29). The first intron is located in the 5′ noncoding region of the gene while the other seven are present in the coding region of the gene (FIGURE 9.29).[389] The introns range in size from 92 to 2,668 nts, and the exons range in size from 25 to 885 nts. A1l the intron–exon boundaries follow the GT-AG rule.[132] The 5′ untranslated region of the protein C gene contains an additional short noncoding sequence corresponding to an untranslated exon. This exon is separated from the translation start codon by a 1,463-bp intronic sequence.[402] Intron A is located in the prepro leader sequence; intron B follows the Gla domain; intron C is located just before the first potential growth factor domain; intron D separates the two potential growth factor domains; intron E follows the second potential growth factor domain; and introns F and G are located in the heavy chain that contains the catalytic domain.

High-level expression of the gene for protein C in HepG2 cells is regulated by a 1,500-bp 5′ flanking region, which includes 66 bp of the noncoding exon.[402] The major transcription start site is located 65-bp upstream from the first intron–exon boundary or 1,515-bp upstream from the initiation Met codon.[402] Two minor transcription start sites are located at –7 and +13 bp relative to the major transcription start site. Cis elements include HNF-1 (–10 to +9 bp), HNF-3 (–25 to –11 bp), a unique liver-specific binding site (12 to +30 bp), and an Spl site in the 5′ noncoding exon (+58 to +65 bp). A strong silencer region is located between –162 and –82 bp, and two possible liver-specific enhancer regions, which interact coordinately with promoter elements, are located between –1,462 and –162 bp.

Several genetic defects of protein C have been found in patients with hereditary thrombophilia, including a nonsense mutation of Arg306, a replacement of Arg169 with Trp at the activation cleavage site, the conversion of Trp402 to Cys,[403–405] promoter mutations of +3 C to T and –2 T to C that disrupt the HNF-1 site, and –15 T to A, –20 A to G mutations that disrupt the HNF-3–binding site,[406,407] and –2 mutations that disrupt HNF-1 binding.[408]

PROTEIN S

Human protein S (Mr 69,000) is a single-chain plasma glycoprotein (7.8% carbohydrate) that contains 10 γ-carboxyglutamic acid (Gla) residues[41] and requires vitamin K for hepatic biosynthesis.[410] Protein S functions as a cofactor of APC in the inactivation of factors Va and VIIIa,[389–400,411] and its deficiency leads to a predisposition for venous thrombosis.[412–415] The concentration of protein S in human plasma is approximately 25 μg/mL,[416,417] 40% of which exists free and 60% in stoichiometric complex with C4b-binding protein.[416] Complex formation does not lead to inactivation of C4b, although protein S no longer functions as a cofactor.[418,419] In the bovine system, another plasma protein binds to protein S.[420]

The amino acid sequence of human protein S has been determined by cDNA cloning.[421,422] The size of its mRNA is approximately 3.5 to 4.0 kb, including two polyadenylation signals at the 3′ end. Protein S is synthesized with a hydrophobic signal sequence and prepropeptide of 41 amino acids (FIGURE 9.30). The mature protein consists of 635 amino adds and starts with a sequence of Ala-Asn-Ser. Starting from the amino-terminus, there is a Gla domain, a thrombin-sensitive region, a short stretch of aromatic residues, four EGF domains, and a sequence homologous to steroid hormone–binding globulin (SHBG, FIGURE 9.30).[423] The cleavage by thrombin of two Arg-Ser/Ala bonds in the second disulfide loop results in the release of a peptide containing residues 53 to 70 and the loss of protein S cofactor activity.[423–426]

The first EGF domain of bovine protein S contains one β-hydroxyaspartic acid (residue 95), while each of the remaining three EGF domains contains one β-hydroxyasparagine (residues 136, 178, and 217).[427] One Asp and three Asn residues at the same positions in human protein S are also very likely hydroxylated, but these residues are not required for anticoagulant cofactor activity or for binding to C4b-binding protein.[428] The carboxyl-terminal portion of the SHBG region is important for the binding of protein S to C4b-binding protein.[429] Potential Asn-linked glycosylation sites are clustered in the middle of the SHBG region. Cloning of human cDNA for protein S has made it possible to express a functional recombinant protein S in mammalian cells.[430,431]

The gene for human protein S (PROS1) has been localized to chromosome 3q11,[432,433] spanning more than 80 kb and containing 15 exons interrupted by 14 introns.[434,435,436] All nucleotide sequences around the intron–exon boundaries follow the AG/GT rule and the consensus sequence. There are six Alu repeats located throughout the gene. The signal sequence is encoded by the first exon, the propeptide and Gla domain by the second exon, the short stretch of aromatic residues by the third exon, and the

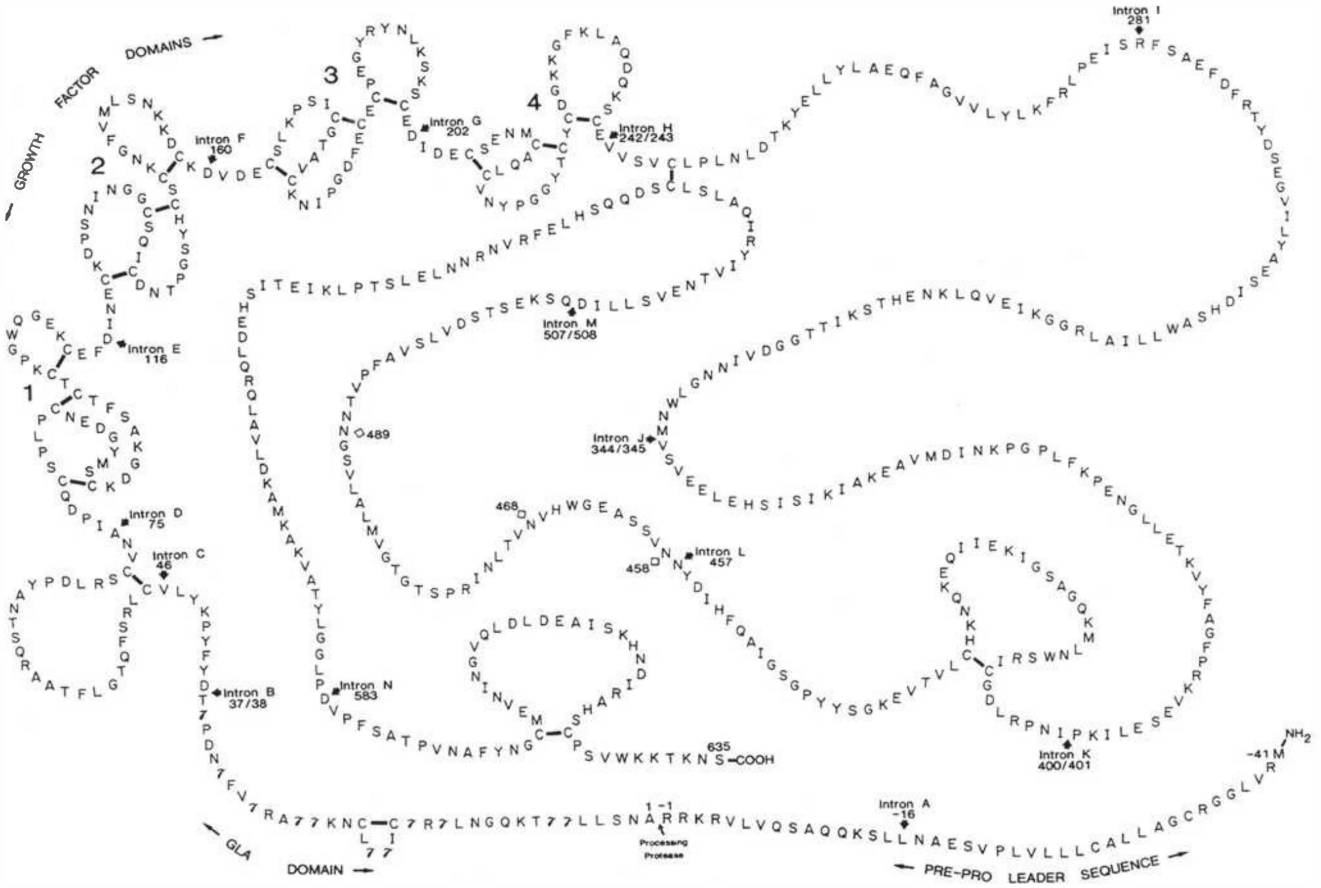

FIGURE 9.30 Amino acid sequence of human prepro protein S and location of the 14 introns (A to N), indicated by *solid arrows*. The prepro leader sequence includes residues –41 to –1. *Open diamonds* indicate potential carbohydrate attachment sites of the Asn-X-Ser/Thr type. Large numbers denote orders of four epidermal growth factor domains, which are followed by a region homologous to SHBGs.

thrombin-sensitive region by the fourth exon. Each of the four EGF domains is encoded by a single exon, while the SHBG region is encoded by seven exons as in the human SHBG gene.[437] Three potential glycosylation sites are encoded within a single exon.

Two copies of the gene for human protein S have been identified, and the second gene is very likely a pseudogene.[438,439] The latter spans over 55 kb and shows the absence of exon I, as well as many nucleotide substitutions, including a stop codon, insertions, and deletions resulting in frameshifts and the consequent in-frame stop codons. Overall homology between the exons of the gene for protein S and those of the pseudogene is 97%, indicating that these two genes diverged recently. A deletion of the middle portion of the gene coding for protein S has been identified in the DNA of patients with protein S deficiency,[439] and dimorphism at position 460 (Ser to Pro) in one of three potential Asn-linked glycosylation sites has been detected.[440]

Antithrombin III

Antithrombin III (Mr 58,200) is a major serine protease inhibitor synthesized in the liver and secreted into the plasma, where it circulates at about 150 μg/mL. Antithrombin III is a single-chain glycoprotein (9% carbohydrate) containing 432 amino acids (FIGURE 9.31) and four glycosylation sites located at Asn96, Asn135, Asn155, and Asn192 (α form). About 10% of the plasma protein is glycosylated at only three positions and lacks glycosylation at Asn135 (β form).[441,442] Antithrombin III is a member of the SERPIN family of suicide protease inhibitors (Table 9.4), 34 of which have been found on 10 different human chromosomes.[443] These proteins have an amino acid sequence homology of 25% to 35% and share a conserved tertiary core domain of about 350 residues that includes eight or nine α-helices and three β-sheets (FIGURE 9.31).

Antithrombin III is a potent inhibitor of thrombin, factor IXa, factor Xa, and factor XIa, a process that is accelerated 2,000-fold or more by heparin, which induces a conformational change and accelerates binding to thrombin.[444–447] The substrate recognition sequence containing the reactive center loop (RCL) of about 20 residues and its reactive Arg393 are located at the top of the inhibitor and are partially obscured in the absence of heparin. In the presence of heparin, an extension (*shown in blue*, FIGURE 9.32) forms at the top of helix D (*shown in yellow*) and a shift to the right occurs in the RCL (*red with black and green spheres*). This makes the reactive Arg393 in the RCL of the inhibitor more readily available to interact with target serine proteases.

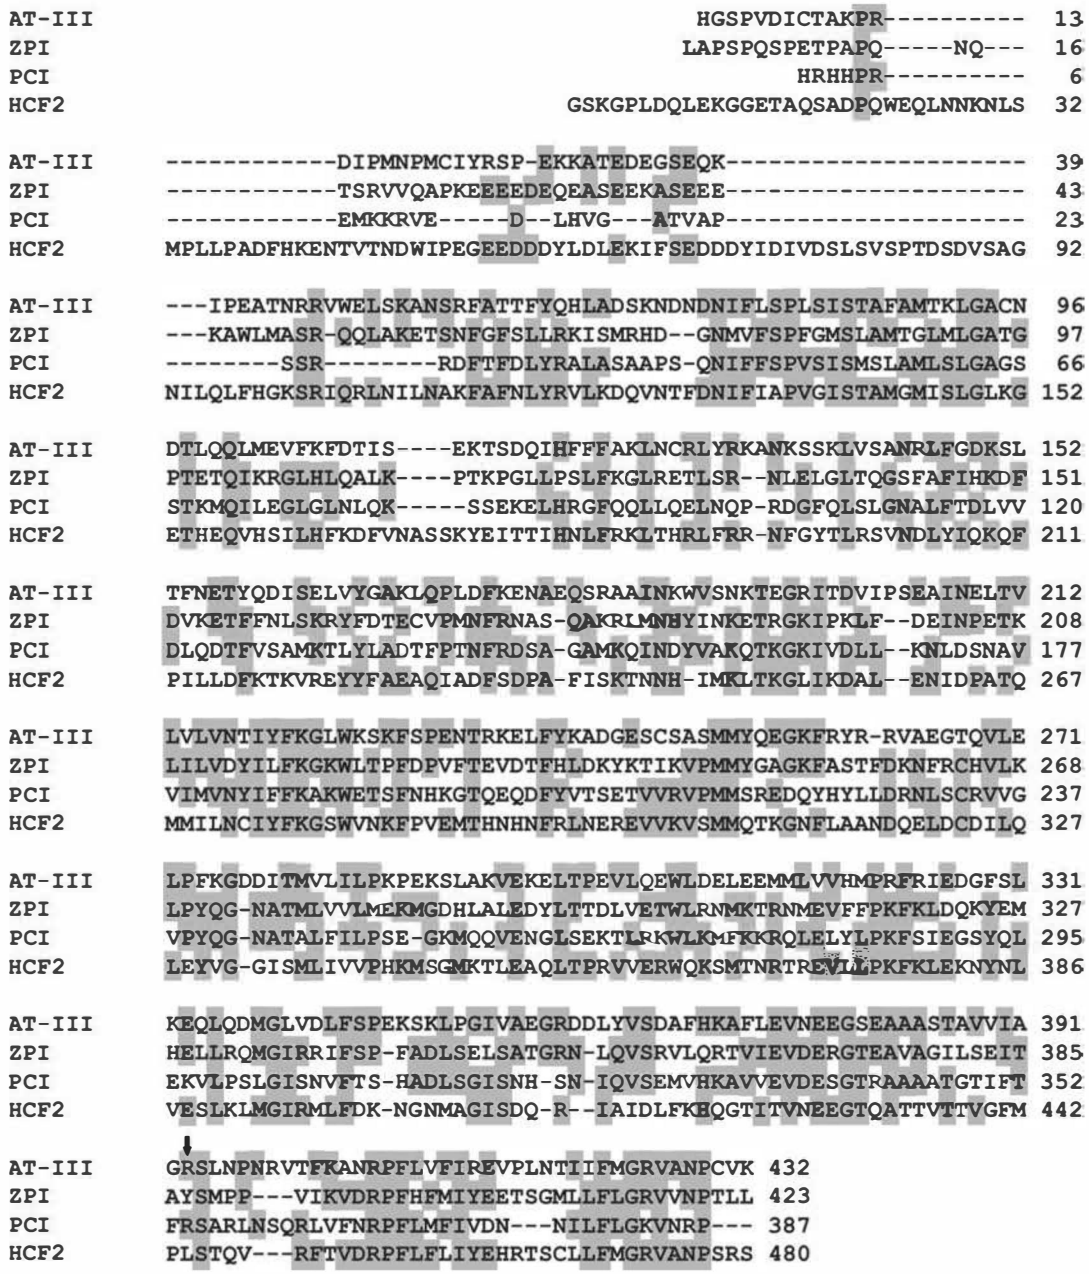

FIGURE 9.31 Alignment of the amino acid sequences of four SERPIN inhibitors of blood coagulation. Identical amino acids in the four proteins are shaded. AT-III, antithrombin III; ZPI, protein Z inhibitor; PCI, protein C inhibitor; HCF2, heparin cofactor 2.

The cDNA coding for antithrombin III was prepared from human liver RNA and predicted a 32–amino acid signal sequence followed by a 432–amino acid polypeptide chain.[441] At the 5′ end of the cDNA clone, a single transcription start site was identified 72 bp prior to the ATG initiation codon. At the 3′ end of the cDNA clone, a poly(A) sequence of AATAAA was observed 49 bp following the termination codon. Typical control regions in the gene for antithrombin III (SERPINC1), such as a TATA box, a CCAAT box, or GC elements, were not identified in the 5′-untranslated region. The gene for antithrombin III is located at chromosome 1q23-25 and contains about 13.4 kb of DNA.[448] It contains seven exons (including exons IIIA and IIIB) and six introns.[448] The gene also has nine full-length Alu repeat elements and one partial length Alu sequence, an unusually high number of Alu repeat sequences for a human gene. More than 50 mutations in the gene coding for antithrombin III have been identified, often located in regions of the gene coding for amino acids located in or near the reactive site loop or the heparin-binding site in antithrombin III.[449]

Tissue Factor Pathway Inhibitor

Tissue factor pathway inhibitor (TFPI) is a serine protease inhibitor that occurs in multiple isoforms called TFPIα, TFPIβ, and TFPIδ.[450–453] It was originally called extrinsic pathway inhibitor

Table 9.4

and lipoprotein-associated coagulation inhibitor. TFPIα (Mr 43,000) is a single-chain glycoprotein protease inhibitor containing 276 amino acids and three potential *N*-linked glycosylation sites and consists of an acidic *N*-terminal region, three tandem Kunitz-type protease inhibitor domains, and a basic *C*-terminal region involved in membrane anchoring (FIGURE 9.33). TFPIα is the major isoform produced in human tissue.[452]

TFPIβ (222 amino acids) and TFPIδ (162 amino acids) are shorter molecules formed by alternative mRNA splicing.[454] TFPIβ contains the first and second Kunitz domains, but lacks

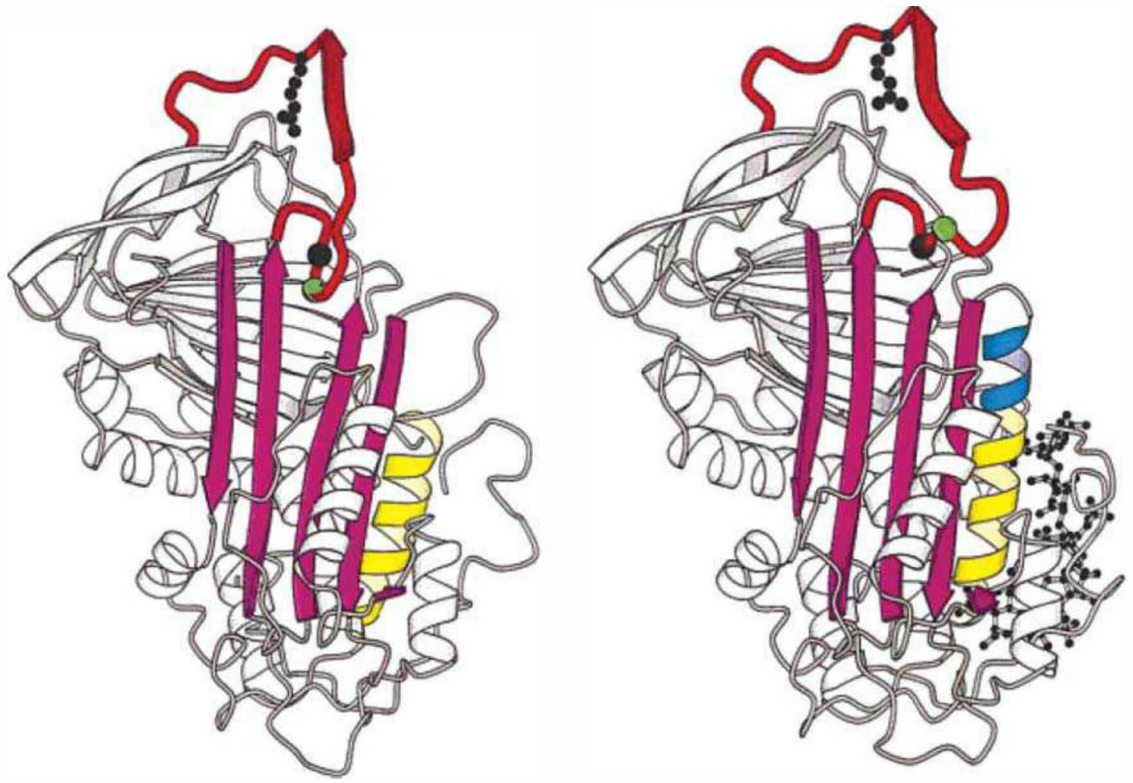

FIGURE 9.32 Ribbon structures of antithrombin III and antithrombin III–heparin (pentasaccharide) complex.[446] The conformational change in antithrombin III induced by heparin is readily seen by comparing the structure on the left (no heparin) and the one on the right with heparin which is bound to the lower right-hand side of the molecule.

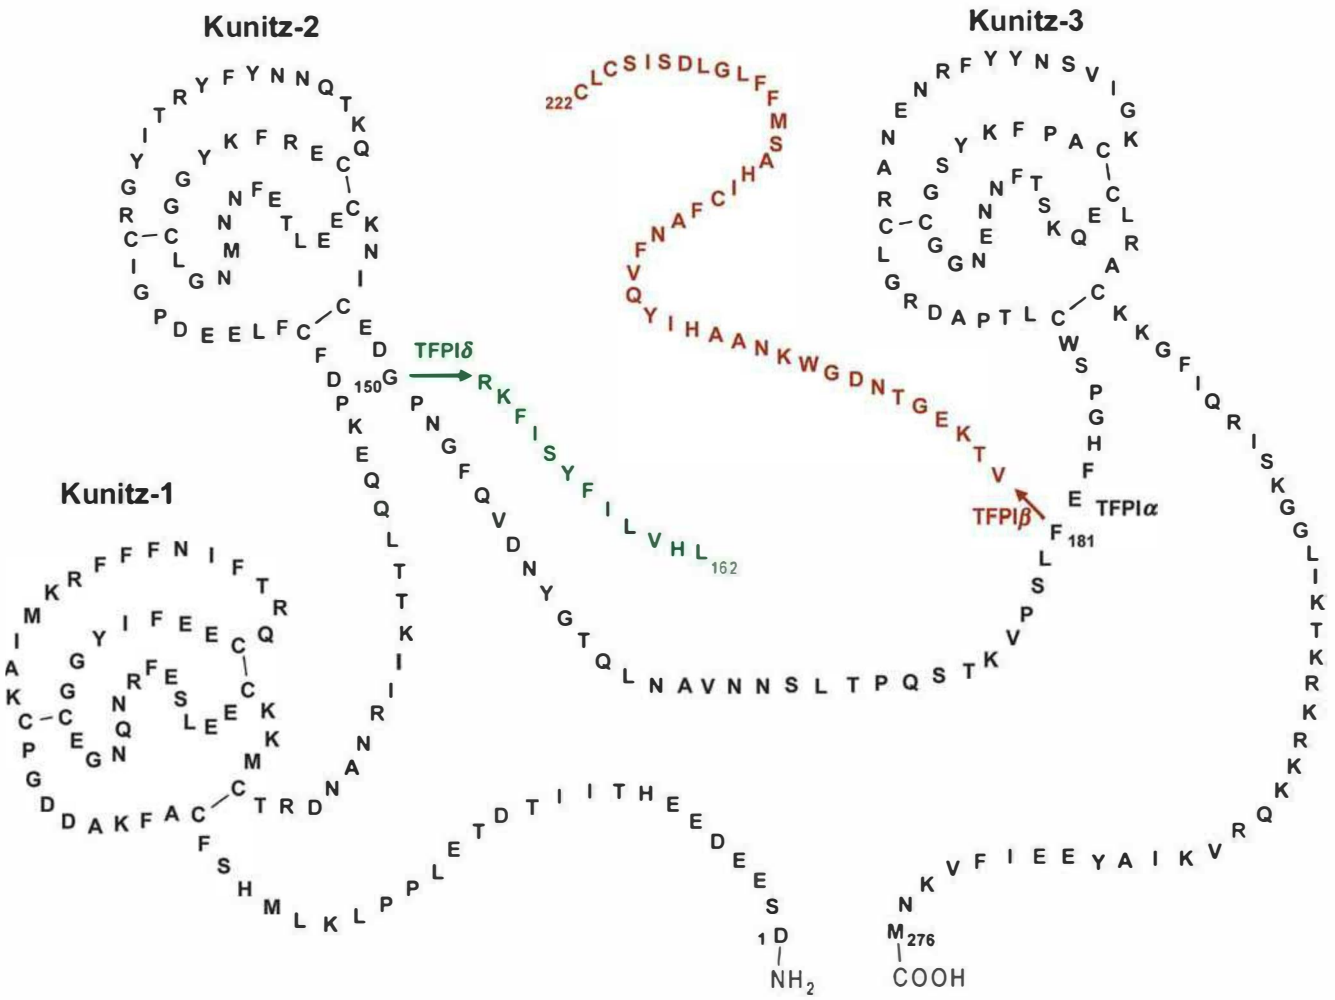

FIGURE 9.33 Amino acid sequence of the α, β, and δ isoforms of TFPI. The acidic *N*-terminal region of TFPIα is followed by three tandem Kunitz-type protease inhibitor domains and a basic *C*-terminal region. The shorter TFPIβ is spliced at Phe181 to Val shown in the red peptide. This reduces the length of the β isoform to 222 amino acids. In the shortest isoform, TFBIδ, the Gly150 is spliced to Arg present in the green peptide reducing the length of the δ isoform to 162 amino acids. (Modified from Maroney SA, Ellery PE, Mast AE. Alternatively spliced isoforms of tissue factor pathway inhibitor. *Thromb Res* 2010;125(Suppl 1):S52.)

the third Kunitz-type inhibitor and the *C*-terminal end. In contrast, the two Kunitz-type protease inhibitor domains in TFPIβ are followed by a completely different *C*-terminal region encoding a glycosyl-phosphatidylinositol anchor attachment sequence that is unrelated to the basic C-terminal region present in TFPIα. TFPIδ (162 amino acids) also has the first two Kunitz domains, followed by still another *C*-terminal sequence of 12 residues (FIGURE 9.33). The physiological role of this isoform is not known.

Factor Xa is inactivated when it binds to the second Kunitz domain of TFPI, while the factor VIIa–TF complex binds to the first Kunitz domain, leading to the inactivation of the factor VIIa–TF complex as well as factor Xa. These reactions may block the continuation of factor Xa generation by the extrinsic pathway of blood coagulation.[455] When major vascular damage occurs, it appears likely that the concentration of TFPI is insufficient to completely inhibit the factor Xa and factor VIIa–TF complex activity.

The cDNA coding for TFPI of placental and fetal liver cDNA libraries[456] contains 1,431 nts that include a 5′ noncoding sequence of 132 nts followed by an open reading frame of 912 nts and a 3′ noncoding region of 387 nts. The open reading frame codes for a signal peptide of 28 residues and a protein of 276 amino acids. A larger mRNA of 4.4 kb was also observed.[457]

The gene for TFPI is on chromosome 2 at 2q31-2q32.1 and spans about 70 kb[458,459] and contains nine exons and eight introns. The signal sequence and *N*-terminal region are coded by exon III, while exons IV, VI, and VIII code for the three Kunitz domains. The *C*-terminal region of the inhibitor is coded by exon IX. Thus far, no TATA box or CCAAT sequences have been observed in the 5′ end of the gene.

Protein Z and Protein Z–Dependent Protease Inhibitor

Protein Z (PZ) is a vitamin K–dependent plasma glycoprotein,[460] consisting of 396 amino acids including 13 Gla residues, one β-hydroxyaspartic acid, and four carbohydrate chains.[461–463] Plasma PZ concentration is 2.9 μg/mL,[464] in complex with protein Z–dependent protease inhibitor (PZPI).[465] PZ is composed

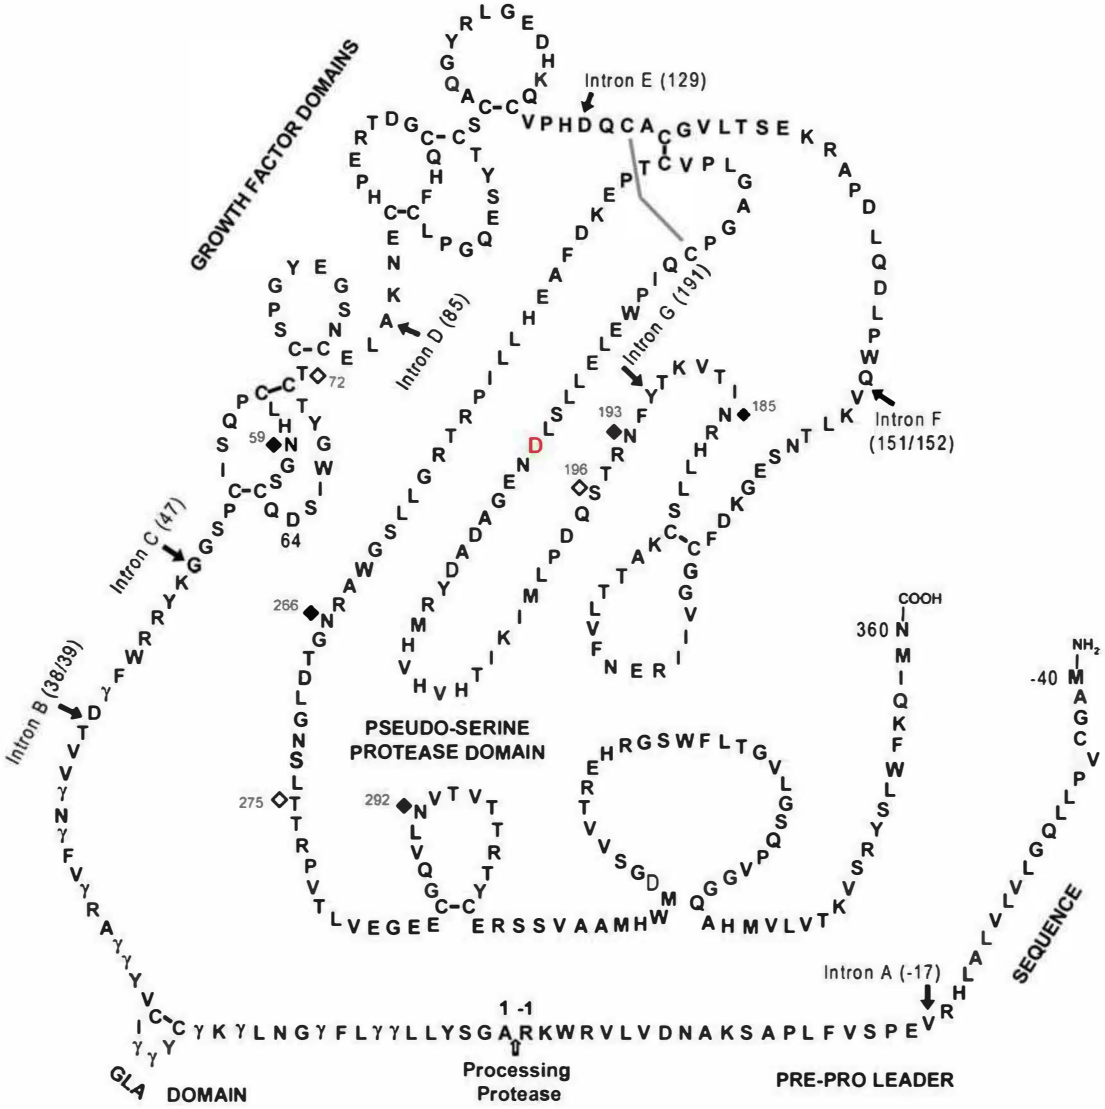

FIGURE 9.34 Amino acid sequence of human prepro PZ and location of introns A to G. The prepro leader sequence (–40 to –1) is removed during biosynthesis by signal peptidase and a processing protease that cleaves the Arg(–1)-Ala bond. Potential *N*-linked carbohydrate attachment sites Asn59, 185, 193, 266, and 292 are shown by *solid diamonds*, while potential *O*-linked carbohydrate attachment sites Thr72, 196, and 275 are shown by *open diamonds*. The single residual amino acid of the catalytic triad Asp221 in the pseudo-serine protease domain is shown in *red*. (From Huang X, Dementiev A, Olson ST, et al. Basis for the specificity and activation of the serpin protein Z–dependent proteinase inhibitor (PZPI) as an inhibitor of membrane-associated factor Xa. *J Biol Chem* 2010;285:20399.)

of 360 amino acids (FIGURE 9.34), including 13 Gla residues and eight potential carbohydrate chains bound to Asn-X-(Ser/Thr) at positions 59, 185, 193, 266, and 292 and three potential *O*-linked carbohydrate attachment sites (Ser/Thr)-X-X-Pro at residues 72, 196, and 275. It seems probable that Asp64 in human PZ is β-hydroxy-Asp, since this residue was identified as β-hydroxy-Asp in bovine PZ.[461] The Gla region of PZ is followed by two EGF-like domains and a serine protease-like domain (FIGURE 9.34). However, the protein is not a zymogen of a serine protease.

The cDNA for PZ is approximately 1.6 kb in length and codes for a prepro leader peptide of 40 amino acids and the mature circulating protein (FIGURE 9.34).[463] The prepro leader contains a typical secretion signal rich in hydrophobic residues, followed by a propeptide sequence that is essential for the carboxylation of 13 amino-terminal Glu residues. The *C*-terminus of the prepropeptide contains an Arg-Trp-Lys-Arg sequence that is recognized by a furin-like protease that cleaves between the last Arg and the *N*-terminal Ala (FIGURE 9.8).

The gene for human PZ (PROZ) is about 14 kb in length and contains nine exons including one alternative exon. The exon/intron boundaries for the eight regular exons are typical consensus sequences of GT-AG. The gene for PZ is localized to chromosome 13 at band q34.[466]

Inhibition of factor Xa by PZPI is accelerated about 2,000-fold in the presence of PZ, phospholipid, and calcium.[467,468,469] PZPI also inhibits factor XIa but does not require PZ for this reaction and does not inhibit other coagulation factors.

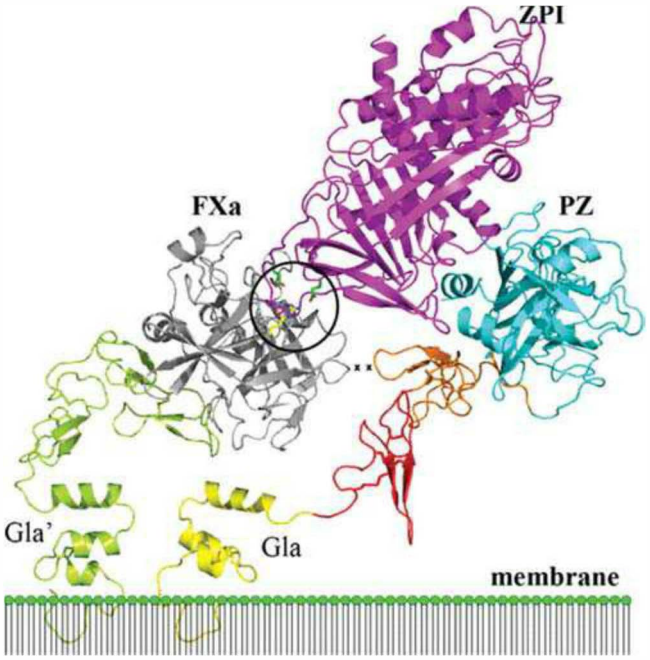

FIGURE 9.35 A model of the ribbon structure of the complex of PZ–PZ inhibitor–factor Xa on a phospholipid surface. PZ pseudo-serine protease domain is colored *cyan*, PZ EGF1 and EGF2 are colored *orange*, and PZ Gla domain is colored *yellow*; protein Z protease inhibitor (ZPI) is colored *magenta*, factor Xa catalytic domain (FXa) is colored *gray*, and factor Xa EGF1, EGF2, and Gla domain are colored *green*. The active site of factor Xa bound to the reactive center of PZ inhibitor is enclosed in a *black* circle. (Huang X, Dementiev A, Olson ST, et al. Basis for the specificity and activation of the serpin protein Z–dependent proteinase inhibitor (ZPI) as an inhibitor of membrane-associated factor Xa. *J Biol Chem* 2010;285:20399.)

PZPI (Mr 72,000) is a single-chain molecule composed of 423 amino acids (FIGURE 9.31), homologous to other members of the SERPIN family of protease inhibitors. Tyr387 was predicted to be at the P1-reactive center of PZPI in contrast to Arg, which is the P1 residue in antithrombin III and protein C inhibitor. PZ circulates in complex with PZPI[470] (FIGURE 9.35). PZ is bound to PZPI through polar and ionic interactions while the Gla region of PZ is bound to calcium and the membrane surface shown at the bottom of the structure. PZPI has nine α-helices and three β-sheets, typical of the SERPIN family. In the ternary complex, the Gla region of factor Xa is also bound to the membrane surface, while its catalytic site binds to PZPI through its P1 Tyr. The phospholipid membrane plays an important role in bringing the three proteins together.

A cDNA of 2.44 kb coding for PZPI[467] contains six potential ATG start sites at the 5′ end of the clone; a sixth ATG is the likely initiation site. The open reading frame of 1,335 bp contains a 21–amino acid signal peptide and five potential *N*-linked glycosylation sites. Northern blot analysis indicated the presence of PZPI mRNA in liver but none in heart, lung, brain, spleen, testis, and kidney.

Protein C Inhibitor

Protein C inhibitor (Mr 57,000) is a single-chain SERPIN that is a potent inhibitor of APC[471] and the thrombin–thrombomodulin complex that converts protein C to APC.[472] Its concentration in plasma is 1 μg/mL.[473] The inhibitor is a glycoprotein composed of 387 amino acids (FIGURE 9.31), containing five potential carbohydrate chains including three starting at residues 230, 243, and 319 (Asn-X-Ser/Thr) and two at residues 20 and 39 (Thr/Ser-X-X-Pro).[473] The P1-reactive site in protein C inhibitor is Arg354, which is the same as in antithrombin III (FIGURE 9.31). The protein contains only one cysteine residue similar to α_1-antitrypsin and α_1-antichymotrypsin. Protein C inhibitor forms a 1:1 molar complex with APC in a reaction accelerated about 50-fold by the presence of heparin. Protein C inhibitor also inhibits thrombin, factor Xa,[474] factor XIa, plasma kallikrein,[475] urokinase,[476] prostate-specific antigen,[477] and sperm acrosin.[478]

A cDNA coding for protein C inhibitor[473] is 2,106 bp in length and codes for a signal peptide of 19 amino acids, a mature protein of 387 amino acids, and a stop codon. The 3′ noncoding region is 839 bp in length but lacked a typical polyadenylation sequence. The cleavage site for signal peptidase is Leu-His.

The gene for protein C inhibitor (SERPINA5) is 11.5 kb in length and contains five exons and four introns. The boundaries for the introns and exons all follow the typical GT-AG sequence. The gene for protein C inhibitor is located on chromosome 14q32.1.[479,480] The 5′ noncoding region of the gene lacks a typical TATA box and CCAAT sequences, but contains several cis elements including an Sp1-binding site (–302 to –294 bp) with strong promoter activity and two AP2-binding sites (–350 to –343 bp) with strong enhancer activity.[481]

CHAPTER

10 Genetics of Coagulation

RODNEY M. CAMIRE AND PARIS MARGARITIS

The determination of the gene, complementary deoxyribonucleic acid (cDNA), and amino acid sequences of all of the proteins known to be involved in the hemostatic process has been completed. This task, begun in the early 1980s, has allowed for (a) deduction of amino acid sequences from the cloned cDNAs of several species, (b) characterization of gene structure and organization, (c) characterization of mutations responsible for inherited abnormalities, (d) characterization of polymorphisms useful for gene-tracking studies, (e) production of large quantities of recombinant protein for research and for therapeutic purposes, and (f) the development of animal models of hemostatic disease through transgenic and gene knockout technologies. It has also made possible the contemplation of novel gene-based approaches for the treatment of bleeding diatheses. This chapter focuses primarily on various genetic aspects of procoagulant, anticoagulant, and fibrinolytic factors involved in human blood coagulation, with emphasis on gene structure and mutations that predispose to bleeding or thrombosis. We have also focused on mutational mechanisms and how new genomic information will impact genetic analysis.

GENOMIC INFORMATION

The completion of the Human Genome Project in April 2003 was an enormous scientific achievement,[1,2] providing substantial advances in the understanding of gene structure and organization, genetic variation, comparative genomics, genomic medicine, and gene interaction with environmental factors. There are currently three major Web portals that serve as central hubs for genome-related resources.[3] The first is the National Center for Biotechnology Information (NCBI) run by the National Institutes of Health (NIH) (http:// www.ncbi.nlm.nih.gov/); the second is Ensembl (http://www.ensembl.org/index.html), which is a collaborative effort between the Wellcome Trust Sanger Institute and European Molecular Biology Laboratory's (EMBL's) European Bioinformatics Institute; and the third is the University of California, Santa Cruz (UCSC) Genome Browser (http://www.genome.ucsc.edu) developed by an academic research group at the UCSC.

An immediate application of genomic sequence information is to accelerate the identification of genes that are associated with human disease. There are several strategies to accomplish this, the most common being genetic linkage analysis (genome-wide linkage scan or homozygosity mapping),[4] by which the chromosomal location of a disease-causing gene can be identified. Genome-wide linkage analysis usually requires families in which several individuals are affected with the disease of interest. Evenly spaced DNA markers are used to trace the inheritance of each copy of each chromosome. Chromosomal segments that do not influence disease segregate randomly, whereas the particular copy that, in each family, carries the disease-causing mutation will be shared among affected family members more often than would be predicted by chance.[5] The DNA markers that are typically used are termed microsatellites, which are di-, tri-, or tetranucleotide tandem repeats in DNA sequences and can be readily followed by simple polymerase chain reaction (PCR) techniques. Typically, the segment of the genome between identified microsatellite markers that influences the disease state is quite large: millions to tens of millions of base pairs in length, spanning dozens to hundreds of genes. However, the human genome project allows researchers to move rapidly from large chromosomal regions to individual candidate genes because all genes identified within any linkage region are immediately available.

The development of a haplotype map of the human genome will facilitate the identification of genes that are affected by environmental factors. A haplotype block of DNA, consisting of a group of nearby alleles or genetic markers that are inherited together, is roughly consistent among all humans, but different individuals have different versions of the blocks, allowing one to identify the relationship between haplotype blocks and diseases.[6] The International Haplotype Map Project (HapMap; http://hapmap.ncbi.nlm.nih.gov/) that aims to define the haplotype structure of human populations should greatly facilitate genetic linkage studies by allowing researchers to find genes that affect health, disease, and individual responses to medications and environmental factors.

MUTATIONS: MECHANISMS AND DATABASES

Alterations in a gene sequence can be neutral, detrimental, or favorable, and are semantically referred to as a mutation when the variation leads to a phenotypic change, a polymorphism when the genetic change is present in >5% of alleles in a population, and a rare sequence variant when the change occurs in <5% of alleles. Therefore, distinct populations show variations not only in disease prevalence but also in the frequency of polymorphic changes.

Types of Genetic Mutations

Point Mutations

A point mutation is defined as a change of a single base pair of a DNA sequence in a gene caused by the substitution of one nucleotide for another. A single codon in frame (missense mutation) may predict replacement of a single amino acid in an otherwise normal protein. When the change results in a stop codon (nonsense mutation), a truncated protein product

results. Sometimes, the mutated proteins are not properly produced, secreted into the blood, or located in the physiologic site. When they do circulate in substantial amounts, the variant protein often circulates with impaired function. When a single base change is phenotypically silent, this is commonly referred to as a single nucleotide polymorphism (SNP). Outside the actual coding region, it is even more likely that nucleotide substitutions are silent. Notable exceptions are mutations in binding sites for transcription factors that regulate gene activity, mutations that affect splicing of the immature RNA, and mutations that may alter the stability of the RNA.

Up to approximately 50% of the single nucleotide substitutions occur as transitions within cytosine–phosphoguanine (CpG) dinucleotides, the most common hot spot for mutation.[7,8] This finding is all the more remarkable when one considers that CpG dinucleotides are underrepresented in most genes, presumably because of the evolutionary loss of these dinucleotides. CpG dinucleotides are hot spots for mutation because they are sites of methylation of the cytosine residue (i.e., a CpG becomes a TpG or a CpA).[7] Methylcytosine readily deaminates to thymine spontaneously. After the C-to-T transition occurs in the reverse or "antisense" DNA strand, the sequence in its complementary coding strand is changed from G to A. Because the common (but not exclusive) codon for Arg is CGx, many CpG dinucleotide mutations are found within Arg codons, producing Arg-to-stop, Gln, His, Cys, or Trp mutations. When the same CpG transition occurs among different families, it often is possible to distinguish independent mutational events from founder effects through haplotype or pedigree analyses. The founder effect is the establishment of a new, typically isolated, population by a few original "founders" that carry only a fraction of the total genetic variation of the parental population.

Insertion/deletion

Insertion/deletion is a type of variation that is defined as a change in the DNA sequence created by the addition or subtraction of nucleotides. When the insertion or deletion is within the triplet open reading frame and the change is a number of nucleotides that is not a multiple of three, this disruption results in a frameshift mutation. During protein translation, a frameshift usually results in a premature stop codon producing a grossly abnormal protein with impaired function and viability.

Categorization of Mutations

Strictly speaking, a recessive mutation implies that heterozygotes (one copy of mutation) have a normal phenotype and that only homozygotes (two copies of the mutation) are phenotypically affected. Recessive-negative mutations display a predominantly recessive inheritance with a nearly infinite number of different mutations. Most mutations in the genes encoding the coagulation and fibrinolytic genes are recessive negative and come to clinical attention when present in homozygous (doubly or compound heterozygous) or hemizygous (for *X*-linked disorders) form.

A dominant mutation refers to a genetic change that lacks phenotypic differences between affected heterozygous and homozygous individuals. Dominant-negative mutations show a dominant inheritance with a narrow spectrum of mutations. From the perspective of family studies, this distinction is informative in that dominant mutations should be suspected after successive generations are affected; recessive mutations normally occur only within one generation. Less commonly, dominant (incomplete) inheritance is seen when there is a mutation that causes a gain of function, the best known example of which is factor V_{Leiden}. Genetically, gain-of-function mutations are clearly less heterogeneous than loss-of-function mutations, as there are infinite ways to destroy gene function, whereas only a few mutations lead to improvement of gene or protein function.

In reality, mutations are not always strictly dominant or recessive, as the penetrance of a mutant phenotype can vary dramatically, largely because of concomitant genetic changes. Therefore, recessive-negative mutations are not always entirely recessive. For example, although homozygous protein C deficiency produces severe thrombotic disease and purpura fulminans at birth,[9] heterozygotes may either experience thromboembolic disease later in life or never develop venous thrombosis.[10,11]

Normal Variants and Polymorphisms

Normal variants and polymorphisms are particularly useful in gene-tracking studies of families with a severe bleeding or thrombotic disorder. In such studies, a polymorphism is used as a marker of a defective gene, followed throughout a family when the actual gene mutation is not known. This approach has been particularly useful in genetic counseling for hemophilia A or B, and is increasingly applied as markers of risk factors for venous thrombosis and cardiovascular disease.[12] In the case of protein C, fibrinogen, factor VII, plasminogen activator inhibitor-1 (PAI-1), and the prothrombin 20210GA variant, a particular relation exists between polymorphisms and plasma levels of specific clotting factors.

Epigenetics

In addition to mutations, epigenetic changes within the genome can also have a direct effect on phenotype. Epigenetics refers to those mechanisms that control gene expression in a potentially heritable way yet do not involve changes to the underlying DNA sequence.[13] These traits exist on top of or in addition to the traditional molecular basis for inheritance. Driving these changes are covalent modifications to cytosine bases and histones (e.g., DNA methylation and acetylation of histones) and changes in positioning of nucleosomes.[14] Epigenetic changes to DNA plays an important role in the normal way cells respond to their environment and contribute to the regulation of many cellular processes. It is not surprising then that aberrant placement of epigenetic marks or defects in the epigenetic machinery lead to human disease. This is now well established in cancer and is becoming more appreciated in cardiovascular and autoimmune disease as well as neurologic disorders.[15] Thus epigenetic factors constitute a key link between genetics, disease and environment playing a decisive role in the underpinnings of human pathology. The Human Epigenome Project (HEP; http://www.epigenome.org/index.php) with the stated goal of cataloging and interpreting genome-wide DNA methylation patterns of all human genes in all major tissues, should allow researchers to make these important links.

Multifactorial Disease

Contrasting with rare monogenetic diseases are the milder and much more common multifactorial or complex diseases, such as type 2 diabetes mellitus, hypertension, coronary artery disease, and venous thrombosis. In venous thrombotic disease, thrombotic episodes typically occur relatively late in life, and in up to

50% of patients, genetic risk factors such as heterozygosity for mutations in coagulation inhibitors or cofactors are found.[16]

Databases of Mutations

Mutations in the genes for essentially all of the coagulation proteins can be found at the Human Gene Mutation Database (HGMD) at the Institute of Medical Genetics, at http://www.hgmd.cf.ac.uk/ac/index.php searching using the relevant gene symbol (Table 10.1). Additionally, a coagulation sequence and structure database (CoagBase; www.isth.org/default/index.cfm/standards/coagbase/) is maintained by the International Society of Thrombosis and Haemostasis, and ClotBase (http://www.clotbase.bicnirrh.res.in) provides a wide range of useful information including a catalog of known mutations for many coagulation factors.[17]

Table 10.1

Characteristics of human coagulation factor genes

Genes	Gene Symbol	Gene ID	Location	Exons	Gene	mRNA	cDNA
Prothrombin	F2	2147	11p11–q12	14	20.3 kb	1,997 bp	1,866 bp

The size of the cDNAs is defined as the number of nucleotides from the start to the stop codons.
EPCR, endothelial cell protein C receptor; TFPI, tissue-factor pathway inhibitor; HMW, high-molecular-weight; tPA, tissue-type plasminogen activator; PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin-activatable fibrinolysis inhibitor; vWF, von Willebrand factor.
Genomic and protein information for each gene can be obtained by using the Gene ID and searching "All Databases" at http://ncbi.nlm.nih.gov/.
Mutations can be found by searching for Gene Symbol at http://www.hgmd.cf.ac.uk/ac/index.php. Some coagulation factors have their own mutation databases. These can be found within each section.

MOLECULAR GENETICS OF HEMOSTATIC PROTEINS

Hemostatic proteins can be divided into procoagulant serine proteases, procoagulant cofactors, anticoagulants, contact activators, and fibrinolytic factors, plus several other relevant proteins fibrinogen, factor XIII, and von Willebrand factor (vWF). While not considered coagulation factors *per se*, both γ-glutamyl carboxylase and vitamin K 2,3-epoxide reductase I (VKOR) play an essential role in hemostasis. These enzymes are involved in the posttranslational carboxylation of specific glutamic acid residues using vitamin K within the amino-terminal Gla domains of vitamin K–dependent proteins (prothrombin, factor VII, IX, X, protein C, S, and Z).[18,19] Warfarin inhibits VKOR, and a deficiency of either of these enzymes is classified as vitamin K–dependent coagulation factors deficiency, typically characterized by hemorrhagic manifestations.[20] Knockout of the γ-glutamyl carboxylase gene in mice results in offspring surviving to term but dying uniformly at birth of massive intra-abdominal hemorrhage.[21]

The proteins considered in this chapter and their gene symbols, chromosomal location, size of gene, mRNA, and cDNA sequences are shown in Table 10.1. Most of the hemostatic proteins have been experimentally knocked-out in mouse models, and where appropriate, these studies are summarized in Table 10.2.

Table 10.2

Genetic models of thrombosis and hemostasis

Gene Knockout	Strain	Viable	Mortality Observed (Days of Gestation)	Phenotype	References
Prothrombin	C57BL/6	No	9–11	Fatal hemorrhage/yolk sac defect	31
Factor X	Swiss	No	11–13	Partial embryonic lethal/intra-abdominal bleeding	54
Factor VII	C57BL6/J	No	At birth	Fatal perinatal bleeding	77
Factor IX	C57BL/6	Yes	—	Severe bleeding following trauma	93–95
Factor XI	C57BL/6	Yes	—	Normal/prolonged aPTT	114
Tissue factor	Several	No	9.5–12	Fatal embryonic bleeding	125–127
Factor VIII	129sv	Yes	—	Severe bleeding following trauma	137
Factor V	C57BL/6J	No	9.5–10	Fatal hemorrhage/yolk sac defect	166
Protein C	Swiss	No	18.5–19	Consumptive coagulopathy	195
Protein S	129sv	No	15.5–17.5	Consumptive coagulopathy	229,230
Thrombomodulin	129sv	No	8.5–10	Embryonic lethal/yolk sac defect	203,205
EPCR	Swiss	No	9–10	Embryonic lethal/placental thrombosis	453
ATIII	C57BL/6J	No	15–16	Consumptive coagulopathy/severe hemorrhage	454
TFPI	C57BL/6	No	10–13	Intrauterine lethality	266
Heparin cofactor II	C57BL/6	Yes	—	Normal; differences in thrombosis model	285
tPA	C57BL/6	Yes	—	Develop normally	330
Plasminogen	C57BL/6	Yes	—	Predispose to thrombosis; ligneous conjunctivitis	346–348
Plasmin inhibitor	C57BL6/J	Yes	—	Develop normally; enhanced fibrinolytic potential	367
PAI-1	C57BL/6	Yes	—	Develop normally; mild hyperfibrinolytic state	397,398
TAFI	C57BL/6	Yes	—	Normal	410
Fibrinogen A chain	C57BL/6	Yes	—	Wound healing defect/failure of pregnancy	424
Factor XIII A chain	C57BL/6	Yes	—	Develop normally; severe uterine bleeding; miscarriages	439,440
vWF	C57BL/6J	Yes	—	Defects in hemostasis and thrombosis; model type 3 vWD	451
γ-Carboxylase	C57BL/6J	No	9.5–18	Massive intra-abdominal hemorrhage	21

EPCR, endothelial cell protein C receptor; ATIII, antithrombin III; TFPI, tissue factor pathway inhibitor; tPA, tissue-type plasminogen activator; PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin-activatable fibrinolysis inhibitor; vWF, von Willebrand factor.

Procoagulant Serine Proteases

Prothrombin

The vitamin K–dependent serine protease zymogen prothrombin plays a central role in the coagulation pathway. Following its activation by the prothrombinase complex (i.e., factor Xa, factor Va, calcium ions, and anionic membranes), the resulting product thrombin participates in numerous biologic processes, including the cleavage of fibrinogen to fibrin, which leads to clot formation (see Chapter 8). The gene encoding prothrombin is on chromosome 11p11–q12 and is approximately 20 kb in length with 14 exons.[22] The mRNA for human prothrombin was cloned in 1983 and is approximately 2 kb in length and includes a 1,866-bp cDNA.[23] The major site of synthesis of prothrombin is in the liver,[24] but minor sites are present in the central nervous system (CNS), skeletal and smooth muscle cells, and the kidney.[25–28] Prothrombin is expressed as a single polypeptide chain of 622 amino acids. Following removal of a 43–amino acid leader sequence, it is secreted into plasma as a 72-kDa protein containing 579 amino acids at a concentration of 1.4 μM.[23,29]

Homozygosity or compound heterozygosity for loss-of-function mutations in the prothrombin gene leads to a bleeding diathesis. There are no known cases of a total deficiency of prothrombin, consistent with the studies in mice showing lethality in utero with a complete absence of the protein.[30,31] Prothrombin deficiency has a prevalence of approximately 1:1,000,000 to 1:2,000,000.[32] Greater than 60 different mutations are known, most of which lead to a variant protein,[32] a number of which have been subjected to detailed biochemical analysis. For example, thrombin Quick I (Arg to Cys at 382) has near normal activity with thrombin-specific low molecular weight (LMW) substrates, but about 100 times lower activity with fibrinogen than that observed with thrombin.[33,34]

A common polymorphism that constitutes a major genetic risk factor for thrombosis is the 20210G to A mutation.[35] Position 20210 in the prothrombin mRNA is where prothrombin pre-mRNA undergoes 3′ cleavage and polyadenylation. This polymorphism was originally found in probands with a strong personal and familial history of venous thrombosis and is associated with slightly elevated plasma levels of prothrombin (~25%).[35] Further epidemiologic data confirmed that the DNA variant confers a three- to fourfold risk factor for venous thrombosis.[36–39] The prevalence of the 20210A allele is between 1% and 2% and is dependent on the geographic origin of the subjects.[40] Homozygotes are relatively rare.[39]

Initial reports indicated that the mutation, located 20 nucleotides downstream of the poly A signal, increases the post-translational 3′ end processing efficiency, thereby leading to a higher rate of transcription.[41] Additional studies showed that the mutant allele influences mRNA stability increasing cytoplasmic half-life.[42] However, these studies have been called into question because prothrombin 20210G and 20210A mRNA levels were found at equal levels in fresh liver tissue from a 20210G/A heterozygote.[43] This study was able to demonstrate that the 20210A mutation affects the position of the 3′-cleavage/polyadenylation reaction, an event that may lead to its abnormal mRNA function. Additionally, *in vitro* studies indicate that the G or A allele at 20210 have equal stability further implicating the importance of mRNA processing and/or translation, not cytoplasmic half-life, in regulating prothrombin expression.[44]

Factor X

Factor X is a vitamin K–dependent plasma protein that plays a central role in blood coagulation. In the presence of its cofactor protein factor Va, activated factor X cleaves two peptide bonds in prothrombin to form thrombin. Factor X is synthesized primarily in the liver, but other tissues also may contribute, such as lung, heart, ovary, and small intestine.[45] The gene for factor X has been cloned and is approximately 27 kb in length, contains 8 exons, and is located on chromosome 13q34–qter, 2.8 kb from the factor VII gene.[46,47] The cDNA has an open reading frame of 1,467 nucleotides and encodes a protein of 488 amino acids (preprofactor X).[48–50] Following proteolytic processing, mature factor X (59 kDa) is a two-chain serine protease zymogen of 445 amino acids, covalently associated through a single disulfide bond, circulating at a concentration of 170 nM.[51,52]

Factor X deficiency is a rare (1:1,000,000) autosomal recessive bleeding disorder.[53] Heterozygotes are usually free of symptoms but may exhibit abnormal bleeding during surgery. Over 50 factor X–deficient families are reported and over 100 different mutations have been identified.[53] Large deletions have been identified but most defects are missense mutations often associated with detectable factor X antigen levels and mild-to-asymptomatic disease.[53] Mice rendered experimentally deficient in factor X show frequent embryonic lethality, and those that survive die shortly after birth from massive intra-abdominal bleeding.[54,55]

A collection of factor X mutations has been described that have differential responses to the intrinsic and extrinsic pathways. For example, factor X Vorarlberg is associated with a marked reduction of activity in the extrinsic system and a much more modest reduction of activity in the intrinsic system.[56,57] These types of mutations imply that factor VIIa/tissue factor (TF) and factor IXa/factor VIIIa likely have different sites of interaction with factor X, despite the fact that they cleave the same bond within the zymogen. At least eight naturally occurring factor X variants display marked differences in activity in the intrinsic and extrinsic systems.[56–64]

Factor X was originally called Stuart-Prower factor after the first individuals in whom factor X deficiency was discovered.[65,66] One of the index cases of the Stuart family is homozygous for a replacement of Val by Met at position 298.[67] A descendent of the Prower case was shown to be a compound heterozygote for an Asp282 to Asn and an Arg287 to Trp mutation.[68] An informative historic sketch on the discovery of factor X has been published.[69]

Factor VII

Factor VII is a vitamin K–dependent serine protease zymogen that circulates in plasma as a single-chain polypeptide (50 kDa) of 406 amino acids at a concentration of 10 nM.[70–72] Like most clotting factors, it is synthesized primarily in the liver, as a 444–amino acid precursor protein. Activated factor VII, in concert with its cofactor, TF, initiates blood coagulation following vascular injury by activating factors IX and X.[73] The factor VII gene is relatively small (~13 kb), contains eight exons, and is located on chromosome 13q34–qter, only 2.8 kb upstream of the factor X gene.[74,75] The full-length mRNA is almost 2.5 kb, whereas the cDNA sequence is 1,335 nucleotides long.

Factor VII deficiency is a rare autosomal disorder with a prevalence of approximately 1:500,000.[76] Individuals with factor VII antigen and activity levels <1% display a moderate-to-severe

tahir99-VRG & vip.persianss.ir

bleeding phenotype. Mutations associated with this phenotype include frameshift, splice site, promoter, and missense mutations, with the total number of mutations now reaching more than 110.[76] The situation is less clear for mutations associated with measurable levels of factor VII activity, as many are asymptomatic.

It is not entirely clear whether a complete absence of factor VII is incompatible with life. For example, the factor VII knockout mouse develops normally to term, but dies shortly after birth from major abdominal and intracranial hemorrhage.[77] In addition, McVey et al.[78] identified a splice site mutation in the factor VII gene that was associated with a complete absence of factor VII and that resulted in fatal intracerebral hemorrhage at the age of 14 days. In contrast, Peyvandi et al.[79] have reported a homozygous 2-bp deletion in the factor VII gene that was associated with a complete absence of factor VII and was nonlethal. Although it is likely that some compensatory mechanism is affecting the phenotype in this individual, this mechanism has not yet been identified.

Several mutations have been identified in the promoter region of the factor VII gene; one of the mutations appears to disrupt the Sp1 binding site, whereas the other two interfere with binding of the transcription factor hepatocyte nuclear factor (HNF)-4 or the binding of an unidentified protein near the transcription state site.[80–82] Additional transcription factors (early growth response [EGR]-1, cAMP response element binding [CREB] protein, and upstream stimulatory factor-1) also bind within the proximal factor VII promoter region.[83] A mutation at −39 resulting in reduced plasma levels and activity may disrupt binding of CREB.[84]

Interest in the relation between elevated factor VII levels and an increased risk of cardiovascular disease was stimulated by the findings of the Northwick Park Heart Study (NPHS I).[78,85] However, results from a second prospective study (NPHS II) did not show a clear correlation between elevated factor VII levels and myocardial infarction risk or the inverse correlation with a factor VII lowering haplotype,[86] and further case–control studies showed that this polymorphism is associated with a lower risk of peripheral arterial disease.[87]

Since cardiovascular disease is a multifactorial outcome, it is likely that the relationship between plasma factor VII levels and arterial thrombosis is influenced by additional thrombotic risk factors such as diabetes, high body mass index, and elevated cholesterol levels.

Factor IX

Factor IX is a vitamin K–dependent serine protease zymogen that plays a critical role in the middle phase of blood coagulation. Activated factor IX is the serine protease component of the intrinsic Xase enzymatic complex, which is also composed of factor VIIIa, anionic membranes, and calcium ions (see Chapters 9 and 14). Factor IX is synthesized primarily in the liver and is composed of 461 amino acids. Following proteolytic processing and removal of the preproregion, it circulates in plasma as a single-chain 415–amino acid protein (55 kDa) at a concentration of 90 nM. The factor IX gene was cloned between 1982 and 1984 and lies on the long arm of the X chromosome, band q27.1.[88–92] The full gene sequence is known and is approximately 31 kb in length and has eight exons.[92] The mRNA is approximately 2.8 kb in length, whereas the cDNA is 1,386 bp long.[89,92]

Loss-of-function mutations in the factor IX gene result in hemophilia B. The prevalence of this *X*-linked disorder is 1 in 25,000 men, whereas women are rarely affected. The fivefold difference in prevalence between hemophilia A and B is roughly equivalent to the difference in size of the coding portions of the factor VIII and IX genes. The clinical manifestation of hemophilia B is almost identical to that for hemophilia A. Several mouse models of hemophilia B have proved useful in the development of new therapies.[93–95]

The first mutation in the factor IX gene, described in 1983,[96] was a deletion that showed up in a screening using Southern blotting of genomic DNA. The first point mutation in factor IX, factor IX Chapel Hill, was discovered by protein sequencing, not by DNA analysis.[97] At present, over 375 different mutations are known in the factor IX gene, many of which can be found in an international database (http://www.kcl.ac.uk/ip/petergreen/haemBdatabase.html). Some mutations occur independently in patients from diverse geographic regions, mostly mutations at CpG dinucleotides, accounting for approximately 50% of the independent missense mutations found in different families.

The numerous mutations in the 5′-untranslated region of the factor IX gene are associated with a certain form of hemophilia B (hemophilia B Leyden), arguably the most fascinating of all promoter mutations.[98,99,100] The unique feature of these variants is that individuals exhibit "recovery" from severe hemophilia with the onset of puberty. Therefore, the disease is characterized by the absence of factor IX expression in childhood (factor IX levels <2%) and a gradual rise in factor IX levels after the onset of puberty (see FIGURE 10.1). Studies using transgenic mice that robustly mimic the hemophilia B Leyden phenotype have uncovered the elusive molecular mechanism underlying the puberty-onset spontaneous amelioration of factor IX levels. This process relates to a puberty-onset gene switch (age-related stability element/age related increase element) and that growth hormone is directly responsible for the puberty-onset recovery of factor IX production.[101]

Three factor IX mutations (i.e., Ala10 to Val, Ala10 to Thr, and Asn9 to Lys) are associated with a unique type of genetic predisposition to bleeding during oral anticoagulation therapy that is attributable to increased warfarin sensitivity.[102–104] The Ala10 and Asn9 residues are within the factor IX propeptide region and are critical for interaction with γ-glutamyl carboxylase and, therefore, γ-carboxylation; mutations at these sites impair this reaction. When receiving coumarins, patients with these variants showed a disproportionate decrease of factor IX activity approaching that of severe hemophilia B. As a consequence, these patients may have bleeding at the very beginning of oral anticoagulation. After discontinuation of treatment, the factor IX levels return to normal.

While mutations in factor IX are generally not associated with thrombosis, elevated levels of factor IX have been associated with venous thrombosis.[105] A patient has been described with a missense mutation in factor IX (Arg338 to Leu; factor IX-Padua) that leads to thrombophilia.[106] The levels of the mutant protein were normal in the patient, but the coagulant activity was approximately eight times the normal level. To date, this is the only reported gain-of-function mutation resulting in a hyperfunctional factor IX protein predisposing to thrombosis.

tahir99-VRG & vip.persianss.ir

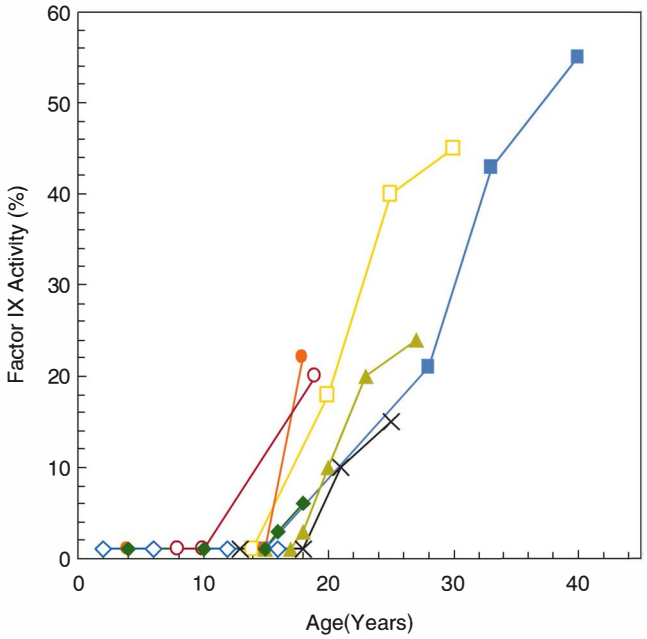

FIGURE 10.1 Factor IX levels measured over time in eight individuals with Leyden variant hemophilia B. These mutations in the promoter result in severe factor IX deficiency until puberty when factor IX levels rise gradually to approximately 30%. (Data from Briet E, Bertina RM, van Tilburg NH, et al. Hemophilia B Leyden: a sex-linked hereditary disorder that improves after puberty. (*N Engl J Med* 1982;306:788–790.)

Factor XI

Factor XI is a serine protease zymogen that contributes to hemostasis by activating factor IX (see Chapter 15A). Factor XI is converted to factor XIa through proteolytic cleavage, either by factor XIIa or by thrombin. A near full-length cDNA encoding factor XI was cloned in 1986, and the structure of the factor XI gene was determined in 1987.[107,108] The gene consists of 15 exons spread over 23 kb of DNA. The factor XI gene is on chromosome 4q34–q35, adjacent to the prekallikrein gene.[108] Factor XI is synthesized in the liver and circulates in plasma at a concentration of 30 nM.[109,110] It is a disulfide-bond–linked dimer of two 80-kDa polypeptides of 608 amino acids each.[109]

Factor XI deficiency is an autosomal disorder characterized by trauma- or surgery-induced hemorrhage and is only rarely characterized by spontaneous bleeds.[111] A mutation database specific for factor XI can be found at: http://www.factorxi.org/. It is usually rare in most ethnic groups but is highly prevalent among Ashkenazi Jews,[112] mutated factor XI genes being as high as 13%.[112,113] Homozygosity for factor XI deficiency is associated with a very mild bleeding tendency, even when factor XI levels are quite low, consistent with factor XI–deficient mice that do not show any increased tendency to bleed.[114]

The recurrence of mutations in Jews is thought to be the result of founder effects.[113] This interpretation is supported by the fact that in other ethnic groups the mutations are more diverse. Well over 150 different mutations are known in factor XI, many of which are associated with decreased antigen levels. The mutations vary from splice site defects and amino acid replacements to frameshift mutations.

Procoagulant Cofactors

Tissue Factor

TF is a cell-associated cofactor protein for activated factor VII, and the enzyme complex is considered to be the physiologic trigger of normal hemostasis and thrombotic disease (see Chapter 11).[73] The gene for TF resides on the short arm of chromosome 1 (p21–p22) and is approximately 12 kb long and contains six exons.[115,116] The size of the predominant TF mRNA in cells is approximately 2.2 kb, with the cDNA being 888 bp long.[115,117–119] TF is an integral membrane protein of 263 amino acids and is initially synthesized with a 32–amino acid signal peptide. TF is expressed constitutively by epithelial cells and adventitial fibroblasts surrounding blood vessels as well as by cardiomyocytes and astrocytes in the brain and is exposed to the blood following injury.[120,121] TF is present in the circulation, associated with hematopoietic cells and their microparticles.[122] Cardiovascular disease, sepsis, and cancer have increased "circulating TF" levels, thus potentially contributing to pathologic thrombosis.[123]

Several studies have identified binding sites for transcription factors that regulate basal and inducible TF gene expression in different cell types. Basal expression appears to be regulated by the Sp1 transcription factor, whereas inducible expression is regulated by c-Fos/c-Jun, c-Rel/p65, and EGR-1.[124] Regulation of TF expression by inflammatory mediators and angiogenic factors suggests that it may contribute to both inflammation and angiogenesis.

At present, there are no published missense mutations in the TF gene and no known TF-deficient patients, suggesting that TF deficiency may be lethal. Support for this concept comes from TF knockout mice that die *in utero* between days 8.5 and 10.5.[125–127] Promoter polymorphisms in the TF gene, however, have been identified. Six novel promoter polymorphisms have been found that are distributed over two haplotypes with equal frequencies, one of which (TF-603A) has been linked to venous thromboembolic disease, suggesting that it might protect against thrombosis by reducing the level of circulating TF, although no link with myocardial infarction has been found.[128] These polymorphisms significantly influence constitutive TF gene expression in human monocytes, but have no major effect on whole blood clotting time.[129]

Factor VIII

Factor VIII is a metal ion–dependent procofactor that circulates in plasma as a heterodimer of a heavy chain and light chain (see Chapter 12). Thrombin-activated factor VIII is the cofactor protein for factor IXa and plays a key role in the activation of factor X.[130] The essential role of factor VIII in blood coagulation is evidenced by the severe bleeding diathesis associated with its deficiency (hemophilia A). The factor VIII gene was originally cloned in 1984 and is approximately 186 kb in length and has 26 exons and lies on the X chromosome (q28).[131–133] The gene encodes a mature mRNA of approximately 9 kb, and the cDNA is 7,056 nucleotides long.[134,135] Preprofactor VIII has 2,351 amino acids, whereas mature factor VIII has 2,332 amino acids and circulates in plasma at a concentration of approximately 0.7 nM.[134–136] A mouse model of hemophilia A was described in 1995.[137] Accounts describing the discovery of the factor VIII protein and gene have been published.[138,139]

The first description of mutations in the factor VIII gene dates to 1985, in which two nonsense mutations in the coding

tahir99-VRG & vip.persianss.ir

sequence and two partial deletions of the factor VIII gene were described.[140] The finding of four distinctly different mutations in the factor VIII gene of otherwise similar patients was the first hint that a large variety of mutations exist in the factor VIII gene in patients with hemophilia.

There is also an unusually common inversion in the factor VIII gene that is highly prevalent among patients with severe hemophilia A.[141,142] This common rearrangement in the factor VIII gene was discovered in 1993 and is present in approximately 40% to 50% of all severe hemophilia A cases.[141] Because it is so prevalent and relatively easy to detect, the discovery of this rearrangement has revolutionized genetic counseling for hemophilia A. It results from an unequal crossover event between a sequence in intron 22 of the factor VIII gene and one of two extragenic copies of this sequence that lie distal on the X chromosome. Inversion of the factor VIII gene by homologous recombination leads to complete disruption of the factor VIII coding sequence and consequently to a severe form of hemophilia A (FIGURE 10.2). Another factor VIII inversion occurs in intron 1 and breaks the factor VIII gene, resulting in production of two chimeric mRNAs[143,144]; the prevalence of this inversion in patients with severe hemophilia A is approximately 4% to 5%.[144]

The molecular pathology of the factor VIII gene is updated and reviewed in an electronic version of the hemophilia A database: http://hadb.org.uk/. As of 2010, there were more than 1,400 unique mutations in factor VIII reported, including some 900 different point mutations. Missense mutations in FVIII span the entire molecule with a relatively equal distribution, except for the central B-domain (FIGURE 10.3), consistent with data indicating that this region is not needed for biologic activity.[145] The effect of these mutations on gene function is diverse. Severe dysfunction is produced by point mutations that introduce premature stop codons and by mutations that destroy splice junctions between introns and exons. On the other hand, these types of missense mutations that predict replacement of the normal amino acid by another amino acid also contain most, if not all, of the mild and moderately severe forms of hemophilia A.

Gene deletions of <100 bp up to several hundred kilobases have been found in many severely affected patients, and gene deletions may be present in up to 5% of such patients.[146] Insertions are relatively uncommon in the factor VIII gene. As with deletions, it is important to distinguish in-frame from frameshift insertions. In the group of large insertions are the so-called LINE (long inserted element) retrotransposons.[147,148] These DNA elements comprise approximately 5% of the human genome. Intact LINEs encode a protein with reverse transcriptase-like activity and have the capacity to spread through the genome through an RNA intermediate. The LINE first identified in patients with hemophilia A was derived from an element on chromosome 22. Subsequent to the original description in hemophilia A, insertion of LINEs has been found to disrupt various other genes.

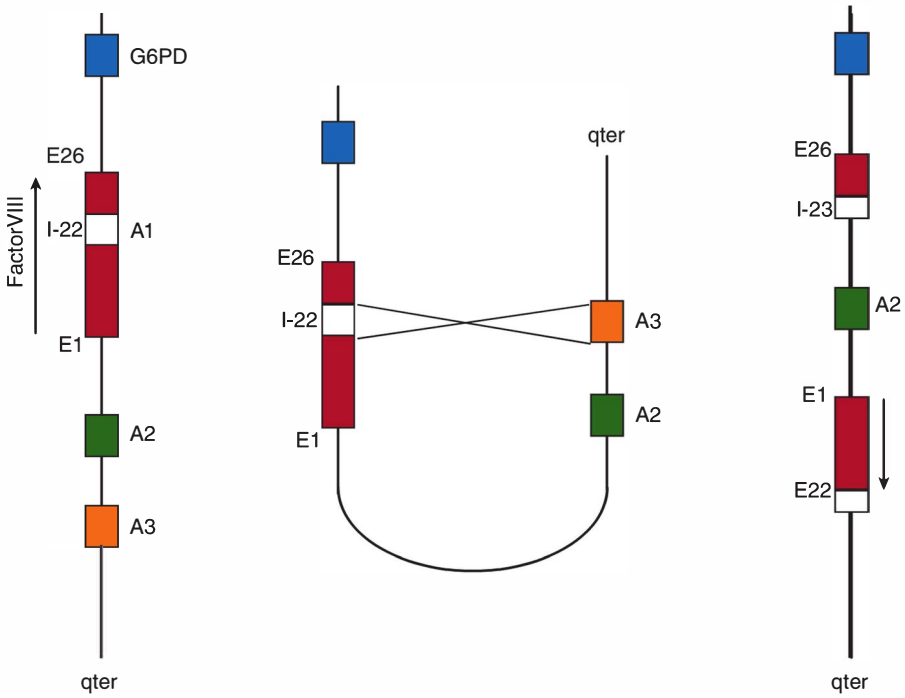

FIGURE 10.2 Factor VIII intron 22 inversion. The **left panel** depicts the normal alignment of the factor VIII gene on the X chromosome. Intron 22 (*white box*) of the factor VIII gene harbors a copy of the so-called A1 gene, whereas highly homologous A2 and A3 genes are located toward the tip of the X chromosome (indicated as qter). The **middle panel** shows alignment of the A1 gene with the A3 gene as it may occur during male spermatogenesis. When this alignment of A1 with A2 (or alternatively A3) results in a nonhomologous recombination, a rearrangement results as depicted at the **right panel**. In this rearranged X chromosome, the integrity of the factor VIII gene is completely disrupted because it is cut in two parts that are now aligned in opposite directions.

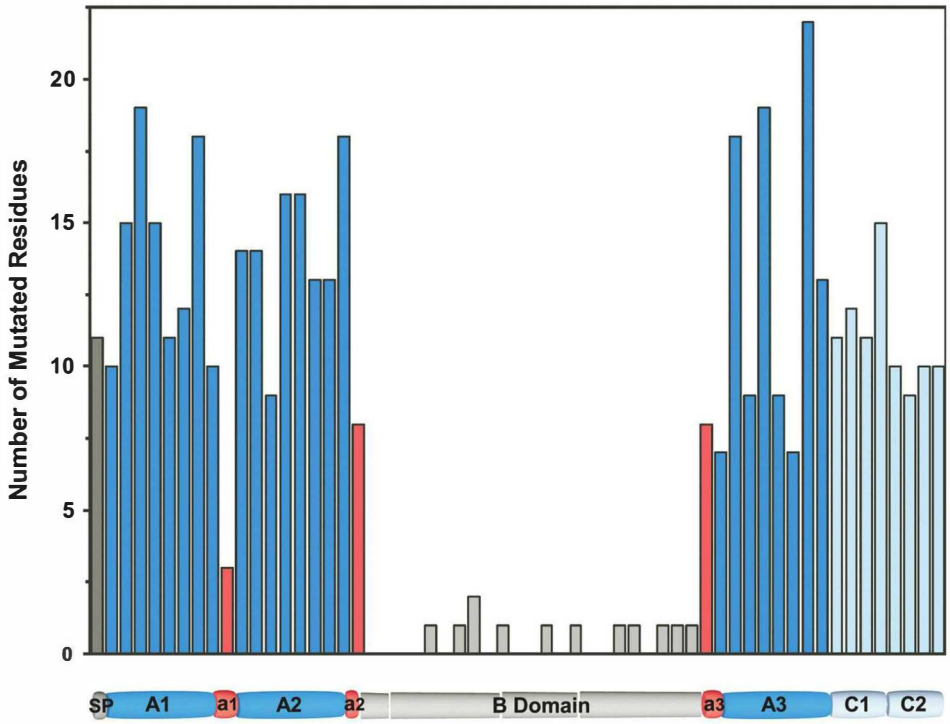

FIGURE 10.3 Graphic representation of missense mutation within factor VIII. Mutations in factor VIII leading to hemophilia A are presented in 40 residue blocks spanning the molecule. Mutations were derived from the hemophilia A mutation database (http://hadb.org.uk) with nonsense mutations excluded. (*J. Coagul Disord* 2010;2:19-27, with permission.)

Factor V

Activated factor V is the cofactor protein for the serine protease factor Xa in the prothrombinase complex. The precursor of factor Va is factor V, a large heavily glycosylated, single-chain protein that is homologous to factor VIII (see Chapter 12).[149] The factor V gene is located on the long arm of chromosome 1q23, not far from the antithrombin gene and is approximately 80 kb in length and contains 25 exons.[150] The first factor V cDNA sequences were published in 1986 to 1987.[151–153] The mRNA is approximately 7 kb, whereas the cDNA sequence is 6,675 nucleotides long. Factor V is synthesized in the liver as a 2,240–amino acid protein and is secreted after preproprocessing as a 2,196 single-chain protein and circulates in plasma at a concentration of 20 nM.[154–156] In addition to plasma factor V, approximately 20% of the total factor V in whole blood is contained in the α-granules of platelets.[156] Although it was originally thought that megakaryocytes synthesize factor V,[157,158] studies in humans indicate that most of the platelet-derived factor V originates from plasma through an endocytotic mechanism.[159–162]

Factor V deficiency is a rare recessively inherited disorder associated with a mild-to-severe bleeding tendency caused by loss-of-function mutations in the factor V gene.[163] It was first described in the 1940s by Owren[164] in Norway. Its incidence is about 1:1,000,000 and there have been more than 200 cases described so far. Because factor V deficiency is so rare and the gene is large, relatively few patients have been characterized genetically, with over 50 mutations reported, including missense mutations, insertions, deletions, and splice-site mutations.

The factor V phenotype is quite variable and correlates poorly with plasma FV levels.[165] Patients with undetectable levels of FV (<1%) due to homozygous nonsense, frameshift, or missense mutations, exhibit the gamut of phenotypes from asymptomatic to severe bleeding. These observations are difficult to reconcile, as FV knockout mice display a severe phenotype where approximately 50% of the embryos do not survive past mid-gestation and the remaining die within hours after birth from excessive hemorrhage.[166] Two recent studies have provided some insight into the possible mechanism that may blunt the phenotype in FV deficiency. These studies show that these patients consistently have low levels of Tissue factor pathway inhibitor (TFPI) and small but detectable amounts of platelet FV which, when released from activated platelets, contributes to thrombin generation.[167,168]

In some cases, factor V deficiency is coinherited with factor VIII deficiency, the molecular basis for which is now clear.[169] Combined factor V and VIII deficiency is a distinct autosomal recessive disorder, and the affected patients demonstrate a moderate bleeding tendency. Approximately 50% of the families described to date are of Mediterranean origin, and the disorder is particularly prevalent among Jews of Middle Eastern and Sephardic origin.[170] Elegant positional cloning studies into combined factor V and VIII deficiency initially identified a candidate gene called *ERGIC-53* (now called *LMAN1*).[169,171,172] *LMAN1* is a mannose-binding type 1 transmembrane protein localized to the endoplasmic reticulum (ER)–Golgi intermediate compartment that likely functions as a molecular chaperone of a specific subset of secreted proteins, including coagulation factors V and VIII. DNA sequence analysis has identified over 30 different mutations in *LMAN1* spread across the entire gene. However, in a subset of patients, no mutation in *LMAN1* could be found, suggesting that mutations in another gene may also

tahir99-VRG & vip.persianss.ir

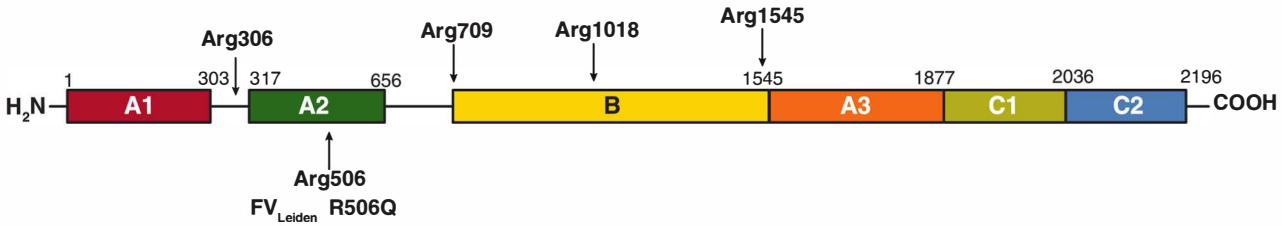

FIGURE 10.4 Illustration of the molecular defect called factor V_{Leiden}. Central in the figure is a schematic illustration of the domain structure of mature factor V as it circulates in plasma (A1-A2-B-A3-C1-C2). Factor V is activated by thrombin or factor Xa. The major cleavage sites for these activators are Arg709, Arg1018, and Arg1545. Activated factor V can be inactivated by (APC). Inactivation occurs by cleavage of a site (Arg306) between domains A1 and A2, at Arg506 within the A2 domain, and at Arg679 (not shown). In factor $V_{Leiden,}$ the codon for Arg506 at the A2 cleavage site is changed to Gln. This amino acid replacement results in loss of the A2 inactivation site and therefore in a factor Va molecule relatively resistant to APC. Mutations have also been identified at the Arg306 cleavage site: factor $V_{Cambridge}$ and factor $V_{Hong\ Kong}$.

be associated with combined factors V/VIII deficiency. This second gene and corresponding mutations causing factor V/VIII deficiency is termed *MCFD2* (multiple coagulation factor deficiency 2).[173] *MCFD2* is localized to the ER–Golgi intermediate compartment through a direct interaction with *LMAN1*. The phenotypes associated with mutations in *MCFD2* and *LMAN1* are indistinguishable and associated only with deficiency of factors V and VIII, although a selective delay in secretion of other proteins has been noted.[169]

The most common genetic defect described in factor V is a gain-of-function mutation. In 1993 Dahlbäck et al.[174] observed that plasma from individuals who experienced venous thrombotic episodes had a reduced response to activated protein C (APC), a condition that was termed *APC resistance*. The genetic basis of this abnormality is a G1691 to A mutation in the factor V gene, which results in a change of Arg506 to Gln at a critical APC inactivation cleavage site in factor Va (FIGURE 10.4).[175,176,177] The mutation was termed *factor* V_{Leiden} and is associated not with a bleeding diathesis but with an increased thrombotic risk. Factor Va_{Leiden} is less readily inactivated by APC, thereby enhancing the procoagulant capacities of factor V.[178–180] This genetic abnormality is prevalent in approximately 3% of whites, representing the most common genetic risk factor in venous thrombosis.[181] An historic sketch on the discovery of APC resistance has recently been published by Dahlbäck.[182]

Most individuals are heterozygous for factor V_{Leiden}, but homozygosity is also seen, and there also exists the so-called pseudohomozygosity for factor V_{Leiden},[183,184] in which one factor V allele carries the 506 mutation and the other harbors a loss-of-function mutation. Mutations at Arg306, another critical APC cleavage site, are also associated with APC resistance and thrombotic disease.[185,186]

Inhibitors of Coagulation

Protein C

Protein C is a vitamin K–dependent plasma serine protease zymogen that plays a central role in regulating blood coagulation as an anticoagulant (see Chapter 19). Thrombin in complex with thrombomodulin on endothelial cells is the major activator of protein C. APC exerts its anticoagulant function by inactivating, via limited proteolysis, factors Va and VIIIa.[182] Human protein C is encoded by a gene on chromosome 2q13–q14 and spans approximately 11 kb and contains nine exons.[187–189] The protein C gene encodes mRNA transcripts of 1.8 and 1.6 kb; the difference appears to result from alternative polyadenylation signals present in the transcript.[190] The cDNA is 1,386 nucleotide long and encodes a mature protein of 461 amino acids. Prior to secretion, a 42–amino acid preprosequence is removed as well as internal proteolytic cleavage, resulting in the secretion of a 419–amino acid two-chain protein (62 kDa) that circulates in plasma at a concentration of 60 nM.[190,191]

Loss-of-function mutations in the protein C gene lead to protein C deficiency, first described in 1981.[192] After this original report, many others confirmed that heterozygosity for protein C deficiency in a significant number of families with venous thrombosis, a disease expected to be related to low levels of protein C. In homozygotes, life-threatening thrombotic symptoms often start immediately after birth and take the form of purpura fulminans.[193,194] Inactivation of the protein C gene in mice leads to lethal perinatal consumptive coagulopathy and is inconsistent with even short-term survival.[195]

More than 300 different mutations have been described for the protein C gene. Each of these mutations is assumed (or has been proved) to lead to absent or defective protein C. Mutations in the protein C gene can be found at: http://www.itb.cnr.it/procmd/. The mutations range from missense mutations (some leading to variant proteins that have proven useful for structure–function analysis of plasma purified protein), promoter mutations, and RNA processing mutations to frameshift mutations.

The protein C database of mutations contains many multiple entries for certain mutations. For instance, the Arg230 to Cys mutation has been documented in 28 apparently unrelated families. Two factors are important when considering these multiple occurrences of mutations. The first is that they may result from a founder effect. In one example, the common origin of several families was traced back to the 18th century.[196] The second explanation for the recurrence of mutations is that they have arisen independently. On the basis of geographic considerations or haplotyping, this has been confirmed for several mutations.[196,197] These recurrent mutations typically occur at CpG dinucleotides. When one plots the relation between specific mutations and the geographic dispersal, the observed curve closely matches the curve that is expected on the basis of the likelihood of a given mutation to occur.[198] This analysis indicates that most multiple reports of mutations reflect recurrent mutation rather than founder effect.

Thrombomodulin

Thrombomodulin is an endothelial cell surface glycoprotein (GP) receptor for thrombin. The thrombin–thrombomodulin complex initiates the protein C anticoagulant pathway by activating the zymogen protein C (see Chapter 19). Several groups have cloned and sequenced the thrombomodulin cDNA and gene.[199–201] The gene is 4.2 kb in length and is located on chromosome 20p12–cen and is unusual in that it does not contain any introns and has a high GC content. The mRNA is approximately 4 kb in length, whereas the cDNA is 1,728 bp long and encodes a protein of 575 amino acids. The mature protein is 559 amino acids in length following removal of the signal sequence. An informative historic sketch on the discovery of thrombomodulin has been recently published.[202]

Given its function in the protein C pathway, a hereditary deficiency of thrombomodulin is a strong candidate for pathophysiologic involvement in venous thrombosis. Mice genetically modified to inactivate or alter (missense mutation) the thrombomodulin gene show increased fibrin deposition and a prothrombotic state.[203–205] Some evidence from clinical studies supports a role for thrombomodulin in thrombotic disease. For example, in the Atherosclerosis Risk in Communities study, soluble thrombomodulin shows a strong, graded, inverse association with and is a good predictor of incident coronary artery disease.[206] Mutations in the thrombomodulin gene occur in patients with thromboembolic disease[207,208] or atypical hemolytic uremic syndrome,[209] several of which have been recently biochemically characterized.[210] The Ala455 to Val polymorphism in whites is not a risk factor for venous thrombosis[211,212]; however, it may be associated with cardiovascular risk in certain populations and may also be associated with varicose veins through linkage with promoter mutations.[213,214]

Protein S

Protein S is a vitamin K–dependent GP with anticoagulant effect in the coagulation pathway (see Chapter 19). Protein S circulates in plasma in two forms: free (~40%) and bound to C4b binding protein, a component of the complement system. Only free protein S has anticoagulant properties. Protein S acts as a cofactor for APC in the inactivation of the procoagulant factors Va and VIIIa, possibly by potentiating the binding of protein C to procoagulant phospholipid surfaces; however, the precise mechanism is not known, and the effects of protein S in modulating APC function *in vitro* tend to be minor.

The human genome contains two protein S genes, one of which is active (*PROS1*), and the other a pseudogene (*PROS2*).[215–217] The *PROS1* gene is approximately 80 kb in length and contains 15 exons and is located on chromosome 3 (3p11.1–q11.2).[218–235,236] The major mRNA species from *PROS1* is approximately 4 kb long, whereas the cDNA is 2,031 nucleotides in length.[218,219] The protein S precursor protein is 676 amino acids long, whereas mature protein S is a single-chain GP of 635 amino acids. The *PROS2* gene is a highly homologous pseudogene of *PROS1* that contains a variety of mutations, such as stop codons and deletions that prohibit proper translation. Moreover, no transcription product of the *PROS2* gene is identified.[220]

Mutations in the protein S gene lead to protein S deficiency, an autosomal dominant trait affecting up to 5% of families with congenital thrombophilia.[221] After the first cases of heterozygous protein S deficiency were described in 1984, numerous reports have appeared.[222–224] The prevalence in the general population is not known with great certainty. The clinical symptoms in heterozygous protein S deficiency are comparable to protein C deficiency and are relatively mild. Only a few cases of homozygous deficiency have been described, and these were associated with severe thrombotic disease and purpura fulminans immediately after birth.[225–228] Mice deficient in protein S (PROS1$^{-/-}$) die in utero from a fulminant coagulopathy and associated hemorrhages.[229,230]

The mutations of protein S deficiency are collated in the HGMD database, currently describing the findings in almost 200 patients. The spectrum of mutations is similar to that for hemophilia B and protein C deficiency, including 154 different point mutations and a translocation.[231] Only 14 of the mutations occur in CpG dinucleotides and are compatible with methylation-mediated deamination.[7] This differs from what was found in hemophilia B or protein C deficiency, in which approximately 30% of the point mutations occur in CpG dinucleotides.

Endothelial Cell Protein C receptor

The endothelial cell protein C receptor (EPCR), a cell-specific type 1 transmembrane protein that binds both protein C and APC, was identified in 1994.[232,233] The protein functions by augmenting protein C activation by the thrombin–thrombomodulin complex, primarily by reducing the apparent K_m for protein C.[234] A soluble form of EPCR (43 kDa) circulates at a concentration of approximately 2.5 nM.[235] The gene for EPCR spans about 6 kb of genomic DNA, contains four exons, and is localized to chromosome 20 (20q11.2).[236,237] The mRNA is approximately 1.4 kb, whereas the cDNA is 717 nucleotides in length and encodes a protein of 238 amino acids.[232] In adults, EPCR is localized primarily on endothelial cells of large blood vessels, but during development it is expressed at high levels on trophoblast giant cells.[238,239]

In view of the role EPCR plays in the protein C pathway, deficiencies of the protein might be expected to be thrombogenic. Although homozygous EPCR deficiency has not been described in humans, the EPCR knockout mouse exhibits placental thrombosis and an early embryonic (E10.5) lethal phenotype.

In 2001, the first mutation in the *EPCR* gene was reported, a 23-bp insertion in the *EPCR* gene in survivors of myocardial infarction and deep vein thrombosis.[240] Its role in thrombosis is difficult to assess because the allelic frequency is low.[241–244] Point mutations have also been described in the promoter region of the gene in four thrombophilic patients and also in the coding region (Arg96 to Cys), but the involvement of these mutations in gene regulation or functional activity could not be clearly demonstrated.[245,246] Elevated levels of soluble EPCR associated with the A3 haplotype (characterized by 13 polymorphisms) are associated with an increased risk of venous thrombosis,[247] but this is controversial, given the wide range of soluble EPCR in plasma of A3 carriers, with only the high levels being associated with venous thrombosis.[247–249] An additional SNP in the A3 haplotype has been associated with reduced risk of premature myocardial infarction, partly by increased levels of soluble EPCR.[250] Further studies are needed in order to evaluate the actual importance of the *EPCR* gene variations in thrombotic diseases.

Antithrombin III

Antithrombin is the major serpin family regulator of blood-clotting proteases in plasma (see Chapter 18). This anticoagulant protein downregulates blood clotting by inhibiting thrombin, factor Xa, and factor IXa, thereby forming a stable equimolar

tahir99-VRG & vip.persianss.ir

complex with the enzymes by an unusual mechanism that is shared by other serpin family protease inhibitors.[251] Inhibition of protease activity is greatly accelerated by the participation of the glycosaminoglycans heparin and heparin sulfate that induce conformational changes that enhance the serpin's reactivity with the enzymes.

The relative abundance (approximately 2.5 μM; 150 μg/mL) of antithrombin and its ease of purification from plasma facilitated the deduction of most of its primary structure by Edman degradation in 1979.[252] The first cDNA sequence was cloned between 1982 and 1983,[253–255] and 10 years later the full gene sequence was published.[256] The 13.5-kb gene is localized on chromosome 1q23–24 and consists of seven exons.[257–259] The mRNA is approximately 1.4 kb long, whereas the cDNA is 1,395 bp long. The deduced primary structure of the protein indicates a 32–amino acid signal sequence and a mature protein of 432 amino acids.

Because of its essential role as an anticoagulant, individuals with deficiencies of antithrombin are at increased risk for thrombosis. The prevalence of this condition in the general population is approximately 1:500.[260] The prevalence in patients with a history of thromboembolic disease is approximately 5%.[261] The first report of antithrombin deficiency was published in 1965,[262] and the first mutation was characterized in 1983.[263] The mutations (>250) are collated on a regular basis in a database of antithrombin mutations: (http://www1.imperial.ac.uk/departmentofmedicine/divisions/experimentalmedicine/haematology/coag/antithrombin/).

Tissue Factor Pathway Inhibitor

TFPI is a trivalent 34-kDa-proteinase inhibitor. The inhibitor, a Kunitz-type protein, plays an essential role in regulating coagulation through the inhibition of a quaternary complex of TFPI, factor VIIa, TF, and factor Xa. The first Kunitz domain (K1) of the TFPI protein is an *N*-terminal acidic region that inhibits factor VIIa complexed to TF. The second Kunitz domain (K2) inhibits factor Xa, and the third Kunitz domain (K3) contains the *C*-terminal basic region. An account of the discovery and isolation of TFPI has been published recently by Broze.[264]

The gene for TFPI is approximately 85 kb, located on chromosome 2q31–q32.1, and contains nine exons. Unlike deficiencies of other coagulation inhibitors (i.e., antithrombin, protein C, and protein S), severe deficiencies of TFPI have yet to be described. However, there may be a decreased threshold for thrombosis as suggested by TFPI resistance, which is defined as poor anticoagulant response to TFPI. This resistance was observed in 4.7% of controls and in 11.0% of patients with venous thrombosis.[265] Heterozygous TFPI knockout mice are phenotypically normal, despite lower levels of TFPI in a factor VIIa/TF inhibition assay.[266] In homozygous TFPI knockout mice, embryonic lethality with signs of yolk sac hemorrhage was seen in 60% of the litter between E9.5 and E11.5.[266] Past E11.5, CNS and tail hemorrhages were present, and none of the knockout mice survived to the neonatal period.

To date, five polymorphisms have been described in the TFPI gene, two in the promoter, two in the coding region, and one in intron 7.[267–270] Several of these have been assessed for their effect on the risk of venous thrombosis, with conflicting results. The Pro15 to Leu polymorphism was first reported to be associated with venous thrombosis,[267,271] but this was not confirmed by subsequent studies.[272,273] There was no association found between the risk of venous thrombosis or coronary heart disease with either the Val264 to Met or the C-399T and T-287C promoter polymorphisms.[267,274] The T-33C polymorphism in intron 7 appears to be an independent risk factor for venous thrombosis but larger independent studies are needed for verification.[275]

Heparin Cofactor II

Heparin cofactor II (HCII), a plasma serine protein inhibitor (serpin), specifically binds and inactivates thrombin in the presence of heparin, heparan sulfate, and dermatan sulfate (see Chapter 18), inhibiting the rate of thrombin activity by 1,000-fold.[276] HCII is highly homologous with antithrombin III, with the notable exception that the equivalent of Arg393 in antithrombin III is a Leu. Its stimulation by dermatan sulfate is unique among the serpins. A full-length cDNA for HCII was isolated and sequenced in 1988,[277] and the complete sequence of the gene, which has five exons and is nearly 13.6 kb in length has been localized to chromosome 22q11.21.[278]

HCII is synthesized in the liver and circulates at a concentration of approximately 1 μM.[279] During the third trimester, HCII levels increase to 150%[280] and thrombin-HCII levels increase fourfold,[281] whereas a 50% decrease in the HCII levels occurs in women with preeclampsia.[282]

Inherited deficiency of HCII has been documented in at least 15 families.[283] Heterozygous deficiency may predispose patients to both arterial and venous thromboembolic disorders, but solid data to support these claims still are lacking.[284] Several mutations in the HCII gene have been described and characterized, three of which are missense mutations and two are frameshifts, one an insertion and the other a deletion. Mice deficient in HCII are viable and fertile without any gross abnormalities, and are born at the expected Mendelian frequency.[285] However, a photochemical model of induced endothelial cell injury suggests that HCII may inhibit arterial thrombosis.

Contact Activation Factors

Factor XII

Factor XII (Hageman factor) is an activator both of the coagulation system and the kinin system. It is synthesized in the liver and circulates as an inactive zymogen. During contact activation, factor XII is proteolytically cleaved at several sites by plasma kallikrein to yield enzymatically active factor XIIa. Factor XIIa is capable of activating prekallikrein and factor XI and is therefore the first component of the contact activation system,[286] but it does not undergo autoactivation.

The amino acid sequence of factor XII was determined between 1983 and 1985,[287,288] and factor XII cDNA was cloned in 1985.[289] The mRNA is 2,048 nucleotides long and encodes a protein of 615 amino acids, and the gene is 12 kb long with 14 exons and is located on chromosome 5q33–qter.[290,291] The promoter of factor XII is TATA-less and contains a functional estrogen response element modulated by HNF-4 in an estrogen-dependent manner.[292]

Factor XII deficiency was first described by Ratnoff and Colopy in 1955 in a patient named John Hageman, who had a prolonged clotting time but no hemorrhagic symptoms.[286] The markedly prolonged activated partial thromboplastin time (aPTT) (>150 seconds) corrects to normal with a 1:1 mix with normal plasma. There is no recognized bleeding tendency or

tahir99-VRG & vip.persianss.ir

clinical consequences,[293–296] and in fact, Mr. Hageman died of pulmonary embolism.

To date, there are over 200 reported cases of factor XII deficiency,[297] with over 20 mutations in the factor XII gene, most of which are missense. The first patient in whom a specific point mutation was identified had a Cys571 to Ser change,[293] affecting the disulfide bond that stabilizes the active center Ser in serine proteases and likely responsible for the moderately severe decrease of factor XII activity (3% level). In one large study of 31 unrelated patients from Austria, Germany, and Switzerland, several novel mutations were found, including missense mutations that directly or indirectly affected the catalytic triad of factor XII, two of which caused shifts in the reading frame of the gene.[295]

In the factor XII 5′ untranslated region, a common C-to-T transition associated with lower levels of factor XII has been proposed to play a protective role against coronary disease as well as a role in responsiveness to therapy.[298,299] In some, but not all, studies reported, low levels of factor XII coagulant activity have been associated with recurrent abortion in up to 14% of women.[300]

Prekallikrein

Plasma prekallikrein (KLKB1, previously known as KLK3) is the zymogen of a serine protease and is activated by factor XIIa. The active enzyme, kallikrein, shows proteolytic activity on a number of substrates, of which, factor XII, high molecular weight (HMW) kininogen, and urokinase are probably of physiologic importance.[301,302] Prekallikrein circulates as a complex with HMW kininogen (HK) at a concentration of about 40 μg/mL. Prolylcarboxypeptidase is a physiologic endothelial cell activator of plasma prekallikrein.[303]

Both amino acid sequence analysis and cDNA cloning have been used to determine the primary structure of prekallikrein.[304] The mRNA is approximately 2.2 kb long and encodes a protein of 638 amino acids.[304] The human prekallikrein gene is approximately 31 kb long, contains 15 exons, and is located on chromosome 4q34–35, not far from the factor XI gene.[305]

Several kindred with plasma prekallikrein deficiency (Fletcher factor deficiency) have been reported[297,306–309] with no detectable prekallikrein activity. Despite this, affected individuals have no bleeding tendency or any other clinical problems. In 2003, the first reports on the genetic basis for prekallikrein deficiency were reported in two separate families[310,311] and to date six missense mutations have been reported.

High Molecular Weight Kininogen

The plasma kininogens are the substrate for kallikrein. HK and LMW kininogen (LK) are two related plasma proteins that derive from the same gene on chromosome 3q26–qter through alternative splicing.[312–315] Normal, mature, secreted, full-length HK is a 626–amino acid protein.

Deficiency of HK is a rare disorder lacking a bleeding or thrombotic phenotype despite a prolonged aPTT >150 seconds. There are approximately 35 reported cases of HK deficiency.[297] One of the originally described patients who was deficient in kininogen with the associated Williams trait was homozygous for a C-to-T transition at nucleotide 586, resulting in an Arg-to-stop mutation in the fifth exon.[316] Fitzgerald trait has a nonsense mutation at amino acid 502 with no functional HK activity and 40% LK antigen.[317]

In a 6-year-old boy who had extensive left vertebral basilar artery thrombosis and a left vertebral artery dissection subsequent to a traumatic injury, a frameshift mutation of a single base pair deletion at amino acid 480 of the mature protein was associated with absent plasma HK because of degeneration into a stop codon downstream.[318]

Fibrinolytic Factors

Tissue-type Plasminogen Activator

Once a clot has been formed, the fibrinolytic system comes into play to dissolve the clot in a regulated fashion. Like the coagulation system, the fibrinolytic system is a network of reactions in which zymogens are proteolytically cleaved to form active enzymes. The final step in the cascade of reactions is the activation of plasminogen to plasmin, which is the principal degrading enzyme of insoluble fibrin.

Tissue-type plasminogen activator (tPA) is a plasma serine protease that mediates plasmin generation and clot lysis by specifically cleaving and activating clot-bound plasminogen.[319] Endothelial-derived tPA is the main endothelial cell–derived blood activator of the fibrinolytic system, modulates cerebrovascular tone, and may play a part in the hemodynamic changes occurring in brain trauma and ischemia.[320–322] The tPA gene is relatively large (i.e., 32.7 kb), contains 14 exons, and is located on chromosome 8 (p12–p11).[323–326] The *tPA* mRNA was isolated in 1983 using a human Bowes melanoma cell line[327] encoding a mature protein of 527 amino acids with a molecular mass of 68 kDa. Endothelial cells secrete tPA primarily as a single-chain GP, but it is converted to the two-chain form by plasmin-mediated cleavage at Arg275.[319] In normal plasma, the antigen concentration of tPA is approximately 0.005 μg/mL (i.e., 70 pM), and most of it in complex with PAI-1.[328,329] A tPA knockout mouse developed normally and did not exhibit any macroscopic abnormality,[330] although microscopic examination revealed mild glomerulonephritis. An informative historic sketch on discovery of tPA has recently been published.[331]

Of the numerous nucleotide sequence differences that have been identified within the *tPA* gene, the most studied is a 311-bp Alu insertion/deletion in intron 8.[332] In one study, the presence of one insertion was associated with an increased risk of myocardial infarction, whereas homozygous carriers had a twofold adjusted risk.[333] These findings, however, could not be confirmed in other investigations, calling into question the role of this variation in arterial disease.[334] Moreover, the risk of acute myocardial infarction and the Alu repeat appears to be dependent on the population studied,[333,335,336] suggesting that additional genetic factors may influence such risk.

Evidence exists that tPA levels can predict cardiovascular disease in apparently healthy individuals.[337] In a search for genetic variations that may effect tPA protein production, eight polymorphisms were identified.[338] One of these polymorphisms located at position –7,351 within the enhancer region of the *tPA* gene was identified and was strongly correlated with endothelial tPA release rates.[338] This polymorphism is within a Sp1 binding site, and the T allele inhibits Sp1 binding and was associated with <50% of the tPA release observed compared to the wild-type C allele. This polymorphism has a strong association with first myocardial infarction and lacunar stroke.[339]

tahir99-VRG & vip.persianss.ir

Plasminogen

The terminal event in the activation of the fibrinolytic system is the generation of the serine protease plasmin, which has a variety of functional properties, the most notable being dissolution of fibrin clots.[319] The precursor of plasmin is plasminogen, a single chain GP of 92 kDa that circulates in plasma at a concentration of 200 μg/mL (i.e., 2 μM). The primary amino acid sequence of plasminogen was reported in 1978.[340] The plasminogen gene encodes an mRNA transcript of approximately 2.9 kb, whereas the cDNA is 2,433 bp in length and encodes a 791–amino acid mature protein with a 19–amino acid signal sequence.[341,342] The gene for plasminogen is localized on chromosome 6q26–q27 in proximity to two genes for apolipoprotein A.[343,344] The gene spans 53.5 kb and contains 19 exons, making it the largest gene among the constituents of the fibrinolytic system.[345] Mice deficient in plasminogen, in addition to developing thrombotic complications, also develop fibrin-rich conjunctival lesions that appear indistinguishable from human ligneous conjunctivitis.[346–348]

Plasminogen deficiency is classified into two types: type I or hypoplasminogenemia (i.e., antigen and activity reduced) and type II or dysplasminogenemia (i.e., normal antigen, dysfunctional protein). The first case of hereditary heterozygous deficiency of plasminogen (type II) linked to thrombophilia was reported by Aoki et al.[349] in 1978, and it is estimated that plasminogen deficiency occurs with a prevalence of approximately 0.5% in the general population and 1% to 3% in thrombosis patients.[350–352] Despite this frequency, there does not appear to be a clear association between plasminogen deficiency and an individual thrombotic risk.[353] Although initial reports suggested that type II plasminogen deficiency in combination with factor V_{Leiden} is a risk of thrombosis, further studies failed to confirm that.[353]

Severe deficiency of plasminogen leads to occlusive hydrocephalus and congenital ligneous conjunctivitis, a rare hereditary disorder characterized by the formation of proliferative pseudomembranes on the conjunctiva and other mucosal membranes.[354–356] The abnormalities in these patients reflect the important role of plasminogen in wound healing and are due to homozygous loss-of-function mutations in the plasminogen gene, such as Arg216 to His or Trp597 to Stop. None of the homozygous or heterozygous individuals developed spontaneous thrombosis, but one of the children had repeated thrombotic occlusions of an implanted catheter.

Plasmin Inhibitor

Within the circulation, rapid inhibition of free plasmin occurs with plasmin inhibitor (PI), which is a serine protease inhibitor (serpin) and which was formally called α_2-plasmin *inhibitor* or α_2-antiplasmin.[357] PI is the primary inhibitor of plasmin and is a single-chain GP with an M_r of 70,000 and circulates in plasma at a concentration of 70 μg/mL (1 μM).[358] Partial and full-length cDNA clones of PI were isolated between 1986 and 1987. The full-length mRNA is approximately 2.3 kb long, encoding a mature inhibitor protein of 464 amino acids (Met-form).[359–361] There is a second form of the inhibitor in plasma that is 12 amino acid shorter (Asn-form),[362] a result of cleavage by anti*p*lasmin *c*leaving *e*nzyme (APCE).[363] The PI gene contains 10 exons and is distributed over approximately 16 kb of DNA and is localized on chromosome 17p13.[364,365]

PI deficiency is a rare autosomal recessive disorder and is characterized by a bleeding tendency, with homozygous patients being more affected.[366] Type I deficiency is defined as the absence or decreased concentrations of the protein, where type II is characterized by a dysfunctional protein. The first deficiency states were reported in 1978, and since then more than 40 cases have been reported.[366] In contrast to patients with a severe deficiency of PI who have mild-to-severe hemorrhagic tendencies, mice that are deficient in PI have a transient enhanced endogenous fibrinolytic activity and do not have an overt bleeding tendency.[367]

There are nine published reports detailing the molecular basis of PI deficiency: (a) a trinucleotide insertion responsible for an additional Ala within the 353 to 357 fragment,[395] (b) a frameshift mutation in exon 10 that is responsible for elongation of the protein,[368] (c) a trinucleotide deletion responsible for a Glu137 deletion,[369] (d) a G-to-A transition responsible for a Val384 to Met substitution,[370] (e) a splicing donor site suppression in intron 2,[371] (f) a single T deletion at nucleotide position 332 in exon 5 that causes a frameshift and shortening of the protein,[372] (g) a splicing donor site mutation in intron 6 that leads to exon 6 skipping,[373] (h) a deletion in codon 71,[374] and (i) cytosine deletion at codon 399.[375] In addition, a polymorphism (Arg6 to Trp) appears to be responsible for enhancing fibrinolysis.[376]

Plasminogen Activator Inhibitor 1

PAI-1, the principal inhibitor of fibrinolysis, is a 50-kDa serpin (serine protease inhibitor) that interacts with and inhibits both tPA and urokinase plasminogen activator. The source of plasma PAI-1 is unclear since endothelial cells, adipocytes, hepatocytes, and megakaryocytes can all secrete it into the circulation.[377] Cofactors for PAI-1 activity include heparin, the presence of which increases PAI-1 activity toward thrombin, and vitronectin, a stabilizing factor. PAI-1 levels show diurnal variations, with a peak level in the early morning, a finding that appears to be associated with the 4G/5G polymorphism.[378]

The *PAI-1* gene is located on chromosome 7q21.3–q22, covers approximately 12.3 kb, and consists of nine exons and eight introns.[379–384] The *PAI-1* gene encodes two distinct species of mRNA approximately 2.3 and 3.4 kb in size. The cDNA of PAI-1 has been cloned by seven different groups and is 1,209 bp in length.[385–389] The promoter of PAI-1 contains a TATA box, lacks a CAAT box, and contains numerous regulatory sequences including two enhancer-like glucocorticoid response elements and nucleotides.[390] Studies have shown a correlation with a functional 4G or 5G genotype in the PAI-1 promoter. Both the 4G and 5G alleles GACACGTG($G_{4\ or\ 5}$) AGT (4G/5G) bind a transcriptional activator at –675 in the PAI-1 5′ untranslated region. However, the 5G allele also binds a repressor protein in an overlapping binding site, resulting in lower levels in the 5G than in the 4G allele. Numerous correlations have shown a significantly higher prevalence of particular cardiovascular disease states with the 4G allele.[391–394]. PAI-1 deficiency has also been documented by a frameshift mutation leading to a premature stop codon[395] or, more recently, in a compound heterozygote patient with a Ala15 to Thr mutation in the signal peptide, resulting in 10% normal activity.[396]

PAI-$1^{-/-}$ knockout mice are viable and show no apparent histologic or hemostatic abnormalities. Challenge with endotoxins in the knockout mice induces a greater resistance to venous thrombosis and a mild hyperfibrinolytic state.[397,398] Other physical challenges in this knockout mouse show tumor growth, angiogenesis, and increased responses to injury.

Thrombin-activatable Fibrinolysis Inhibitor

Thrombin-activatable fibrinolysis inhibitor (TAFI), also known as procarboxypeptidase B and procarboxypeptidase U, is a zymogen found in plasma that may play an important role in hemostasis by linking both coagulation and fibrinolysis.[399] Activated TAFI, when exposed to a fibrin clot, catalyzes the removal of *C*-terminal lysines, thereby diminishing the cofactor activity for plasminogen activation. This in turn reduces plasmin production on fibrin, slowing clot lysis or prolonging fibrinolysis.[399] This inhibitor has been characterized by three independent laboratories, and was cloned in 1991.[400–402] The TAFI mRNA is approximately 1.7 kb in length, whereas the cDNA is 1,272 nucleotides long. The human *TAFI* gene was characterized in 1999, is located on chromosome 13q14.11, and consists of 11 exons spanning approximately 48 kb of DNA.[403] TAFI is synthesized in the liver as a prepropeptide of 423 amino acids, which includes a 22–amino acid signal sequence. It has a molecular mass of 60 kDa and circulates in plasma at a concentration of approximately 70 nM.[404]

Making use of a large population-based case–control study on venous thrombosis, the Leiden Thrombophilia Study found that an elevated TAFI antigen level was only a mild risk factor for venous thrombosis.[405] In addition, an elevated TAFI level was a mild risk factor for coronary artery disease and ischemic stroke.[406,407] In contrast, however, two studies have reported that high TAFI antigen levels are associated with a lower risk of coronary events.[408,409] Although no reports have yet described individuals with TAFI deficiency, the phenotype is likely to be mild because TAFI knockout mice do not exhibit any abnormal phenotypes, even in arterial and venous injury models.[410]

In addition to several polymorphisms in the promoter and coding sequence, another SNP is associated with reduced TAFI levels, a C to T change at nucleotide position 1,040 resulting in a Thr325 to Ile substitution.[411,412] However, biochemical characterization revealed that this particular mutation increases the thermal stability of the protein, resulting in enhanced activity of activated TAFI and consequently in an increased antifibrinolytic potential.[412,413] At present, it is unclear whether this polymorphism influences thrombotic disease, although it is a contributing factor in hereditary thrombophilia.[414]

Other Hemostatic Proteins

Fibrinogen

The final reaction in the coagulation cascade is the formation of an insoluble fibrin network from fibrinogen. Fibrinogen is a complex molecule, a 340-kDa GP that consists of two disulfide-linked monomers (see Chapter 16). Each of the monomers consists of three polypeptide chains encoded by three distinct genes: Aα, Bβ, and γ.[415] The fibrinogen to fibrin transformation is initiated after thrombin proteolytically removes two acidic peptides, fibrinopeptide A and fibrinopeptide B, from the *N*-terminus of the Aα and Bβ chains, respectively. Removal of these peptides exposes sites (often denoted A and B knobs) on the fibrinogen molecule that favor intermolecular reactions between fibrin dimers and therefore allows polymerization and formation of a fibrin network.[415]

The cDNAs encoding the Aα, Bβ, and γ chains were cloned in 1993.[416–419] The mRNA for the Aα chain is approximately 2.2 kb nucleotides long and encodes a 625–amino acid long mature protein.[416,419] The Aα gene also has been cloned and is approximately 5.4 kb and contains five exons,[419] and there is also a variant Aα form in plasma (<2%) that is extended by 236 amino acids and that is encoded by a sixth exon. The Bβ mRNA counts 1,918 nucleotides and encodes a protein of 461 amino acids. The Bβ gene is approximately 8 kb and contains eight exons.[418] The fibrinogen γ gene is approximately 8.4 kb long and contains 10 exons. The gene encodes two slightly different forms of the γ chain: γA and γB.[416] The most abundant form is γA, which is produced from mRNA and spliced at nucleotide 7,774 in exon 9. The γB mRNA is not spliced after exon 9, leading to read-through at the donor splice site and the addition of 20 codons before a stop codon is reached. Exon 10 is not used, and polyadenylation occurs at a different site. The genes encoding the fibrinogen chains cover approximately 50 kb and are located on chromosome 4q28.[420–422] The genes in the fibrinogen locus are linked in the order $\gamma \rightarrow$ A$\alpha \leftarrow$ Bβ.[444] The direction of transcription of the Bβ gene is therefore reversed compared to the direction of transcription of the other two genes. Transcription of the three genes occurs in a coordinated fashion, in which transcription from the Bβ gene is the rate-limiting step.[423]

A knockout model shows that homozygous mice deficient in fibrinogen (Aα chain–deficient) are born at the expected Mendelian frequency,[424] but, approximately 30% manifest overt bleeding in the peritoneal cavity, skin, and soft tissues around joints in the neonatal period. Long-term survival in the mice deficient in fibrinogen varies and is highly dependent on genetic background; in pregnancy, mice show fatal uterine bleeding around the 10th day of gestation.

Afibrinogenemia, first described in 1920, is a rare autosomal recessive disorder associated with spontaneous, postsurgical, and postpartum bleeding of variable severity.[76] It is characterized by a severe deficiency of fibrinogen both in the plasma and the platelet. More than 30 afibrinogenemia-causing mutations have been reported, most in the Aα with just a few in the Bβ gene.

Dysfibrinogenemia is characterized by a variant form of fibrinogen, mostly because of a missense mutation that replaces an amino acid.[425,426] Most patients of dysfibrinogenemia present themselves in heterozygous form, with abnormal fibrinogen subunits covalently linked to normal ones, leading to an overall abnormal fibrinogen and fibrin. A large number of different mutations have been documented (>500) in dysfibrinogenemia, and they are collected and presented on an electronic database: http://site.geht.org/site/Pratiques-Professionnelles/Base-de-donnees-Fibrinogene/Database-English-Version/Fibrinogen-variants-Database-_79_.html.[427]

Homozygotes for dysfibrinogenemia may have severe bleeding, but this is not always the case. Most bleeding episodes are mild to moderate and may occur postoperatively, postpartum, antepartum, and as a result of delayed wound healing. Thrombotic problems include deep venous thrombosis, thrombophlebitis, pulmonary embolism, arterial thrombosis, and joint arterial and venous thrombosis. In patients with a history of venous thrombosis, the prevalence of dysfibrinogenemia is approximately 0.8%.[428] Patients who experience a thrombotic event may also have a history of bleeding (27%).

Elevated fibrinogen levels are an important risk factor for cardiovascular disease.[429–433,434] The best studied genetic determinants are two promoter polymorphisms in the fibrinogen Bβ gene, a G/A site at nucleotide −455 and a C/T variant site at −148. The two variant sites are in complete linkage equilibrium.[429] Individuals homozygous for the −455A allele have 0.28 g/L higher fibrinogen levels than GG homozygotes.

tahir99-VRG & vip.persianss.ir

Additional SNPs that are associated with circulating fibrinogen levels have been identified by genome-wide association studies that reside outside the fibrinogen genes.[430] Extrapolating from several studies on polymorphic fibrinogen gene variations, it is suggested that qualitative and quantitative modifications may be equally or more important in determining the risk of venous thromboembolism and cardiovascular disease, respectively.[431]

Factor XIII

Activated factor XIII is the final component of the blood clotting cascade and is responsible for cross-linking fibrin (see Chapter 17). Plasma factor XIII is a tetrameric molecule composed of two A subunits (83 kDa) and two B subunits (80 kDa), and platelet factor XIII consists only of two A subunits.[432] The factor XIII-A subunits belong to the transglutaminase family of proteins. Thrombin cleaves a peptide bond within the A chain, forming factor XIIIa, which stabilizes the fibrin clot. This is accomplished by a transglutaminase reaction forming covalent bonds between Lys and Gln side chains near the carboxyl-termini of the $\gamma\gamma$ chains (within strands) and between $\gamma\alpha$ chains (within the mesh). The factor XIII-A subunit gene has been localized to chromosome 6p24–25 (F13A) and is approximately 160 kb and contains 15 exons.[433,434] The mature A subunit has 731 amino acids. The factor XIII B subunit gene (F13B) is approximately 28 kb in length, has 12 exons, and is located on chromosome 1q31–32.1.[435,436] The mature protein has 641 amino acids and contains 10 short consensus repeats known as *sushi* domains.[437]

Factor XIII deficiency is a rare autosomal disorder that is associated with a severe bleeding diathesis when factor XIII levels are <1%. It is subdivided in type I and II for FXIII B or A deficiency, respectively.[438] Women with inherited factor XIII deficiency have recurrent abortions and difficulty carrying a pregnancy to term. The inheritance of this disorder is not completely recessive because increased bleeding has been reported for some heterozygous individuals, but most heterozygotes are asymptomatic.

The role of factor XIII during pregnancy and placental/uterine hemostasis was demonstrated with factor XIII A knockout mice.[439,440] Despite being able to become pregnant, knockout mice with factor XIII A frequently died of excessive vaginal bleeding with massive placental hemorrhage and subsequent necrosis at gestational day 10. This phenotype correlates with spontaneous miscarriage in humans with factor XIII deficiency.

More than 70 mutations have been identified in factor XIII deficiency, most of which affect the A gene, most of which being missense or nonsense. A mutation database can be found at: http://www.f13-database.de/. Polymorphisms of both the A and B subunit genes should prove useful in distinguishing A chain from B chain defects in family studies.[432] A common mutation in the factor XIII A subunit has been implicated in some, but not all, studies as a risk factor for vascular disease. This Val34 to Leu dimorphism, which is three amino acids from the activation site of factor XIII, is protective against myocardial infarction and predisposes to intracerebral hemorrhage,[441,442] especially in homozygote form.[443] The contribution of this mutation in coronary heart disease is controversial.[438]

von Willebrand Factor

vWF is a large multimeric adhesive GP that is involved in adhesion of platelets to the subendothelium at sites of vascular damage (see Chapter 13). vWF also plays a critical role in stabilizing the procoagulant cofactor, factor VIII. In response to numerous stimuli, vWF is released from platelet α-granules and from Weibel-Palade bodies of endothelial cells, and is constitutively secreted by endothelial cells and possibly produced in placental syncytiotrophoblasts.[444] In plasma, vWF circulates at concentrations of approximately 10 mg/mL. The vWF protein (monomer, 250 kDa) exists as a series of multimers that are linked by disulfide bonds located near the *C*-terminal end of each subunit (see FIGURE 10.5).

The *vWF* gene, located on the short arm of chromosome 12 (12p13.3), is approximately 178 kb in length and contains 52 exons.[445,446] A partial, highly homologous pseudogene is present on chromosome 22q11–13 and is approximately 21 to 29 kb in length.[446] This pseudogene has no known function, but its presence complicates genetic analysis of von Willebrand disease (vWD). Several groups originally cloned the cDNA for vWF

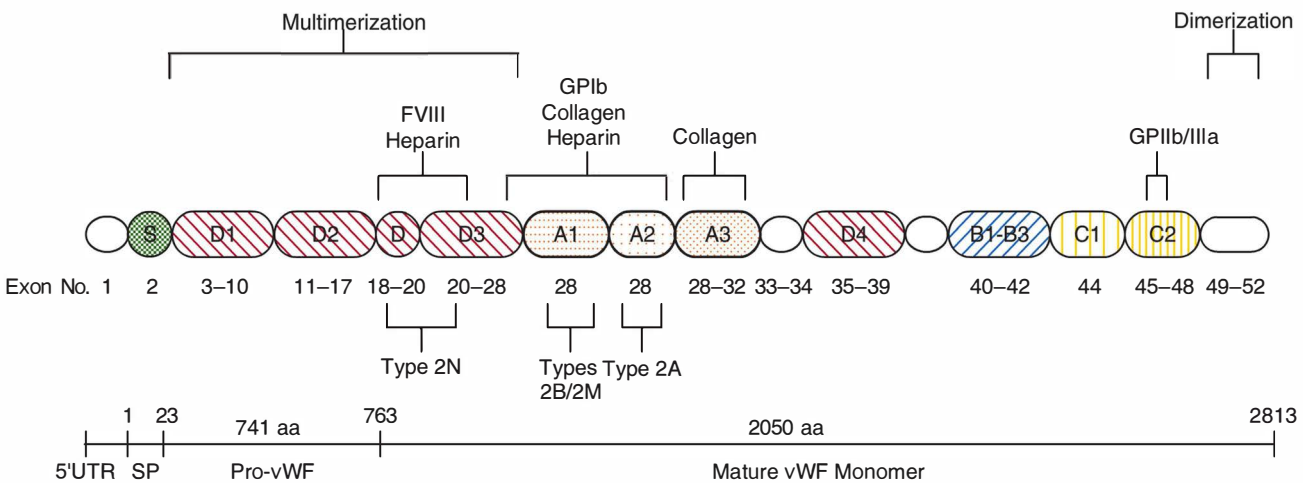

FIGURE 10.5 Gene organization of vWF. The 52 exons of the *vWF* gene are shown along with the indicated protein domain regions. Potential functional binding sites with other proteins are also shown. Type II mutation hot spots between exons 18 and 28 are indicated. GP, glycoprotein. See also Chapter 13.

tahir99-VRG & vip.persianss.ir

in 1985 to 1986,[447–450] known to be almost 9,000 bp long and encoding a protein of 2,813 amino acids.

vWD is a congenital bleeding disorder caused by defects at the vWF locus. This autosomally inherited mucocutaneous bleeding disorder was first reported by Erik von Willebrand in 1926 in a large family from the Aland Islands off the coast of Finland. On the basis of phenotypic and genetic characteristics, an updated classification of vWD has been adopted.[20] Type 1 deficiency includes patients with a partial quantitative deficiency of vWF levels in plasma. Type 2 deficiency refers to a qualitative deficiency and there are four subtypes (2A, 2B, 2M, and 2N). Type 3 vWD comprises patients with extremely low or undetectable levels of vWF. Symptomatology of vWF deficiency includes easy bruising, nosebleeds, and hematomas. Excessive menstrual bleeding and heavy bleeding following oral cavity, tooth extraction, tonsillectomy, and adenoidectomy are also common. A mouse model of vWF has been described, and these mice very closely mimic severe (type 3) human vWD.[451] Mutations and polymorphisms identified in the *vWF* gene can be found at: http://www.shef.ac.uk/vwf/index.html.

The inheritance of vWD varies with the type of deficiency. Type 2 deficiency accounts for approximately 75% of all vWD.[452] Heritable variances are modest and not solely linked to the vWF locus. Notably, variation in vWF is highly linked to an individual's ABO blood type. In non–type 3 disease, vWF levels increase during pregnancy and during stress, such as at the time of drawing blood. Individuals with blood type O have vWF levels 25% to 35% lower than individuals of blood types A, B, or AB. Variations are influenced by polymorphisms including a −1793G > C SNP. vWD is viewed as the most frequent bleeding disorder, with an estimated prevalence of 1% in the general population. The frequency of vWD is highly dependent on the criteria used in establishing the diagnosis. Experts differ on the definition of vWF type 1 deficiency from <15% levels to levels below 50%.[452]

Type 1 and types 2A, 2B, and 2M variants are most commonly dominant. Type 2A is the most common subclass and refers to qualitative variants with decreased platelet-dependent function associated with absence of HMW forms of vWF multimers; type 2B mutations increase the affinity of vWF for platelet GP Ib; type 2M refers to variants that share decreased platelet-dependent function that is not the result of the absence of HMW forms; and finally, type 2N refers to those vWF variants with a decreased affinity for factor VIII (FIGURE 10.5).

Type 3 deficiency is the most severe form of vWD and inherits as a recessive trait. This form is caused by homozygosity for complete loss-of-function mutations in the *vWF* gene. As is the case in hemophilia A and B, an almost infinite number of possible mutations lead to this phenotype. This fact, combined with the large size of the *vWF* gene, underlines the difficulty in routinely identifying mutations in type 3 deficiency.

SUMMARY

The completion of the Human Genome Project in 2003 has made gene and cDNA sequences immediately available, thereby providing a powerful means of discovering hereditary factors in multifactorial/multigenic diseases such as thrombosis. However, it is not genes alone but the interplay of genetic and environmental factors that determines phenotype. A challenge for the future will be to determine which combinations of genetic changes directly or indirectly influence complex disease states, and genome sequences from other animals may also prove useful in defining informative genetic changes. These sequences should also prove useful in furthering our understanding of the evolution of blood coagulation. The availability of genetic information for the hemostatic proteins has also made possible the safe and efficient production of pharmacologically relevant proteins for therapeutic purposes and provides new methods for the treatment of diseases using gene- and cell-based therapy approaches.

CHAPTER

11 Tissue Factor and the Initiation and Regulation (TFPI) of Coagulation

JAMES H. MORRISSEY AND GEORGE J. BROZE, JR.

Blood circulates as a liquid, but once it escapes from an injured blood vessel, it must rapidly gel, or clot, to form a hemostatic plug in order to limit further blood loss. On the other hand, pathologic activation of the blood clotting system within the lumen of blood vessels is a major cause of human death and disability. This chapter focuses on the mechanism of initiation of the blood clotting system, both in normal hemostasis and in many thrombotic diseases. Two main pathways for triggering the blood clotting cascade were initially described: the intrinsic pathway and the extrinsic, or tissue factor (TF), pathway. The intrinsic pathway is so called because it appeared to be an intrinsic property of plasma; that is, when blood or plasma is placed in a glass tube, it will clot spontaneously. This pathway is more accurately called the *contact pathway* because it is activated when plasma contacts artificial surfaces like glass or clay. The contact pathway *per se* is not thought to be of primary importance in normal hemostasis because individuals in whom it is inactive (owing to a severe congenital deficiency in factor XII) exhibit no bleeding tendency. The contact pathway is considered in detail in Chapter 15B.

The TF pathway of blood clotting is triggered when plasma comes into contact with cells that express the integral membrane protein, TF, on their surfaces. TF is abundant on a variety of cell types found outside the vasculature but is present only in tiny amounts within the vasculature. After vascular injury, blood is exposed to cells bearing TF, whereupon TF binds factor VII—one of the soluble clotting factors—with high affinity. It is the complex of TF and factor VII (or, more accurately, the activated form known as *factor VIIa*) that initiates the blood clotting cascade in normal hemostasis. In addition, TF triggers the clotting cascade in a variety of thrombotic disorders.

OVERVIEW OF THE INITIATION OF BLOOD COAGULATION BY TISSUE FACTOR AND FACTOR VII

The clotting cascade comprises a series of reactions involving the activation of zymogens (inert precursors of enzymes) by limited proteolysis. With the exception of thrombin, the newly generated proteases have low enzymatic activity until they bind to specific protein cofactors on suitable phospholipid (PL) surfaces. Such binding events potentiate the activity of clotting proteases by as much as several 100- to 1,000-fold.

The first enzyme in the clotting cascade consists of two subunits: a serine protease, factor VIIa (the catalytic subunit), and a protein cofactor, TF (the positively acting regulatory subunit). Because TF is an integral membrane protein, the complex of TF and factor VIIa (TF:VIIa) is tethered to the cell surface. Free factor VIIa is a weak enzyme, but TF:VIIa is the most potent known activator of the blood clotting cascade.

All the serine proteases of the blood clotting cascade, including factor VII, circulate in the plasma as inert zymogens. Furthermore, most protein cofactors of the clotting cascade circulate as inert procofactors. (TF is a notable exception; it does not require proteolysis for activity.) A nagging question for many years has been: How can the clotting cascade be initiated through the assembly of a collection of inert precursors? The answer appears to come from the fact that trace amounts of active factor VIIa are present in the circulation at all times.

The active forms of most serine proteases of the clotting system have extremely short plasma half-lives (measured in seconds) because plasma contains high concentrations of protease inhibitors. Free factor VIIa, however, is not reactive with plasma protease inhibitors.[1] When injected into animals or humans, factor VIIa has a long circulating half-life of approximately 2 hours, similar to the approximately 5-hour half-life of zymogen factor VII.[2] Therefore, any factor VIIa that is generated *in vivo* can circulate for considerable periods.

TF binds factor VII or VIIa with high affinity, resulting in a 1:1 complex of the two proteins on the cell surface. As depicted in FIGURE 11.1, once bound to TF, factor VII is rapidly converted to factor VIIa by limited proteolysis.[3] So, there are two ways to form the TF:VIIa complex: through direct capture of circulating factor VIIa by TF or through capture of factor VII followed by conversion to factor VIIa.

Once formed, the TF:VIIa complex triggers clotting in two ways. TF:VIIa can activate factor IX via limited proteolysis (reaction 1 in FIGURE 11.2). The newly generated factor IXa then binds with a protein cofactor on a PL surface to form the IXa:VIIIa complex, which catalyzes the conversion of factor X to Xa. Alternatively, TF:VIIa can directly activate factor X (see reaction 2 in FIGURE 11.2). This latter mechanism predominates in most *in vitro* conditions, in which factor X is the preferred substrate for TF:VIIa.

Where does the first burst of serine protease activity come from if all the enzymes and their essential cofactors circulate as inactive precursors? It turns out that trace levels of factor VIIa are present in the circulation of all normal individuals, making up approximately 1% of the total factor VII concentration (but with considerable individual variation).[4] Exposure of TF to plasma therefore results in assembly of both TF:VII and TF:VIIa complexes, and only the latter are enzymatically active. However, these low initial levels of TF:VIIa are thought to trigger enough of the clotting cascade to result in the back-activation of the rest of the bound factor VII by downstream proteases. A variety of coagulation proteases activate factor VII to VIIa *in vitro*, including factors IXa, Xa, and XIIa; thrombin; plasmin; and factor

tahir99-VRG & vip.persianss.ir

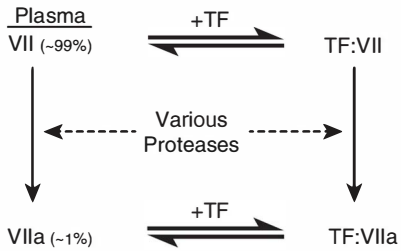

FIGURE 11.1 Two pathways for the formation of the TF and factor VIIa complex (TF:VIIa). Plasma contains a mixture of approximately 1% active factor VIIa and 99% zymogen factor VII. Both factors, VII and VIIa, bind reversibly to TF with similarly high affinities to generate TF:VII and TF:VIIa complexes, respectively. Factor VII can be converted to factor VIIa by a variety of plasma proteases (see text), and factor VII bound to TF is an especially good substrate for conversion to factor VIIa.

VII–activating protease.[3,5–11] In addition, the TF:VIIa complex catalyzes the autoactivation of factor VII bound to TF.[12,13] It is currently unclear which of these proteases plays the major role in activating TF-bound factor VII during clotting, although many consider factor Xa the most likely candidate.

It is also presently unclear where or how circulating factor VIIa is generated. One important clue comes from the discovery that patients with hemophilia B (who lack factor IX) have plasma factor VIIa levels that are only 10% of normal.[14] Thus, factor IX (presumably as factor IXa) participates in formation of much of the circulating factor VIIa found in plasma. Another clue is that factor VIIa levels rise postprandially, especially after high-fat meals.[15,16] This rise occurs in individuals who are deficient in factor XI or XII but not in factor IX,[17] suggesting that activation of factor VII occurs on lipoprotein particles, apparently involving factor IXa. Consistent with this notion, plasma factor VIIa levels are very low in patients with familial abetalipoproteinemia.[18] And finally, factor VIIa levels are higher in lymph than in plasma,[19] suggesting that at least some of the factor VIIa may be generated extravascularly and returned to the circulation by the lymph.

TISSUE FACTOR PROTEIN STRUCTURE

TF is also known as *thromboplastin, CD142*, and *coagulation factor III*. It is a glycosylated membrane protein consisting of a single-polypeptide chain of 261 or 263 amino acids (the two forms are nearly equal in abundance), with variability in length owing to microheterogeneity at the amino-terminus.[20–22] The calculated molecular weight of TF's polypeptide chain is 29,447 Da or 29,593 Da, whereas the mobility of the fully glycosylated protein on sodium dodecyl sulfate (SDS) gels suggests a molecular weight of approximately 45,000 Da.[23] TF belongs to the class 2 cytokine receptor superfamily.[24] Topographically, TF is a type I integral membrane protein, with its amino-terminus located outside the cell and its carboxyterminus inside the cell. The overall domain structure of TF is given in FIGURE 11.3. The extracellular portion is composed of two fibronectin type III domains, which are a variation on the immunoglobulin fold.

The extracellular domain of TF has three *N*-linked carbohydrate chains,[25] which were found to be completely dispensable

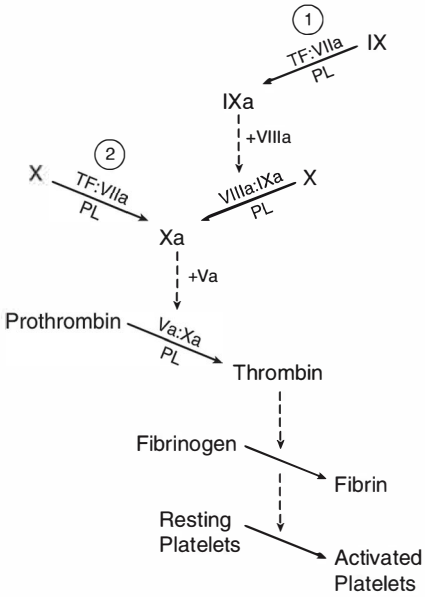

FIGURE 11.2 Simplified map of the blood clotting cascade initiated by the complex of TF and factor VIIa (TF:VIIa). The TF:VIIa complex can initiate clotting by activating either factor IX (*reaction 1*) or factor X (*reaction 2*). Regardless of the mechanism for triggering the clotting system, all clotting pathways converge at the formation of factor Xa, which assembles on a PL surface with its protein cofactor (factor Va) to catalyze the conversion of prothrombin to thrombin. Thrombin is responsible for converting fibrinogen to fibrin (again, by limited proteolysis), which spontaneously polymerizes to form a gel, or fibrin clot. In addition, thrombin is a potent activator of platelets (see Chapter 33). In this simplified clotting cascade, a number of back-activation reactions have been omitted. For example, factors Va and VIIIa circulate as inert precursors (factors V and VIII, respectively) and are activated following limited proteolysis by thrombin or factor Xa. The reactions involving hemostatically relevant factors XI and XIII, as well as all of the inhibitors of the clotting system, have also been omitted.

for clotting activity since the recombinant protein produced in bacteria was fully functional.[26] Recently, this conclusion was challenged by a study reporting that TF without carbohydrates had substantially reduced cofactor activity toward factor VIIa,[27] although a following study by others reported no detectable role for the carbohydrate chains of TF in any of its functions, including coagulant activity, intracellular trafficking, or cellular signaling.[28]

The extracellular domain of TF has two disulfide bonds,[29] at least one of which (the Cys186–Cys209 bond) is reported to be essential for coagulant activity,[30] although this conclusion has been disputed.[31] The Cys186–Cys209 disulfide bond has been proposed to play a role in TF encryption/decryption,[32] although this conclusion has also been disputed[31,33] (see section, *Modulation of Factor VIIa Activity by Tissue Factor*).

TF has a single membrane-spanning domain that anchors the protein to the cell surface. Membrane anchoring of TF is essential for full procoagulant activity, although the exact nature of the membrane anchor does not appear to be important for its clotting activity.[34]

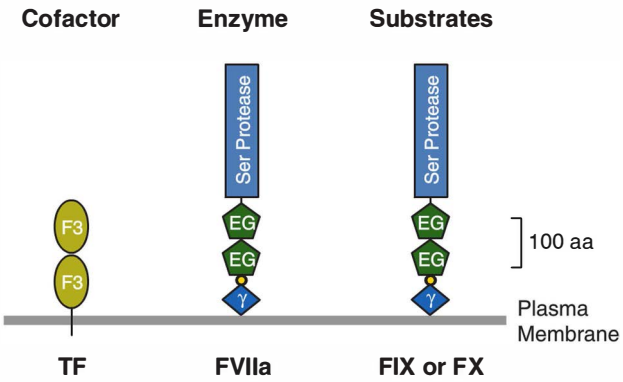

FIGURE 11.3 Schematic representation of the domain structure of TF, factor VII/VIIa (FVIIa), and factors IX and X (FIX and FX). The two fibronectin type III domains of TF are indicated as *F3*. The Gla domains of factors VII, IX, and X are indicated by *γ*, whereas the EGF-like domains are indicated by *EG* and the serine protease domains by *Ser Protease*. The aromatic stack is indicated by a small circle between the Gla and EGF domains. aa, amino acids.

The short (23–amino acid long) cytoplasmic domain of TF contains a cysteine residue to which palmitate or stearate is attached by a thioester linkage.[29] In addition, the cytoplasmic domain can be phosphorylated on serine.[35] Deletion of the cytoplasmic domain has no discernible effect on TF procoagulant activity,[34] making its role in blood clotting unclear, but there is increasing evidence that the cytoplasmic domain of TF may be important in some of TF's nonhemostatic roles (see section, *Nonhemostatic Functions for Tissue Factor and Factor VII*).

TF has been purified from human brain and placenta using factor VII affinity chromatography[23,36] and immunoaffinity chromatography.[37,38] Larger quantities can be obtained as the recombinant protein expressed in eukaryotic or prokaryotic cells.[26] Purified TF can readily be reconstituted into PL vesicles by using a variety of techniques.[39–41] A soluble form of TF consisting of the isolated extracellular domain[42] has proved useful in structure/function studies because it is easy to produce and handle.

Several groups have solved x-ray crystal structures of human and rabbit soluble TF.[43–47] Soluble TF is an elongated and apparently rather rigid molecule in which the two fibronectin type III domains are joined at an angle of approximately 120 degrees. In addition, the x-ray crystal structures of the complex of soluble TF and factor VIIa have also been determined (discussed in the section, *Structure of the Tissue Factor and Factor VIIa Complex*). Further reference to crystal structures of TF and factor VII may be found at http://www.tf7.org/xray.htm.

SITES OF TISSUE FACTOR EXPRESSION: NORMAL AND PATHOLOGIC

TF, being an integral membrane protein, is mainly found on the surface of cells in which it is synthesized. TF is abundant in a variety of cell types distributed throughout the body, including adventitial cells surrounding all blood vessels larger than capillaries; differentiating keratinocytes in the skin; and a number of epithelial cell types, including those present in mucous membranes and many organ capsules.[48,49,50] The distribution of TF can be rationalized by the requirement that it be present throughout the body, ready to trigger the clotting cascade at any time and place following vascular injury. This pattern of expression has been described as constituting a protective "hemostatic envelope" surrounding the vasculature, organ structures, and the entire organism.[48] In addition, TF is abundant at anatomic sites in which the risk—or the deleterious consequences—of bleeding is high, such as the renal glomerulus and throughout the brain.[48,50]

Spontaneous bleeding in patients with hemophilia occurs most commonly in anatomic locations such as skeletal muscle and joints, which contain especially low levels of TF.[48] Patients with hemophilia may bleed at these sites because direct activation of factor X by low levels of TF:VIIa is insufficient for hemostasis, and they lack the amplification step provided when TF:VIIa activates factor IX. Conversely, patients with hemophilia do not tend to bleed excessively from superficial cuts, which may be explained by the abundance of TF in the skin—exposure of large amounts of TF should allow direct activation of factor X in quantities sufficient for hemostasis.

In normal blood vessels, TF is readily detectable only in the adventitial cells within the vessel wall; TF antigen or messenger ribonucleic acid (mRNA) is usually undetectable in vascular smooth muscle and endothelial cells.[48,49,50] Atherosclerotic plaques, however, contain significant levels of TF mRNA and antigen, associated with monocytes and smooth muscle cells within the plaque.[49,51–54] TF antigen is also present in the acellular core of atheromas, most likely derived from cells that have undergone necrosis. TF in plaques can bind factor VIIa and is fully functional.[53,54] In healthy arteries, TF is separated from the lumen by both the intima (endothelium and underlying basement membrane) and the media (multiple layers of vascular smooth muscle cells). In atherosclerosis, however, blood is separated from TF by only a thin monolayer of endothelial cells—a much more dangerous situation. It is generally accepted that myocardial infarction is triggered by rupture or fissure of atherosclerotic plaques in coronary arteries,[55] exposing TF to blood within the lumen of the artery and triggering the formation of a thrombus that may occlude the vessel. Similar mechanisms likely precipitate other forms of arterial thrombosis, such as ischemic stroke.

TF is expressed in a variety of malignancies, where it can lead to thrombotic disease (e.g., in Trousseau syndrome). This can be caused by the expression of TF by the tumor cells themselves, by infiltrating monocytes, or by stromal cells. The association of TF with malignancy and its role in tumor pathology is reviewed in detail[56,57] and in Chapter 125.

Experiments using specific inhibitors of TF:VIIa have demonstrated that coagulopathies associated with sepsis and septic shock are mediated by TF, and furthermore that TF:VIIa contributes directly to mortality in sepsis.[58,59] Mice engineered to express very low levels of TF were protected against coagulopathy and mortality following challenge with bacterial endotoxin, and this was true even when low TF expression was limited to hematopoietic cells.[60] These studies underscore the importance of monocyte TF in driving the life-threatening coagulopathy of sepsis.

TISSUE FACTOR GENE: STRUCTURE AND REGULATION

Located on chromosome 1 at p21–22,[22,61] the TF gene (locus abbreviation, *F3*) spans 12.4 kb and contains six exons interrupted by five introns.[62] The first exon contains the

5′ noncoding sequence of the mRNA and also encodes the signal peptide, which directs the protein to the membrane and which is removed during biosynthesis. The first exon is located within a CpG island, a GC-rich deoxyribonucleic acid (DNA) region approximately 1 kb long that contains an unusually high density of CpG codons. The next four exons encode the extracellular domain, whereas the sixth exon encodes the transmembrane and cytoplasmic domains. The sixth exon also contains the relatively long 3′ noncoding sequence, which is unusual because it includes an Alu-family repeat sequence that persists in the mature mRNA. The mRNA for TF is approximately 2.3 kb long, although in some cell types such as monocytes, minor amounts of a larger TF mRNA species (~3.1 kb) are also observed.[22] The longer mRNA retains the first intron, and it is thought not to encode an active protein.[63,64]

Another alternatively spliced form of TF mRNA, initially discovered in certain leukemia cells, lacks the 5th exon.[65] When translated, it would encode a TF protein lacking a portion of the extracellular domain (normally encoded by exon 5) that is replaced by a novel amino acid sequence derived from reading exon 6 out of frame. Bogdanov et al.[66] have identified this alternatively spliced TF mRNA in a variety of normal cell types and have also discovered that the protein product of this alternatively spliced TF mRNA can be detected at low levels in plasma as an apparently soluble protein (discussed in the section, *Blood-Borne Tissue Factor*).

The TF gene is inducible in a variety of cultured cells. Quiescent fibroblasts in the dermis have no detectable TF antigen,[48] and serum-starved fibroblasts in culture also do not express TF. When cultured quiescent fibroblasts are stimulated with serum or with various mitogenic cytokines, transcription of the TF gene is rapidly induced.[67,68]

Expression of TF on activated monocytes and macrophages is an important effector function of these cells in inflammation. Monocytes isolated from peripheral blood usually have undetectable levels of TF but express this protein strongly after stimulation with various inflammatory mediators.[69,70] This directly parallels the observation that TF is expressed in circulating monocytes following intravenous administration of endotoxin or bacteria.[71] Furthermore, leukocytes (in particular, monocytes) have been shown to mediate the Schwartzman reaction in endotoxin-stimulated animals.[72] As with fibroblasts, the primary level of regulation of TF gene expression in monocytes is transcriptional.[73] In addition, endotoxin treatment of monocytes prolongs the half-life of TF mRNA.[63]

In cell culture, vascular endothelial cells can be induced to express TF robustly in response to a variety of inducers, including interleukin-1, tumor necrosis factor-α, and bacterial endotoxin.[69,70] *In vivo*, however, TF is expressed during severe sepsis by endothelial cells in only a few, highly restricted areas, such as in the splenic microvasculature.[74] This suggests that additional factors, which are not necessarily replicated *in vivo* during sepsis, may govern TF expression in cultured endothelial cells. Endothelial expression of TF has been observed *in vivo* in other conditions, however, including placental villitis[75] and graft rejection.[76,77]

In addition to studies with fibroblasts, monocytes, and endothelial cells, induction of TF gene expression has been studied in other cell types, including vascular smooth muscle cells and keratinocytes.[69,70] A variety of agents that are capable of inducing TF expression have been identified.[78] Transcriptional control of TF gene expression has been studied in several cell types, including monocytic cells, fibroblasts, and vascular endothelial and smooth muscle cells. These studies have identified transcription factor-binding sites flanking the promoter of the TF gene: Sp1 sites are important in basal transcription of the TF gene, whereas Egr-1 sites, AP-1 sites (binding c-Fos/c-Jun heterodimers), and a nuclear factor kappa B site (binding c-Rel/p65 heterodimers) are important in inducible expression of TF in response to bacterial endotoxin, serum, or phorbol ester, depending upon the cell type.[79] TF gene expression is also induced by hypoxia in several cell types.[80]

FACTOR VII PROTEIN STRUCTURE

Factor VII, a glycosylated plasma protein, consists of a single-polypeptide chain of 406 amino acids with an overall molecular weight of approximately 50,000 Da.[7,81,82] Synthesized by the liver, it circulates in plasma at a concentration of about 500 ng/mL (10 nM).[83] The domain structure of factor VII is depicted in FIGURE 11.3. Starting with the amino-terminus of the protein, it consists of the γ-carboxyglutamic acid–rich domain (Gla domain), the hydrophobic or aromatic stack, two epidermal growth factor (EGF)-like domains, and the serine protease domain. Molecular cloning revealed that factor VII has the same domain structure as factors IX, X, and protein C; shares considerable sequence homology with these coagulation serine proteases; and has a similar gene organization of introns and exons[84,85] (see Chapter 9).

Typical of vitamin K–dependent coagulation proteins, factor VII is synthesized with a signal peptide on its amino-terminus that directs the protein to the endoplasmic reticulum for secretion, followed by a propeptide that directs the cell to modify glutamic acid residues in the Gla domain. The signal and propeptides are removed before secretion. Two types of complementary DNA clones for human factor VII have been identified, one of which has an additional 22 amino acids in the propeptide.[84] Products of alternative splicing, these two forms of factor VII mRNA encode identical mature protein and appear to be functionally equivalent.

Factor VII contains 10 γ-carboxyglutamic acid (Gla) residues in its Gla domain, resulting from vitamin K–dependent modification of glutamic acid residues during biosynthesis. As with other vitamin K–dependent coagulation proteins, these Gla acid residues are essential for activity. Specifically, the Gla domain confers on factor VII the ability to bind, in a reversible and Ca^{2+}-dependent manner, to membranes containing negatively charged PLs. In the crystal structure of the TF:VIIa complex, the Gla domain contains seven bound Ca^{2+},[86] although three of these Ca^{2+}-binding sites are probably actually occupied by Mg^{2+} *in vivo*.[87]

The aromatic stack of factor VII is a short amino acid sequence containing a small cluster of aromatic residues. It is adjacent to the Gla domain and, although encoded by a separate exon, is classified by some investigators as a part of the Gla domain. The two EGF domains have a typical growth factor-fold and disulfide-bonding pattern. The first EGF domain binds a single Ca^{2+} with relatively high affinity,[86,88] whereas the second EGF domain does not bind Ca^{2+}. The first EGF domain of bovine factor VII contains the modified amino acid, β-hydroxyaspartic acid, whereas this modification is absent in human factor VII.[89]

The serine protease domain of factor VII is homologous to the digestive enzymes trypsin and chymotrypsin and exhibits

trypsin-like substrate specificity (i.e., cleaving peptide bonds after arginine or lysine). It has a typical serine protease catalytic triad composed of His193, Asp242, and Ser344. As with many other coagulation serine proteases, the protease domain of factor VII binds a single Ca^{2+}.[86,90] The protease domain also binds zinc ions, which inhibit factor VIIa enzymatic activity.[87,91,92]

Zymogen factor VII is converted to factor VIIa, the enzymatically competent form, by proteolysis of a single peptide bond between Arg152 and Ile153. The result, factor VIIa, is composed of two disulfide-linked polypeptide chains. The light chain of factor VIIa, consisting of the Gla domain, aromatic stack, and both EGF domains, has 152 amino acids and a molecular weight of approximately 20,000 Da. The heavy chain, consisting of the serine protease domain, has 254 amino acids and a molecular weight of approximately 30,000. Unlike many other coagulation zymogens, factor VII does not release an activation peptide when converted to factor VIIa.

Factor VII contains two *N*-linked carbohydrate chains attached to residues Asn145 and Asn322.[89] It also contains two short, *O*-linked carbohydrate chains attached to the first EGF domain: glucose, glucose–xylose, or glucose–$(xylose)_2$ attached to Ser52; and a single fucose attached to Ser60.[93]

Factor VII can be purified from plasma using conventional chromatography[7,81,82] or immunoaffinity chromatography.[94] Recombinant human factor VII has been produced in cultured mammalian cells.[89] Truncated forms of factor VII have been produced in which the Gla domain has been removed (Gla-domainless factor VII) by limited proteolysis[95,96] or by expression of the truncated recombinant protein.[97] Gla-domainless factor VII may or may not contain the aromatic stack, depending on the site of cleavage. Furthermore, a form of factor VII lacking both the Gla domain and the first EGF domain has also been produced recombinantly,[98–100] and it fails to bind to TF.[98] Factor VII mutants have been produced, in which the activation cleavage site has been mutated so that it cannot be activated by the usual activators,[101] which demonstrated that zymogen factor VII had no detectable enzymatic activity. In addition, the active site serine (Ser344) has been mutated to alanine, generating a form of factor VIIa without enzyme activity which has been useful in investigating the conversion of factor VII to VIIa.[12]

STRUCTURE OF THE TISSUE FACTOR AND FACTOR VIIA COMPLEX

The x-ray crystal structure of the complex of soluble TF and active site–inhibited factor VIIa has been solved to a resolution of 2.0 Å,[86] and the structure of a similar complex inhibited with a modified version of bovine pancreatic trypsin inhibitor has been solved to a resolution of 2.1 Å.[102] The structure of TF in these complexes is very similar to that of soluble TF alone, confirming the relative rigidity of this molecule. Within the complex, factor VIIa is a highly elongated protein that forms extended contacts with TF (see FIGURE 11.4). The main sites of contact on factor VIIa are located in the first EGF domain and the protease domain, with additional points of contact within the second EGF domain and the aromatic stack region of the Gla domain. The sites of contact on TF are located on both fibronectin type III domains and the interfacial region between them.

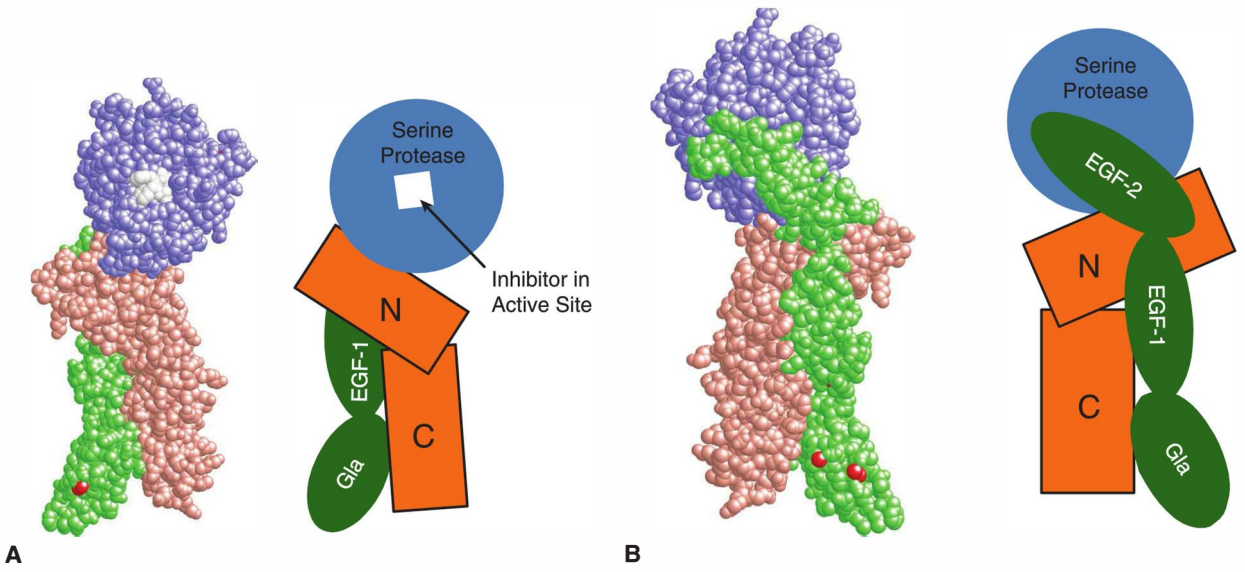

FIGURE 11.4 Two views of the x-ray crystal structure of the complex of soluble TF and active site–inhibited factor VIIa **(left)** and diagrammatic representations of the domain organizations of TF and factor VIIa **(right)**. **A:** "Front" view of the TF:VIIa complex, with the active site facing the viewer. **B:** "Back" view of the complex, with the active site facing away from the viewer. The membrane surface would be located at the bottom of each complex. TF is shaded *brown*, whereas factor VIIa is shown in *green* (light chain) and *blue* (heavy chain). In addition, the tripeptidylchlormethylketone inhibitor in the active site of factor VIIa is colored *white* and calcium ions are *red*. For the TF representation, *N* and *C* refer to the *N*-terminal and *C*-terminal fibronectin type III domains, respectively. For the factor VIIa representation, the Gla domain is labeled *Gla* and the EGF-like domains are labeled *EGF-1* or *EGF-2*. The serine protease domain and the inhibitor are also labeled. The two views of the TF:VIIa complex were generated with the program RASMOL,[424] using the atomic coordinates file 1DAN[86] from the Protein Data Bank.

Several studies have used domain swapping and site-directed mutagenesis to identify the binding sites on TF and factor VIIa that permit them to interact with each other,[103–106] revealing that some contacts are important for stabilizing the binding of TF to factor VIIa (chiefly with the first EGF domain of factor VIIa), whereas others appear to be important in enhancing the enzymatic activity of factor VIIa (chiefly with the protease domain of factor VIIa). These findings are reviewed in detail elsewhere.[105,106]

The portion of the Gla domain located at the bottom of the factor VIIa molecule (as shown in FIGURE 11.4) contains three solvent-exposed hydrophobic residues that are proposed to be inserted into the hydrophobic core of the PL bilayer.[107] The carboxy-terminus of soluble TF is also located near the bottom of the structure, as presented in FIGURE 11.4; in intact TF, this part of the molecule is linked to the membrane anchor by a short peptide sequence. Therefore, in the views given in FIGURE 11.4, the membrane surface should be located at the bottom of the complex, with TF linked to the membrane by its membrane-anchoring domain and with VIIa interacting with PL head groups through the Gla domain. Fluorescence resonance energy-transfer experiments indicate that the TF:VIIa complex is oriented almost perpendicular to the membrane, with the active site of factor VIIa located approximately 78 Å above the membrane surface.[108,109] This same orientation was observed in detailed molecular dynamics simulations of the TF:VIIa complex on membranes.[110]

MODULATION OF FACTOR VIIA ACTIVITY BY TISSUE FACTOR

When factor VIIa binds to TF, its ability to catalyze the hydrolysis of small peptidyl-amide or peptidyl-ester substrates is enhanced 20-fold to 100-fold, depending upon the substrate.[42,111–113] This is usually accomplished by an increase in the catalytic rate constant (k_{cat}) and, in some cases, by a decrease in the Michaelis-Menten constant (K_m), indicating that TF is an allosteric activator of factor VIIa.

Substrate hydrolysis by serine proteases is a multistep process,[114] and the mechanism by which TF enhances the enzymatic activity of factor VIIa is not completely understood. Studies with a slowly hydrolyzed model substrate have shown that TF enhances the rate of substrate hydrolysis by factor VIIa chiefly by enhancing substrate affinity of factor VIIa rather than by altering the rates of any of the subsequent catalytic steps.[115]

A wealth of structure–function studies combining site-directed mutagenesis and x-ray crystallography have enhanced the understanding of the allosteric activation of factor VIIa by TF.[116,117] Insights into the mechanism of allosteric activation of factor VIIa have also been obtained by designing mutants of factor VIIa that have enhanced enzymatic activity in the absence of TF.[118,119] One of the most surprising results comes from the crystal structure of zymogen factor VII, which exhibits extensive β-strand re-registration relative to the crystal structures of factor VIIa.[100]

Serine protease zymogens are converted to active enzymes by limited proteolysis, whereupon the newly generated amino-terminus folds back into the protein to stabilize the oxyanion pocket.[120] It has been proposed that free factor VIIa exists in two states in equilibrium with each other: one in which the protein is catalytically active and a second, zymogen-like state, in which the amino-terminus of the heavy chain is not properly folded back into the catalytic domain.[121,122] Surprisingly, in the crystal structure of factor VIIa obtained in the absence of TF or any inhibitor in the active site, the amino-terminus of the factor VIIa heavy chain was still folded back into the catalytic domain and the oxyanion pocket was intact.[99]

Free factor VIIa proteolytically activates factors IX and X extremely slowly, but when it binds to TF that has been incorporated into suitable PL vesicles, its activity is enhanced many 1,000-fold.[123–125] (Factors IX and X will bind to PL vesicles only if they contain negatively charged PLs, most particularly phosphatidylserine; therefore, TF is most often reconstituted into vesicles containing a mixture of phosphatidylserine and the neutral PL, phosphatidylcholine.) There are three main reasons for this rate enhancement. First, the reversible binding of factors IX and X to PL surfaces raises the concentration of these substrates in the vicinity of the enzyme TF:VIIa, which reduces the apparent K_m. Second, TF is an allosteric activator of factor VIIa enzymatic activity. Third, TF appears to provide an extended binding site (exosite) for macromolecular substrates, as identified by site-directed mutagenesis.[97,126,127]

The fact that most coagulation reactions are restricted to two-dimensional surfaces substantially complicates the interpretation of their enzyme kinetics.[128–130] In addition, coagulation reactions can occur *in vivo* under conditions of stasis or under conditions of considerable blood flow. Andree and Nemerson[131] have published extensively on the effects of flow on the kinetics of factor X activation by the TF:VIIa complex.

It has long been known that resting, intact cells have much lower procoagulant activity than do cells that have been damaged, lysed, or treated with calcium ionophore.[132] Although present on the surface of intact cells, TF becomes fully active only when the membrane properties of the cell are altered,[133,134] a process that is sometimes referred to as decryption of "encrypted" cell-surface TF. There are several potential explanations for TF encryption/decryption. The first is that most cells restrict the distribution of aminophospholipids (such as phosphatidylserine) to the inner leaflet of the plasma membrane.[135] Exposure of negatively charged PLs on the outer leaflet is necessary for efficient binding of substrate (i.e., factor IX or X), so the membrane asymmetry of intact cells will tend to limit the activity of TF. When cells are lysed, damaged, or treated with calcium ionophore, PL asymmetry is lost, resulting in the exposure of phosphatidylserine and phosphatidylethanolamine on the outer leaflet of the plasma membrane, thereby enhancing the activity of TF:VIIa. Another potential explanation in some cell types is that TF may associate with caveolae, areas of the cell surface with altered lipid composition.[136,137] It has been also proposed that dimerization or oligomerization of TF in the membrane may reduce its activity and that damage or lysis of cells may foster the formation of TF monomers with enhanced activity.[138]

Finally, it has been proposed that Cys186 and Cys209 of TF participate in an unusual "allosteric" disulfide bond that can readily be broken or re-formed (i.e., reduced or reoxidized) to switch TF from a predominantly signaling form to a highly procoagulant form on cell surfaces.[139] It has further been proposed that extracellular protein disulfide isomerase (PDI) may regulate TF encryption/decryption via this allosteric Cys186–Cys209 bond, and also derivatization of these Cys residues via S-nitrosylation or glutathionation.[32] These proposals have been disputed by others, in reports that the Cys186–Cys209 bond of

TF is not required for coagulant activity and that PDI appears not to play a direct role in TF encryption/decryption.[31,33,140]

TF:VIIa has an extremely restricted substrate specificity; its main natural substrates appear to be factors VII, IX, and X. Factor X is the favored substrate under most *in vitro* conditions, although activation reactions taking place on intact cells can show a preference for either factor IX or factor X[125,141–143] for reasons that are not clear. When factor IX is activated, two peptide bonds must be cleaved. TF:VIIa complex catalyzes the cleavage of one of these bonds (i.e., at Arg180) more efficiently than the other (i.e., at Arg145), and, furthermore, factor Xa and TF:VIIa complex can synergize to activate factor IX to IXa more efficiently.[144]

Factor VII is a substrate for factor VIIa[145] in an autoactivation reaction enhanced by TF.[12] This reaction requires that the TF:VIIa and TF:VII complexes encounter each other by lateral diffusion in the plane of the membrane.[13] Autoactivation of factor VII might be important in initiating the clotting cascade, but its precise role is yet to be elucidated.

The TF:VIIa complex can cleave multiple peptide bonds in factors V and VIII, including both activation and inactivation cleavage sites,[146,147] although the physiologic significance of this is uncertain.

TISSUE FACTOR PATHWAY INHIBITOR

In 1947, Thomas[148] and Schneider[149] showed that blood contained an inhibitor of TF-initiated coagulation. Ten years later, Hjort[150] described many of the *in vitro* properties of the inhibitor, but it took an additional 30 years before the inhibitor was isolated.[151] Previously called antithromboplastin, anticonvertin, TF inhibitor, extrinsic pathway inhibitor, or lipoprotein-associated coagulation inhibitor, in 1991 the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis settled on the currently used name, tissue factor pathway inhibitor (TFPI).

STRUCTURE OF TFPI ISOFORMS

The TFPI gene spans about 90 kb on the long arm of chromosome 2 (q32) and contains 10 exons (GenBank: NC_000002.11).[152,153] All the splice junctions between exons are of the same type (type I), suggesting that the TFPI gene was assembled during evolution through a process of gene duplication and exon shuffling. Two alternatively transcribed isoforms of TFPI have been identified. TFPIα (GenBank NM_006287.4) is the originally isolated form of TFPI. The mature TFPIα protein contains an acidic amino-terminus, followed by three tandem Kunitz-type protease inhibitory domains, and a basic carboxyterminus (FIGURE 11.5). With posttranslational modifications, including *N*- and *O*-linked glycosylation and partial phosphorylation of Ser2, the molecular mass of TFPIα is approximately 43 kDa.[154,155] In TFPIβ (GenBank NM_001032281.2), an alternative carboxyterminus is inserted at residue 182, which directs the attachment of a glycosyl phosphatidylinositol (GPI) anchor (FIGURE 11.6). The protein mass of TFPIβ is less than that of TFPIα (22 vs. 32 kDa), but it migrates on SDS-PAGE at the same apparent molecular weight as TFPIα due to additional *O*-linked carbohydrate.[156] In human umbilical vein endothelial cells and endothelial-like cell lines (EAhy926, ECV304), the ratio of TFPIα/TFPIβ mRNA varies between 5 and 10.[157]

Kunitz-type inhibitors act by a standard mechanism in which the inhibitor feigns to be a good substrate, but, after the enzyme binds, subsequent cleavage between the P_1 and P_1' amino acid residues of the inhibitor occurs slowly or not at all. The P_1 residue is an important determinant of the specificity and activity of these inhibitors. In kinetic terms, Kunitz-type inhibitors produce slow, tight-binding, competitive, and reversible enzyme inhibition. In the reaction, the Kunitz inhibitor forms an initial "encounter" complex (EI) with the enzyme, and this complex then "slowly" isomerizes to a much tighter form (EI*). "Slow" implies that the final degree of inhibition does not occur immediately and "tight-binding" means that the inhibition occurs at a concentration of the inhibitor that is near to that of the enzyme being inhibited. The Kunitz-2 domain of TFPI mediates factor Xa binding and inhibition, whereas the Kunitz-1 domain is necessary for the inhibition of factor VIIa in the TF:VIIa complex.[158] The Kunitz-3 domain of TFPIα lacks protease inhibitory activity.[159] TFPI also inhibits trypsin and chymotrypsin reasonably well and inhibits cathepsin G, plasmin, and activated protein C (APC) poorly; the physiologic significance of these other inhibitory reactions, however, is obscure.

DISTRIBUTION OF TFPI

The microvascular endothelium is felt to be the major source of TFPI *in vivo*. Northern blot analysis shows the highest TFPI mRNA levels in the placenta and lung and the lowest in the brain.[160] Studies of normal tissues have detected TFPI protein in the endothelium of the microvasculature, smooth muscle cells, monocytes/macrophages, megakaryocytes/platelets, mesangial cells, fibroblasts, microglia, cardiomyocytes, and mesothelial cells.

Plasma TFPI

The plasma concentration of TFPI is approximately 1.6 nM (~70 ng/mL). Most of the circulating TFPI is bound to lipoproteins (~80%), and manipulations that alter the levels of low-density lipoprotein (LDL), a major carrier of TFPI, also affect TFPI levels.[161–163] TFPI circulating with LDL is 34 kDa and appears to represent a substantially truncated form, which lacks a large portion of Kunitz-3 domain and the *C*-terminal domain of TFPIα.[161,164] The 41 kDa form of TFPI that is bound to high-density lipoprotein seems to represent a similar carboxy-truncated form that is linked in a mixed disulfide bond with monomeric apolipoprotein-AII. Whether the lipoprotein-associated TFPIs are extensively truncated forms of TFPIα or modified forms of TFPIβ has not been established, and the mechanism underlying the association of 34 kDa with LDL has not been determined. Nonlipoprotein-bound or "free" TFPI is 20% of total plasma TFPI and is a combination of forms of TFPIα with limited carboxyterminal truncation produced by an as yet to be unidentified protease(s) (10%) and full-length TFPIα (10%). The concentration of full-length TFPIα is reduced in the plasmas of patients with factor V or protein S deficiency, and binding interactions between full-length TFPIα and these proteins have been demonstrated.[165,166] Whether these interactions affect the expression, proteolytic degradation, or clearance of TFPIα remains to be determined. Oral contraceptives and hormone replacement therapy reduce plasma levels of TFPI.[167–170]

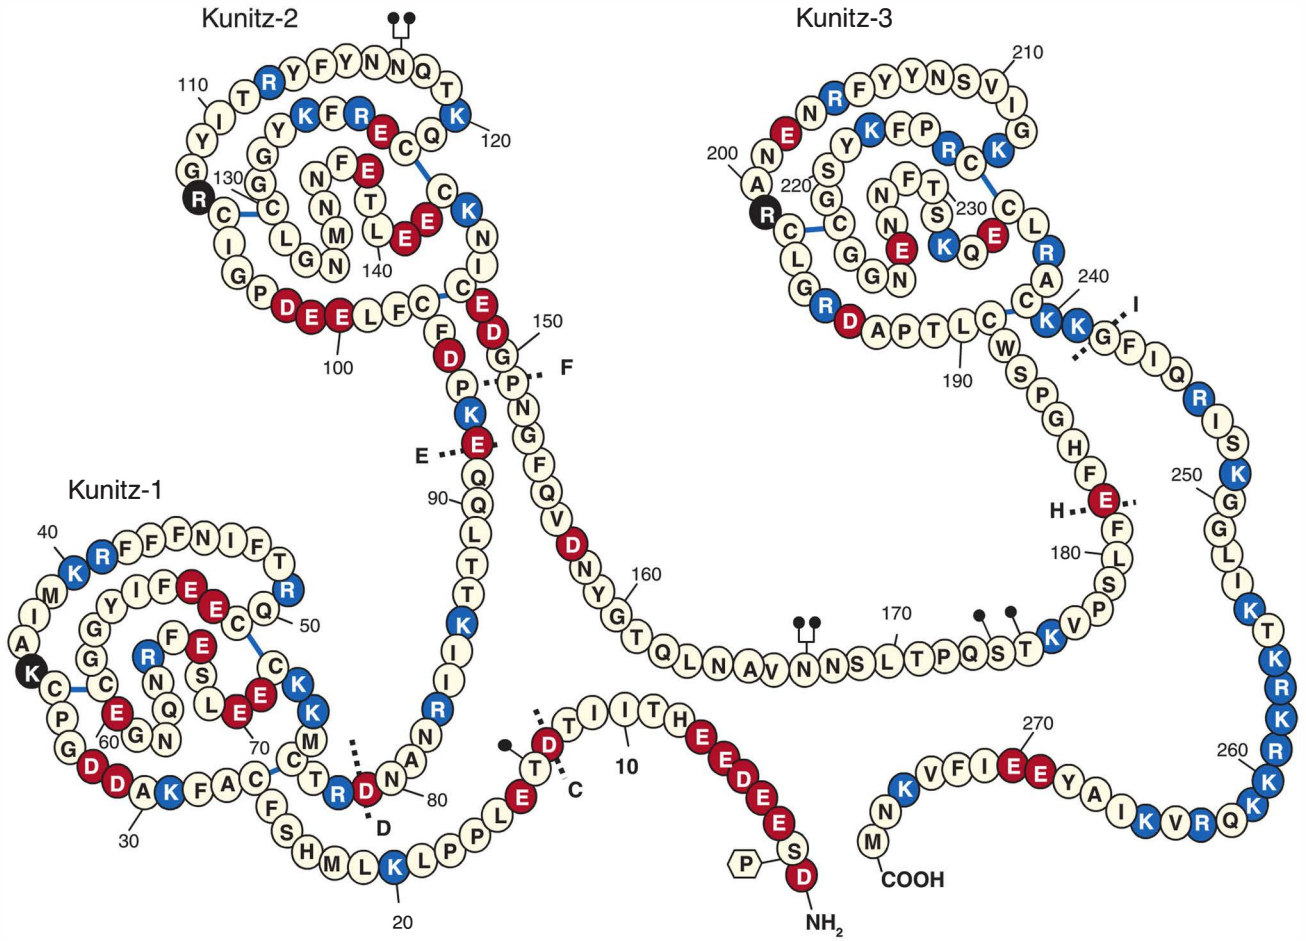

FIGURE 11.5 Structure of TFPIα. Amino acids are identified by the single-letter code (*encircled*). Positively charged amino acids are shown in *red*, negatively charge amino acids in *blue*, and neutral amino acids in *white* (histidine residues are considered uncharged). The Kunitz domains are labeled and the basic P_1 residues at the active site cleft for each domain is shown in *black*. *N*-linked glycosylation sites are denoted at N117 and N167 by and *O*-linked glycosylation sites are denoted at T14, S174, and T175 by . Partial phosphorylation at Ser2 is also shown . The sites of introns in the TFPI gene are labeled with *dotted lines* and *capital letters*. (Figure created by Thomas Girard.)

Platelet TFPI

TFPIα is expressed by megakaryocytes, stored in platelets at a site separate from α granules, and released in response to thrombin and other agonists.[171,172] In "coated" platelets produced by dual agonist stimulation (e.g., thrombin/collagen), a proportion of the released TFPIα remains bound and functional at the platelet surface. Similar to other ligands detected on the surface of coated platelets, transglutaminase inhibitors prevent this retention of surface TFPIα.[172] The full-length TFPIα carried by platelets is 8% to 10% of the total TFPI in blood, which is comparable to the quantity of soluble full-length TFPIα in plasma. Therefore, it is likely that platelets are a major source of full-length TFPIα, the most anticoagulantly active form of TFPI (see below), at local sites of coagulation where platelets aggregate. On the other hand, polyphosphates released from the dense granules of platelets reduce the anticoagulant effect of TFPIα in plasma coagulation assays, apparently in part through their enhancement of factor V activation.[173,174]

Cell-Associated TFPI

Several reports have documented the low-affinity, heparin-inhibitable binding of TFPIα to cells, the internalization and degradation of TFPIα through the action of LDL-receptor–related protein (LRP), and the rapid clearance of TFPIα in animals.[98,175–183] These studies used recombinant TFPIα (rTFPIα) that lacked the post-translational modifications found in mammalian TFPIα. In contrast, the rTFPIα produced by a mammalian cell line (mouse C127) does not bind to cells or interact with LRP in the same fashion as *Escherichia coli* rTFPIα and is cleared from plasma at a 10-fold slower rate.[184] Therefore, the studies that used nonmammalian-derived TFPI should probably be viewed with considerable caution.

A substantial fraction of the TFPI produced by endothelial cells remains at the cell surface, associates with caveolae, and is released by phosphatidylinositol-specific phospholipase C (PIPLC). These are properties of GPI-anchored proteins. The PIPLC-induced release of TFPIβ is consistent with its possession of an intrinsic GPI anchor.[157] It has been reported that

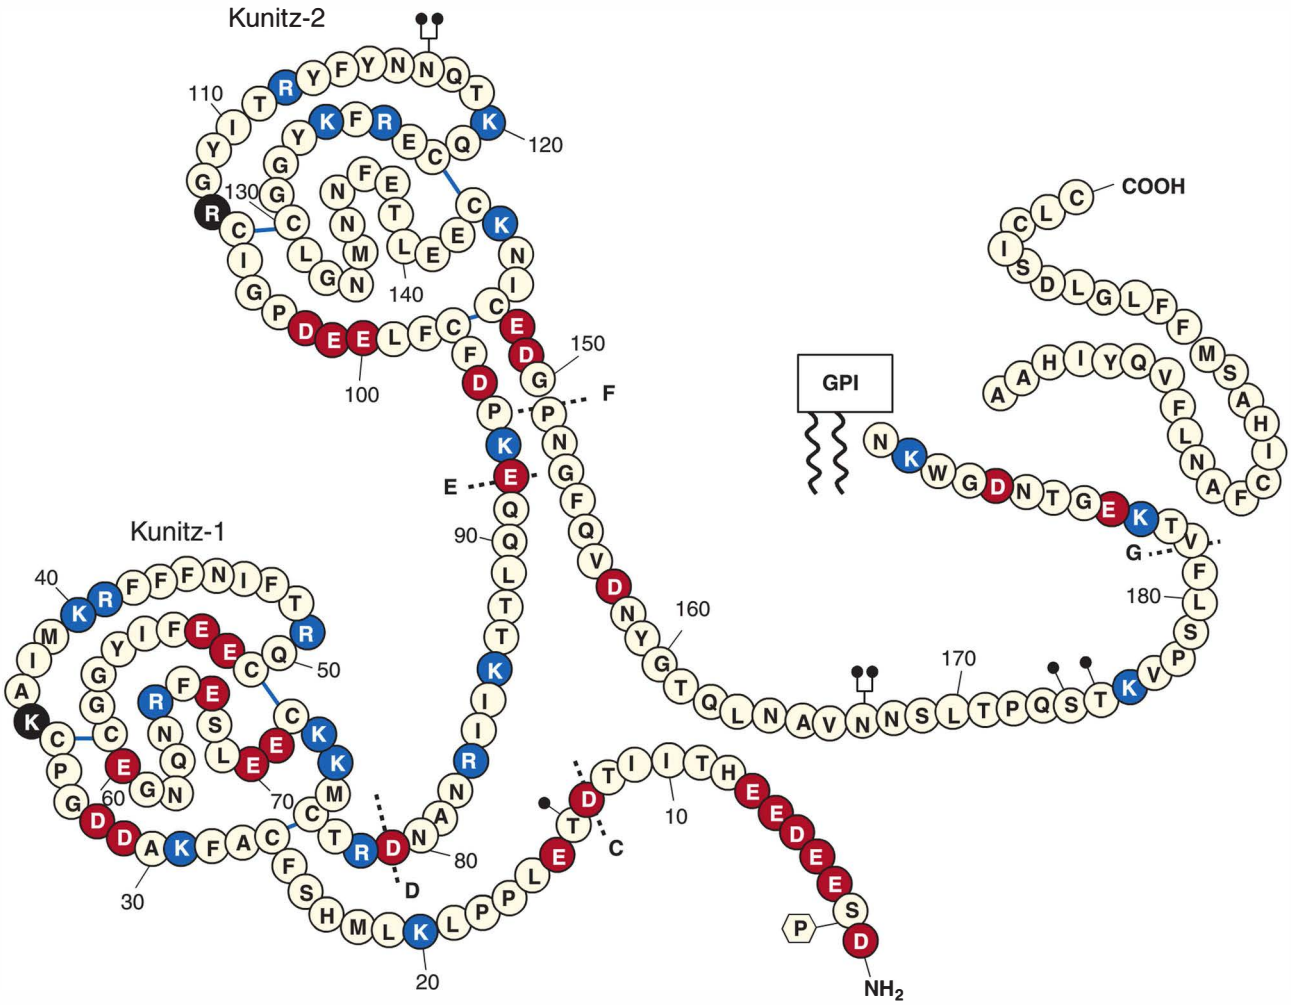

FIGURE 11.6 Structure of TFPIβ. Symbols as denoted in the legend of FIGURE 11.5. The GPI anchor is shown attached to mature TFPIβ along with the released carboxyterminal peptide. (Figure created by Thomas Girard.)

cell-surface TFPIα is also released by PIPLC treatment.[185,186] Since the amino acid sequence of TFPIα does not contain the canonical motifs to direct the attachment of a GPI anchor, this implied that the cell-surface binding of TFPIα may involve its interaction with a separate GPI-anchored coreceptor(s), which controlled its cellular trafficking and surface expression.[187] Subsequent work, however, has shown that it is TFPIβ that is released by PIPLC from endothelial cells and placental microsomes.[188] In endothelial cells induced to produce TF, GPI anchorage of TFPI serves to redistribute TF:VIIa to caveolae in a factor Xa–dependent manner.[136,185,189] GPI anchorage, however, may not be a requirement for TF:VIIa inhibition by cell-surface TFPI as chimeric forms of rTFPI anchored by GPI or transmembrane domains produce similar levels of TF:VIIa inhibition.[190] Endothelial cell–associated TFPI represents a substantial reservoir of TFPI *in vivo*, suggesting that the regulation of TF-mediated procoagulant and cell-signaling activities in the endothelium is a critical physiologic role of TFPI. Whether TFPI is attached to the surface of other TFPI-expressing cells (e.g., vascular smooth muscle cells, monocytes/macrophages) in the same manner as it is in endothelial cells remains to be determined.

Releasable TFPI

Heparin, thrombin, and shear increase the expression and release of TFPI from cells in culture.[157,187,191–196] The release of TFPI induced acutely by these agonists appears to involve the redistribution of TFPI from stores located near the plasma membrane (perhaps caveolae) to the cell surface, with the subsequent release into the media of a portion of the total cellular TFPI. During this process, the TFPI available at the surface of the cells remains unchanged or increases. The parenteral administration of heparin or low molecular weight heparin, but reportedly not the heparin pentasaccharide (fondaparinux), rapidly increases the circulating levels of total TFPI in plasma 1.5- to 3.0-fold.[197–200] It is full-length TFPIα that is released in this process, raising the plasma concentration of full-length TFPIα 10- to 20-fold.

Degradation of TFPI

In vitro experiments have shown that TFPIα can be proteolytically degraded by a variety of proteases, including thrombin, plasmin, neutrophil elastase, cathepsin G, factor Xa (when at molar excess over TFPIα), cell-derived matrix metalloproteinases, and

bacterial omptins.[201–207] Plasmin-mediated degradation of TFPI in plasma and on the monocyte surface has been demonstrated in patients following thrombolytic therapy and indirectly on the cells of the lung in septic baboons.[208,209] The degradation of TFPI by neutrophil proteases, especially elastase, has been shown to enhance microvascular coagulation, thereby limiting the tissue dissemination of bacterial pathogens, but also increasing vascular thrombosis.[210] This cleavage of TFPI by neutrophil elastase is facilitated by neutrophil-derived externalized nucleosomes, which form neutrophil extracellular traps that serve to colocalize elastase and TFPI. In tissue culture cells, APC cleaves TFPI between its Kunitz-1 and Kunitz-2 domains in an endothelial protein C receptor–dependent process and thereby reduces cell-surface TFPI activity.[211]

FUNCTIONS OF TFPI

TFPI limits coagulation both through the inhibition of factor Xa, a process enhanced by protein S, and through factor Xa–dependent feedback inhibition of TF:VIIa (FIGURE 11.7). TFPI-mediated inhibition of factor Xa generation by TF:VIIa and the inability to rapidly produce additional factor Xa through the action of factor IXa:factor VIIIa helps explain the bleeding seen in hemophilia.[212–214] Thus, neutralization of TFPI

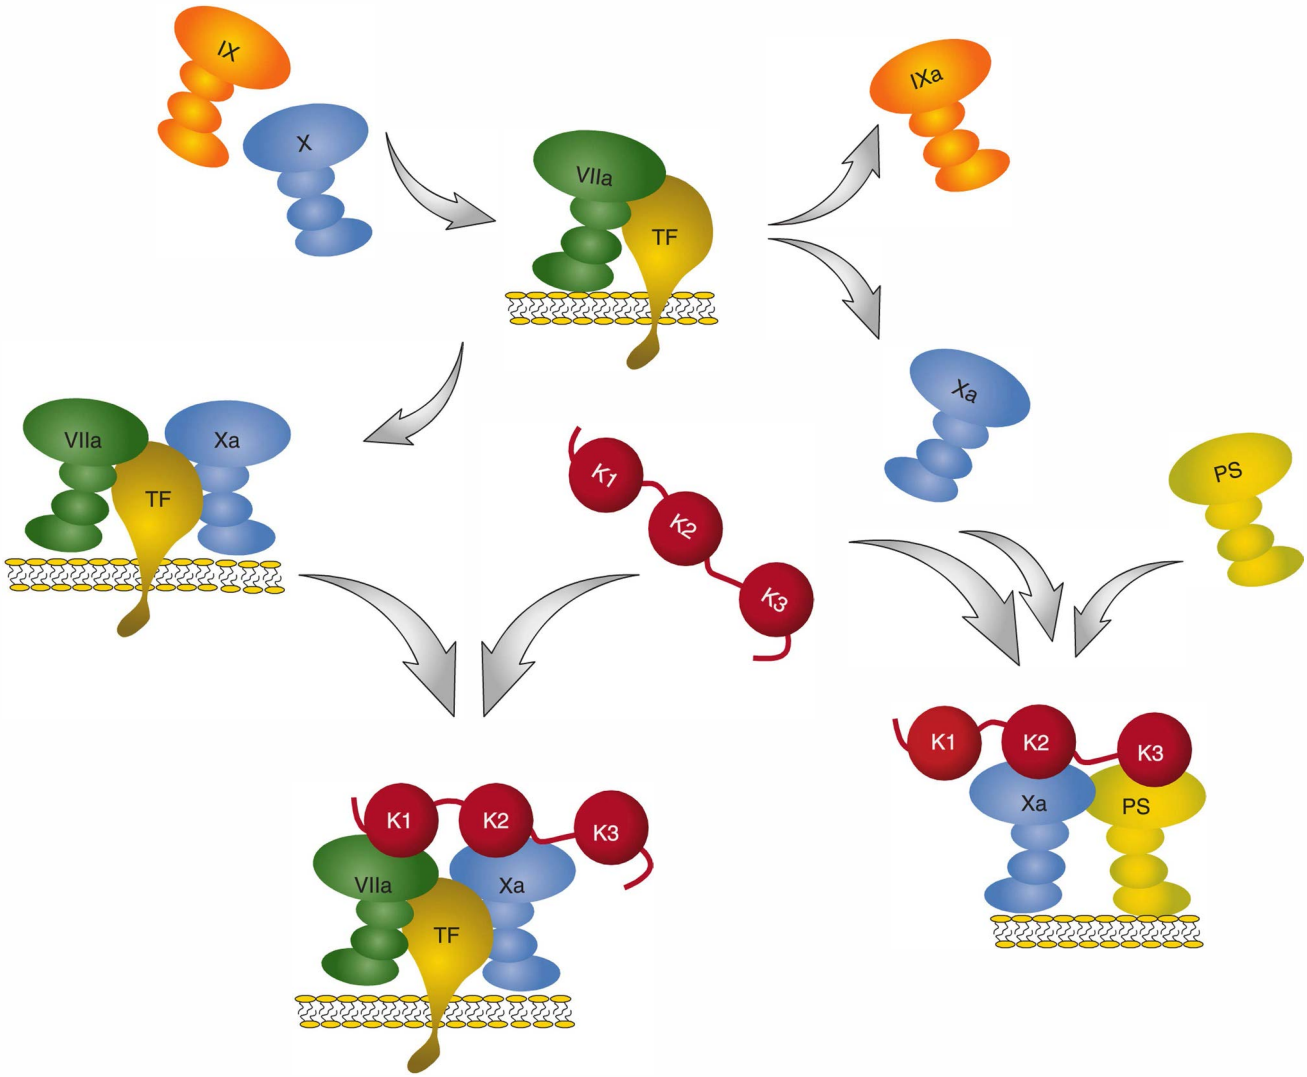

FIGURE 11.7 Functions of TFPIα. The TF:VIIa catalytic complex on a PL surface activates factors X and IX **(top)**. TFPI **(center)** binds to the transient ternary TF:VIIa:Xa complex **(left)** produced during the activation of factor X, forming a quaternary TF:VIIa:Xa:TFPI inhibitory complex **(bottom)** in which the Kunitz-1 and Kunitz-2 domains of TFPI bind and inhibit factor VIIa and factor Xa, respectively. On the right, factor Xa, protein S, and TFPI are shown forming an inhibitory complex at a PL surface in which the Kunitz-2 domain binds and inhibits factor Xa and the Kunitz-3 and carboxyterminal domains of TFPIα are required for interactions with protein S and PLs. Direct inhibition of factor Xa by TFPI and an alternative two-step pathway for TF:VIIa inhibition in which a factor Xa/TFPI complex binds to TF:VIIa producing the final quaternary inhibitory complex are not shown. Also not depicted are the factor VIIa/TF and factor Xa inhibition produced by cell membrane-bound TFPIα and TFPIβ. The Kunitz-1, Kunitz-2, and Kunitz-3 domains of TFPI are labeled K1, K2, and K3, respectively. (Figure created by Thomas Girard.)

action has been explored as a potential therapeutic modality for hemophilia.[215–217]

Factor Xa Inhibition

The inhibition of factor Xa by TFPI is through its Kunitz-2 domain,[158,159] but other parts of the TFPI molecule are important for this inhibitory effect. The carboxyterminal domain of TFPIα is required for rapid and efficient factor Xa inhibition, and cleavage of TFPI between Kunitz domains 1 and 2 (e.g., by neutrophil elastase) dramatically reduces the ability of TFPI to inhibit factor Xa.[159,204,218,219] The inhibition of factor Xa by TFPI in the presence of physiologic calcium ion concentrations is enhanced by procoagulant PLs.[218] The basic carboxyterminal region of the TFPIα molecule is important for this effect and presumably permits the simultaneous interaction of factor Xa and TFPIα with the PL surface. Under these conditions, the kinetic inhibitory constants (Kis) for the EI and EI* complexes of TFPI with factor Xa are 2 to 4 nM and 50 pM, respectively.[218,220] The TFPIβ isoform lacks the carboxyterminus of TFPIα and demonstrates relatively weak inhibition of factor Xa when tested in soluble phase.[221] The inhibition of factor Xa by TFPIβ, however, is likely to be significantly enhanced when it is bound to a PL surface via its GPI anchor.

Protein S substantially enhances the inhibition of factor Xa by TFPIα in the presence of PLs and calcium ions by increasing the affinity of the initial EI between factor Xa and TFPIα 10-fold, to near the concentration of full-length TFPIα in plasma (FIGURE 11.7).[220] An optimal effect requires the carboxyterminal domain of TFPIα and appears to involve at least in part a direct interaction of protein S with the Kunitz-3 domain of TFPIα.[222] As protein S binds factor Xa in a calcium ion- and PL-dependent fashion,[223] the most straightforward explanation for the potentiating effect of protein S on factor Xa inhibition by TFPIα is that an association between protein S and TFPIα serves to increase TFPIα's interactions with PLs and with factor Xa at PL surfaces.

Heparin and other polyanions accelerate factor Xa inhibition by TFPIα. The heparin dose response exhibits an optimum, suggesting that the polyanion forms a template upon which factor Xa and TFPI simultaneously bind.[218,224] Basic residues within the carboxyterminus and Kunitz-3 domains of TFPIα are required for optimal heparin binding, and progressive carboxyterminal truncation of the TFPI molecule produces forms with decreasing affinity for heparin.[224,225] Rather than a specific binding epitope, charge density on the glycosaminoglycan appears to be most important for TFPI binding.[226]

Tissue Factor:Factor VIIa Inhibition

Factor Xa–dependent inhibition of TF:VIIa by TFPI requires the Kunitz-1 domain and involves the formation of a quaternary TFPI-factor VIIa–TF-factor Xa (TFPI:VIIa:TF:Xa) complex (FIGURE 11.7).[212,227] The final quaternary complex could be produced in a two-step process in which TFPI first binds factor Xa and then the factor Xa–TFPI complex binds and inhibits TF:VIIa. That this two-step pathway can occur has been documented *in vitro*. Kinetic studies, however, strongly suggest an alternative pathway in which TFPI interacts with the ternary complex of TF:VIIa:Xa, which forms transiently during the activation of factor X and from which the product factor Xa dissociates relatively slowly.[228] As a result, TF:VIIa inhibition is extremely rapid, and the concentration of active factor Xa that escapes regulation depends linearly on the quantity of available TF. That protein S significantly enhances the formation of the factor Xa–TFPI complex, but does not increase the inhibition of TF:VIIa by TFPI, is consistent with this alternative pathway.[229] The Gla domain of factor Xa and Lys165–Lys166 of TF, which are structures required for the optimal recognition of factor X by TF:VIIa, are also important for the inhibition of TF:VIIa by factor Xa–TFPI.[227,230,231]

Full-length TFPIα inhibits factor Xa much faster than carboxyterminal truncated forms of TFPI.[159,219,224] In contrast, full-length and carboxyterminal truncated forms of TFPIα appear to inhibit factor X activation by TF:VIIa at comparable rates.[232–234] GPI-anchored TFPIβ is the preeminent regulator of TF/VIIa on cells expressing both TFPI and TF.[156] The requirement of factor Xa for the inhibition of TF:VIIa by TFPI is not absolute and high concentrations of TFPI will inhibit TF:VIIa in the absence of factor Xa.[159,235] This factor Xa-independent inhibition of TF:VIIa by TFPI, however, is of uncertain physiologic relevance.

Anticoagulant Activity

The anticoagulant activity of TFPI in plasma assays is due to its inhibition of factor Xa and not its inhibition of TF:VIIa. The exogenous addition of TFPIα to plasma inhibits the coagulation induced by factor Xa, the X-coagulant protein of Russell viper venom, and TF to a similar extent.[219] An optimal effect requires the presence of protein S and is dependent on the Kunitz-3 and carboxyterminal domains of TFPIα.[222] In plasma containing physiologic concentrations of full-length TFPIα (~0.16 nM), a similar effect of protein S and TFPI on thrombin generation can be demonstrated, but only at low concentrations of TF (<14 pM) or factor Xa (250 pM).[236] At higher concentrations of TF, the rate and extent of factor Xa generation produced by factor IXa:factor VIIIa as well as TF:VIIa is presumably sufficient to overwhelm the factor Xa inhibition mediated through TFPIα and protein S. When the coagulation response to higher concentrations of TF is limited by activation of the protein C pathway (e.g. addition of APC or thrombomodulin to plasma), however, the effect of protein S–dependent TFPI inhibition of factor Xa is again apparent.[236,237,238] Indeed, the combination of the actions of APC and TFPIα, enhanced by their mutual cofactor protein S, serves to synergistically limit coagulation.

While the full-length form of TFPIα is required for optimal factor Xa inhibition and the anticoagulant effect of TFPI in one-stage coagulation assays,[219,222,239] the TF:VIIa inhibition produced by the carboxyterminal truncated forms of TFPI, present at 10-fold higher concentrations than full-length TFPIα, in plasma is demonstrable in two-stage assay systems.[239] It seems likely that the attachment of the carboxyterminal truncated forms of TFPI to large lipoprotein particles in plasma would hinder the recognition of cellular TF:VIIa, but this has not been directly tested.

The critical importance of the regulation of TF-induced coagulation by TFPI has been demonstrated in gene-disrupted mice that express isoforms of TFPI lacking the Kunitz-1 domain (TFPIΔK1). These isoforms cannot inhibit TF:VIIa and presumably possess dramatically reduced anti–factor Xa activity.[204] The homozygous TFPIΔK1 mice die *in utero* of disseminated intravascular coagulation and a consumptive coagulopathy,[240] but can be rescued by concomitant factor VII or TF

deficiency.[241,242] The anticoagulant properties of TFPIα have been shown to limit pathologic processes that are dependent on TF's procoagulant activity, such as thrombosis and intimal hyperplasia following vascular injury,[243,244] and cancer metastasis[245] in animal models.

Inhibition of TF Cell Signaling

The cell-signaling effects of TF are produced not only indirectly through the actions of thrombin (and perhaps factor Xa) generated downstream in the coagulation cascade but also directly through TF-dependent cell-surface complexes (see section, *Tissue Factor as a Signal Transducer*). Factor VIIa bound to TF, including cryptic TF and factor Xa in the transient TF:VIIa:Xa complex, initiates cell signaling by cleaving and activating protease-activated receptor (PAR)-2.[246,247] TF-dependent signaling through PAR-2 enhances the inflammatory response, angiogenesis, and cellular migration and appears to play an important role in tumor growth and development.[57,248–259] The target of TFPI action is the TF:VIIa:Xa complex, and PAR-2 activation produced by this complex is suppressed by TFPI. The PAR-2 signaling induced by factor VIIa bound to cryptic TF is presumably not affected by TFPI as this complex does not engage factor X(a).[247]

Anti-TF antibodies, active site blocked factor VIIa (VIIai), and TFPIα were shown to reduce the inflammatory response, coagulation changes, and mortality in a baboon model of *E. coli* sepsis.[58,260,261] Treatment with active site blocked factor Xa (Xai) prevented thrombin generation and the resultant coagulopathy, but did not affect mortality in the same baboon model.[262] These results are consistent with the notion that upstream, TF-dependent signals play an important role in inflammation in general and in the pathophysiology of sepsis in particular. A subsequent large phase III clinical trial in sepsis, however, failed to demonstrate an effect of rTFPIα on mortality.[263] The dose of rTFPIα administered in the trial was limited due to hemorrhagic complications noted at higher doses in a prior phase II clinical trial[264] and produced plasma levels (~4 nM) that were >10-fold lower than those that had been shown to be efficacious in the baboon model of *E. coli* sepsis.[261] In the phase III clinical trial, the lower dose of rTFPIα minimally reduced thrombin generation and, in contrast to the baboon studies, did not affect the inflammatory response assessed by interleukin-6 (IL-6) levels. Similarly, preclinical studies had shown that rTFPIα limited inflammation and mortality in animal models of acute lung injury, but a subsequent large clinical trial in severe community-acquired pneumonia, which also used reduced doses of rTFPIα, did not detect an effect on mortality.[265]

TF Independent

Some studies have suggested roles for TFPIα in biologic processes unrelated to its inhibition of the actions of TF, for example bacterial growth,[266–268] angiogenesis,[269–271] and lipoprotein metabolism.[272] In most cases, the observed effect of TFPIα appears to be mediated through its basic carboxyterminal peptide.[266,267,270,272] The levels of full-length TFPIα or carboxyterminal peptide required to elicit these responses, however, are considerably higher than those likely to be encountered *in vivo*. Therefore, additional investigation will be required to determine the physiologic relevance of these observations.

DEFICIENCY OF TFPI

Severe deficiency of TFPI has not been described in humans and may be incompatible with survival. Homozygotic TFPIΔK1 gene disruption in mice produces embryonic lethality[240] and heterozygotic disruption increases thrombosis and intimal hyperplasia following vascular injury,[273] atherosclerosis in the apoE-null mouse model,[274] and the thrombotic phenotype of mice with factor V_{Leiden} or thrombomodulin deficiency.[275,276] Although TFPI certainly plays a key role in the regulation of TF-initiated coagulation, a clear relationship between plasma levels of TFPI and thrombosis has been difficult to demonstrate in humans. In this regard, it must be noted that circulating TFPI represents only a fraction of the total intravascular TFPI that is readily available (see sections, *Cell-Associated TFPI* and *Releasable TFPI*). Two studies, however, have reported a weak association of low levels of plasma TFPI (≤10th percentile) with venous thrombosis[170] and arterial vascular disease.[277] Several polymorphisms within the TFPI gene have been described, but convincing evidence for a relationship between TFPI genotype and thrombotic risk is lacking.

Other Inhibitors of TF:VIIa

In the presence of heparin and under conditions of saturating TF, antithrombin also inhibits the TF:VIIa complex with a second-order rate constant of 5.6×10^3/M/s.[278,279] The heparin enhancement of antithrombin inhibition appears to involve the allosteric mechanism, since the heparin pentasaccharide (fondaparinux) produces a similar effect.[280] Antithrombin and heparin, however, only modestly affect factor X activation by TF:VIIa under the more physiologic conditions of limiting TF.[281,282] This is due to the competition of the substrate, factor X, for TF:VIIa and the exchange of uninhibited factor VIIa for the inhibited factor VIIa–antithrombin complex at TF-binding sites.[283,284] Antithrombin with heparin likely plays a more important role in regulating TF-induced coagulation by inhibiting the activation of factor VII by factor Xa, thrombin, factor IXa, and other proteases. Thus, in reactions containing zymogen factor VII, rather than factor VIIa, the activation of factor X is dramatically delayed in the presence of antithrombin and heparin.[281,282] Plasminogen activator inhibitor-1 and protein C inhibitor have also been shown to inhibit VIIa in the TF:VIIa complex, but the physiologic role of these reactions is not clear.[285,286]

Several artificial inhibitors of TF:VIIa complex have been developed. These include a potent inhibitor consisting of the light chain of factor Xa linked to the first Kunitz domain of TFPI[287] and other Kunitz-type inhibitors that have been engineered for increased reactivity with TF:VIIa.[288,289] An inhibitor with enhanced potency for factor VIIa was created by linking a modified Kunitz-type inhibitor with a mutated form of soluble TF.[290] In addition, an inhibitor that targets TF:VIIa complex, termed *NAPc2*, has been cloned from hookworms[291] and has been evaluated in clinical studies as a novel antithrombotic agent.[292] Blocking antibodies to TF or factor VIIa have been utilized in animal models of sepsis and thrombosis, in which they reduce the severity of coagulopathy or thrombosis.[58,293–295] Active site–blocked factor VIIa (factor VIIai) has also been successfully used as a selective inhibitor of TF function in animal models of thrombotic disease.[59,260,296–298] Novel peptide inhibitors that bind to exosites on factor VII/VIIa and allosterically inhibit factor

VIIa have been reported.[299] Several studies have reported that blocking TF:VIIa complex is effective in decreasing thrombosis without causing bleeding side effects associated with other antithrombotic agents.[298,300–302] This suggests that inhibitors directed at TF or factor VII may have advantages over conventional antithrombotic drugs, an area that will doubtless continue to be the subject of considerable research interest in the future. Indeed, several lead compounds for the development of small molecule inhibitors of TF:VIIa have been reported.[302–304]

DIAGNOSTIC AND THERAPEUTIC USES OF TISSUE FACTOR AND FACTOR VIIA

The commonly employed prothrombin time (PT) clotting assay uses a source of TF as the procoagulant agent. Typically, PT reagents are made from homogenates of brain, lung, or placenta (of human, rabbit, or bovine origin) and are often referred to as *thromboplastins*. Because these reagents have varying amounts of TF, PLs, and contaminants, they have varying potencies. A major application of the PT assay is to monitor dosage for oral anticoagulant therapy, but the results obtained with this assay may vary according to the sensitivity of the thromboplastin reagents. To control for differing thromboplastin sensitivities, a standardization system for these reagents has been developed—the international sensitivity index (ISI)—which is used in conjunction with a normalization method, termed the international normalized ratio, for reporting prolongations of the PT in patients receiving oral anticoagulant therapy.[305] Recombinant thromboplastin reagents are now commercially available that are made from purified, recombinant TF that has been reconstituted into PL vesicles. Because the recombinant reagents have a defined composition, their ISI values can be adjusted readily by the manufacturer to more closely resemble international reference standards for thromboplastins[306] (see Chapter 50).

A clotting test has been developed that uses soluble TF in place of full-length TF[4] to measure trace levels of circulating factor VIIa. This assay takes advantage of the fact that soluble TF does not promote the conversion of factor VII to VIIa,[307] so clotting times are dependent upon the preexisting levels of plasma factor VIIa.

Soluble TF has also been used as the toxic payload in experimental antineoplastic agents. In this approach, soluble TF is linked to targeting molecules in order to deliver it to tumor vasculature, where it can kill tumors by infarction.[308]

Recombinant human factor VIIa has been developed for use as a pharmaceutical agent, termed *eptacog alfa*, and has been marketed under the brand names NovoSeven or NiaStase. It is approved for use in treating bleeding episodes in patients with hemophilia who have intractable inhibitors (blocking antibodies) to factor VIII and who therefore fail to respond to factor VIII replacement therapy.[309] It is also being investigated as a more general hemostatic agent[310] and has seen increasing "off-label" use to control bleeding in nonhemophilic patients.[311] High levels of plasma factor VIIa permit the bypass of the factor VIIIa:factor IXa part of the clotting cascade in a manner that is not fully understood. High levels of factor VIIa may do this by enhancing the activity of TF that is exposed at sites of vascular injury or by directly activating factor X (especially in the presence of negatively charged PLs at the site of injury) in a TF-independent manner.[312] Newer-generation variants of recombinant factor VIIa with increased intrinsic enzymatic activity[313] or longer circulating half-lives[314] are under development and testing, which may have advantages for treating bleeding.

ROLES OF FACTOR VII/VIIA AND TISSUE FACTOR IN PROTHROMBOTIC STATES

The blood clotting system is composed of multiple hemostatic factors that can be subdivided into procoagulant, anticoagulant, and fibrinolytic arms, which must act in a balanced fashion so that blood clots are formed only for the purpose of stopping blood loss following injury. Certain hereditary conditions and disease states can predispose individuals to episodes of thrombosis and are often called *prothrombotic* or *hypercoagulable* states. Alterations in the quantity or activity of a number of hemostatic factors—including factor VII and TF—have been reported to be associated with altered risk of thrombotic disease.

Several methods exist for quantifying plasma factor VII levels, including measurements of total factor VII mass (factor VII + VIIa), factor VII coagulant activity (FVII:C), or factor VIIa. Total factor VII mass is typically quantified by measuring factor VII antigen levels (FVII:Ag)[315] or by the coupled amidolytic assay (FVII:Am), an activity assay in which factor VII is quantitatively converted to factor VIIa.[316] FVII:C assays measure the procoagulant activity of factor VII in a plasma sample in a clot-based assay. Because some of the factor VII is converted to VIIa during the test, FVII:C assays measure an aggregate of both factor VII and factor VIIa.[317,318] Factor VIIa levels can be measured using a soluble TF-based clotting assay[4] or a commercial ELISA in which active factor VIIa reacts with a biotinylated enzyme inhibitor.

Elevated plasma factor VII was initially identified as a risk factor for thrombotic disease in several epidemiologic studies,[319,320] particularly when fatal events were analyzed in long-term follow-up.[321] Other epidemiologic studies have reported correlations between elevated plasma factor VII:C or VIIa levels and angina pectoris, transient ischemic attacks, diabetes, uremia, and peripheral vascular disease.[322–331] These studies are complicated by the fact that the activation state of plasma factor VII is influenced by plasma lipid levels.[15,16,332,333] On the other hand, other studies have failed to find a relation between factor VII levels and thrombotic disease.[334,335] Population studies have reported that factor VII levels are unrelated to the degree of carotid artery thickness or other manifestations of vascular disease.[336–340]

Several studies have directly investigated the relation between plasma factor VIIa levels and risk of thrombotic disease. Some studies have found significant positive correlations,[341] whereas a few have found significant negative correlations.[342,343] In some studies, factor VIIa levels were found to be significantly related to the risk of thrombotic disease only in women.[341,342] The relation between variation in plasma factor VIIa levels and risk of thrombotic disease is therefore currently unclear.

Naturally occurring polymorphisms have been identified in the factor VII gene. This includes a substitution of Gln for Arg353 in the protease domain of factor VII[344] as well as mutations in the promoter region of the gene.[345–348] These polymorphisms are associated with variation in factor VII levels, and, furthermore, some of these markers are in strong linkage disequilibrium with each other.[335,347,349] Some studies[350] have found factor VII genotype to be associated with thrombotic risk, but

others[351,352] have not obtained similar results, and this area remains controversial.[335,349]

BLOOD-BORNE TISSUE FACTOR

TF antigen has been detected at low levels in plasma and urine, and these levels increase significantly in certain pathologic states, such as disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, diabetic microangiopathy, glomerulonephritis, and certain leukemias.[353–356] Whole blood TF activity levels increase following endotoxin challenge and in other settings in which intravascular activation of the blood clotting system can occur, such as sickle cell disease.[357–359]

Giesen et al.[360] reported that TF-containing microparticles, along with monocytes and granulocytes that were positive for TF antigen, accumulated in thrombi formed *ex vivo* by flowing blood over collagen-coated surfaces. Because the perfusions lasted only 5 minutes, there was clearly insufficient time for *de novo* synthesis of TF by leukocytes, and therefore this protein must have come from a preexisting source. Furthermore, these studies suggested that blood-borne TF may play an important role in thrombus formation. Subsequent studies from the same laboratory[361] and other studies have continued to demonstrate that blood-borne TF can be detected at low levels in blood and that it appears to accumulate in thrombi, where it can play an active role in thrombus propagation (reviewed by Morrissey,[362] Morel et al.,[363] and Giesen and Nemerson[364]).

The source of blood-borne TF is currently a matter of intense research. The TF-bearing microparticles shed from leukocytes seem to be a likely source. Monocytes are capable of synthesizing TF following exposure to inflammatory mediators, but low levels of leukocyte TF expression in nonpathologic settings could contribute to blood-borne TF microparticles. TF has been reported to exist in multiple forms intravascularly—as a soluble protein; as a membrane protein in microparticles; and on the surface of, or within, monocytes, granulocytes, and platelets.[360,365–370] Not all of these reports agree with each other, and, in particular, the results concerning the presence of TF in platelets and granulocytes are controversial.[371–373]

HEREDITARY DEFICIENCIES IN TISSUE FACTOR

Human deficiencies in TF have not been reported, leading to the presumption that TF is essential for life. When the TF gene was inactivated in mice, heterozygotes were normal and healthy, but the homozygous TF-null mice died between days E8.5 and E11.5 of embryonic development.[374,375,376] The TF-null embryos exhibited abnormalities in the yolk sac vasculature by approximately day E9.5, and their death was attributed to bleeding from both embryonic and extraembryonic vessels[374,375] and subsequent wasting owing to insufficiency in vitelloembryonic circulation.[376] Some investigators have suggested that these developmental abnormalities may be caused by nonhemostatic roles of TF that are essential for normal blood vessel development[377] (see section, *Nonhemostatic Functions for Tissue Factor and Factor VII*). Interestingly, genetic background influences the morbidity of TF-null mice: In a 129/Sv background, all TF-null embryos died by midgestation, whereas in a C57BL/6 background, two populations of null embryos were observed, one that died at midgestation and another that died at birth.[378]

Although TF-null mice die during embryogenesis, mice in which only the cytoplasmic domain of TF has been deleted develop normally and show no bleeding tendency.[379,380] In addition, fibroblasts from these mice show normal signal transduction when factor VIIa binds to the mutant TF. On the other hand, these mice have reduced immunoinflammatory responses, macrophage function, and susceptibility to arthritis[381]; and they have blunted leukocyte responses to bacterial endotoxin challenge and decreased susceptibility to death from endotoxemia.[382]

TF-null mice can be rescued by using a human TF "minigene" that is expressed at only 1% the level of the endogenous murine TF gene.[383] These low-TF mice develop normally but have shorter life spans than do wildtype mice. Female low-TF mice may have fatal bleeding episodes during pregnancy, and low-TF mice exhibit frequent spontaneous hemorrhage, deposition of hemosiderin, and fibrosis in cardiac tissue.[384] Interestingly, mice engineered to express extremely low levels of factor VII also show significant hemosiderin and fibrosis in their hearts.[384] Mice lacking the cytoplasmic tail of TF did not exhibit the same phenotype as low-TF mice, again excluding a role for the cytoplasmic tail in the fibrosis and early death associated with low-TF mice. TF levels are much higher in cardiac muscle than in skeletal muscle,[48] suggesting that TF plays a role in protecting the myocardium from ongoing vascular damage and subsequent hemorrhage. Interestingly, TF has been implicated in cardiomyopathy as a result of increased expression of mRNA and antigen in cardiomyocytes during myocardial ischemia.[385]

HEREDITARY DEFICIENCIES IN FACTOR VII

Hereditary deficiency in factor VII is a rare, recessive autosomal disorder in humans.[386] Individuals with severe factor VII deficiency may exhibit life-threatening bleeding episodes, although the correlation between factor VII:C levels and bleeding tendency is not particularly strong. The molecular basis for inherited factor VII deficiency has been determined for a number of individuals, resulting in the identification of a variety of nonsense, missense, and splice-site mutations throughout the factor VII coding region, as well as a few small deletions and at least one mutation in the promoter region that causes reduced factor VII levels[387] (see Chapter 53).

Factor VII knockout mice develop normally *in utero* but die neonatally from massive hemorrhage.[388] This finding parallels that of a splice-site mutation in the human factor VII gene, which results in an in-frame deletion of the region encoding the first EGF domain of factor VII in the mature mRNA.[389] A human infant who is homozygous for this mutation had no detectable plasma factor VII activity and no developmental abnormalities, but died from severe postnatal bleeding. Taken together, these results indicate that a total lack of factor VII is not compatible with life.

NONHEMOSTATIC FUNCTIONS FOR TISSUE FACTOR AND FACTOR VII

Tissue Factor as a Signal Transducer

A role for TF as a signaling molecule is now well documented and appears unconnected to its role in coagulation. Initial reports established that binding of factor VIIa to TF evoked intracellular calcium responses in a variety of cell types.[390,391]

These observations were followed by reports of phosphorylation of several mitogen-activating protein (MAP) kinases, such as p38 and JNK, in response to binding of factor VIIa to TF.[392,393] Activation of the Src family members, c-Src, Lyn, and Yes, by TF:VIIa complex in fibroblasts triggers activation of the downstream GTPases Rac and Cdc42 by phosphatidylinositol 3-kinase,[394] ultimately resulting in p38 MAP kinase activation and cytoskeletal reorganization. Interestingly, these responses depend on the catalytic activity of factor VII because factor VIIai (which binds tightly to TF but which has no enzymatic activity) or blocking anti-TF antibodies abolish these effects.[391–393,395]

A body of evidence shows that TF:VIIa can transduce signals by activation of PAR-1 and PAR-2.[396,397] However, TF:VIIa readily activates downstream coagulation proteases, such as factors IXa and Xa, and, indirectly, thrombin. Because some of these proteases are potent PAR activators, it has been a matter of some speculation whether TF:VIIa directly or indirectly activates PARs. Some groups have reported that factor X is required to generate an intracellular response through TF:VIIa.[246,247] Riewald and Ruf[247] have proposed that newly activated factor X remains bound to TF:VIIa long enough for it to be presented within a ternary TF:VIIa:Xa complex to PARs. Factor Xa in this transient ternary complex is therefore proposed to activate PAR-1 and PAR-2 more efficiently than either TF:VIIa or factor Xa alone. One report has shown that the combination of factor VIIa and factor Xa, but not factor VIIa alone, strongly induced migration of breast cancer cells by MAP kinase phosphorylation.[398] On the other hand, certain studies have employed specific factor Xa inhibitors, such as tick anticoagulant protein, or thrombin inhibitors, such as hirudin, in their experiments to show that neither factor Xa nor thrombin is necessary for TF signaling.[392,399,400] These differences in apparent mechanism could potentially arise from the use of different cell types or different concentrations of factor VIIa.

Both TF and PAR-2 are specifically upregulated in response to inflammatory stimuli.[401,402] Ahamed and Ruf[403] showed that phosphorylation of the TF cytoplasmic domain was induced by PAR-2 but not PAR-1 upon ternary TF:VIIa:Xa complex formation. Other coagulation proteases failed to induce phosphorylation of the TF cytoplasmic domain in endothelial cells, suggesting that PAR-2 activation distinguishes between upstream and downstream coagulation protease signaling. The reported effects of PAR-2 and TF suggest that these systems could act in concert to control cell migration. Indeed, it was recently demonstrated that binding of TF to factor VIIa resulted in increased cell migration in a breast cancer cell line because of specific upregulation of interleukin-8 through PAR-2.[255]

The function of the cytoplasmic domain of TF in signaling is not completely defined. It is not essential for induction of gene expression by TF:VIIa,[404] but both intra- and extracellular domains of TF are required for the prometastatic function of TF, at least in some model systems.[405,406] Serine residues in the cytoplasmic tail of TF are phosphorylated by protein kinase C–mediated events.[35] Chimeric molecules, generated from extracellular and transmembrane parts of the interleukin-2 receptor and the cytoplasmic domain of TF, interacted with actin-binding protein-280 (ABP-280) by the cytoplasmic domain of TF.[407] Ser253 and Ser258 in the cytoplasmic tail of TF were crucial for this interaction. ABP-280 is fundamental for normal cell migration and implicates TF in cytoskeletal organization.

Binding of factor VIIa to TF on human fibroblasts can enhance chemotaxis by 100-fold.[400] This stimulation takes place via platelet-derived growth factor-B isoform through activation of phospholipase C. Adhesion and migration of mononuclear phagocytes on endothelial cells have been shown to be TF dependent.[408] TF-based peptides and antibodies to TF inhibited this migration. This evidence, along with the role of the TF cytoplasmic tail in binding of ABP-280 and the association of TF with PAR-2, demonstrates a possible function for TF in adhesion and migration. These findings may provide an explanation for the value of inhibiting TF:VIIa activity in reducing neointima formation in animal models with restenosis.[297]

Tissue Factor in Angiogenesis and Tumor Development

A role for TF in both embryonic and tumor angiogenesis has been described extensively. It is likely that TF contributes to angiogenesis by both clotting-dependent and clotting-independent pathways.[409] Clotting-dependent pathways are likely to involve the production of the downstream protease thrombin, activation of PAR-1 (and possibly other PARs), and subsequent signal transduction. Clotting-independent pathways may involve phosphorylation of the cytoplasmic tail of TF.[410]

A significant relation exists between TF expression and tumor vascularization.[411,412] In a mouse xenograft model, transfection of tumor cells with antisense TF or injecting specific antibodies to TF reduced tumor growth and vascularization.[413,414] Factor VIIai has been shown to have antimetastatic properties, demonstrating the importance of factor VIIa proteolytic activity in the metastatic process.[406] Overexpression of TF in tumor cells contributes to an angiogenic phenotype by both upregulating the expression of the proangiogenic molecule vascular endothelial growth factor (VEGF) and downregulating the antiangiogenic protein thrombospondin.[410,413] Significant correlations exist between expression of TF and VEGF in human tumors.[411,415,416] Embryos lacking VEGF or TF have similar histopathologies.[417,418] Together, these findings suggest that VEGF and TF might regulate similar functions *in vivo*. One study, using TF mutants lacking the serine residues in the cytoplasmic domain, showed that this domain of TF was essential in VEGF regulation.[419] This report was not substantiated by others,[420] and some investigators have suggested that upregulation of VEGF requires generation of factor Xa.[421,422] Despite conflicting reports on the mechanism involved, it is clear that TF can indeed upregulate VEGF. The converse is also true, that is, VEGF upregulates TF expression by Egr-1 on endothelial cells.[423] The wealth of information derived from mouse genetics and clinical studies has led to the idea that TF plays direct and indirect roles in tumor development and neovascularization.

CHAPTER

12 Factor V and Factor VIII

RANDAL J. KAUFMAN, PHILIP J. FAY, LAURA POPOLO, AND THOMAS L. ORTEL

Factor V and factor VIII are two homologous nonenzymatic proteins that play a critical role in blood coagulation, an essential process that involves the sequential activation of plasma proteases in response to blood vessel injury. Factor V and factor VIII circulate in plasma in inactive forms that are devoid of coagulant activity. In their active state, factors Va and VIIIa serve as cofactors for their respective proteases (factor Xa and factor IXa), resulting in a striking enhancement of their catalytic activity.

To maximally express their function, factor VIIIa and factor Va need to assemble into enzyme complexes. Factor VIIIa together with factor IXa, calcium ions, and phospholipid membranes forms the *intrinsic Xase complex*. This complex catalyzes the proteolytic conversion of the serine protease factor X to factor Xa. Subsequently, factor Xa, factor Va, Ca^{2+}, and phospholipid membranes form the *prothrombinase complex* that converts prothrombin to thrombin. The thrombin-mediated conversion of soluble fibrinogen to insoluble fibrin generates a stable platelet–fibrin clot at the site of vascular injury. Thus, factor V and factor VIII catalyze pivotal steps in the coagulation cascade. This is also underscored by the clinical findings, which indicate that conditions of factor V or factor VIII deficiency lead to parahemophilia and hemophilia A, respectively.

The activation of factor V and factor VIII consists of proteolytic cleavage catalyzed by thrombin or factor Xa. The activation process has been the subject of intense investigation during the last two decades. Since proteolysis is an irreversible protein modification, it needs to be spatially and temporally controlled. Efficient inactivation mechanisms targeting the cofactors exist and are essential for normal hemostasis. One key reaction in down-regulating coagulation is the inactivation of factor Va by the anticoagulant-activated protein C (APC). Cleavage of factor Va at specific sites converts it into factor Vai with a complete loss of cofactor activity. Factor VIIIa is also a substrate of APC, but the intrinsic instability of factor VIIIa may make this reaction irrelevant from a biologic perspective.

Although the knowledge of factor V and factor VIII and their regulation has progressed significantly over the last two decades, the molecular mechanisms by which protein cofactors factor V and factor VIII accelerate substrate cleavage remains to be fully defined. The difficulties in having homogeneous preparations of these factors were partially overcome by the advent of recombinant DNA technologies. However, the dynamics and interactions of these factors with partners (ions, membranes, activators and inhibitors, plasma proteins) are many, and their analyses require a reductionist approach and a rather complex process of critical integration and interpretation of the results obtained. The molecular models that were recently built on the basis of the crystal structures of factor VIII, factor Vai, and their interacting proteins (proteases and substrate-proteases) provide a background to gain insight into the mechanistic details of how the structure of these factors changes to fulfill their function.

FROM GENE TO PROTEIN

Factor V and Factor VIII: Historical Background

Coagulation factor V and factor VIII were discovered in the 1930s and 1940s. Quick[1] first reported the identification of a labile factor in plasma that was necessary for the rapid conversion of prothrombin to thrombin. At approximately the same time, Owren[2] identified a patient with a severe bleeding disorder (parahemophilia), who lacked this factor. This protein, which was the fifth coagulation factor to be discovered, was designated factor V. Subsequent work established that activated factor V functions as a nonenzymatic cofactor in the *prothrombinase* complex.[3] The observation that a factor V mutation is the most common risk factor for venous thrombosis[4] has drawn attention to this protein, leading to many advances in the field.

Factor VIII identification was tightly linked to characterization of hemophilia A, a severe bleeding disorder caused by deficiency of factor VIII. Transfusion of whole blood was shown to successfully treat a hemophilia-associated bleeding episode by 1840.[5] In 1911, Addis[6] demonstrated that normal plasma can shorten the clotting time of hemophilic blood. It was 25 years later when Patek and Taylor described the role of factor VIII in hemostasis and designated the factor as "antihemophilic globulin."[7] In the 1950s, plasma concentrates and then in 1965, cryoprecipitates were developed for treatment of bleeding episodes associated with hemophilia A. In the early 1980s, factor VIII was purified from human plasma[8] and subsequently the gene was cloned. At approximately the same time, the human factor V gene was isolated. Over the past three decades, considerable efforts have been made defining the cofactor activity and its regulation.

Organization of Factor V and Factor VIII Genes

The genes encoding human factor V and factor VIII,[9,10] named *F5* and *F8*, respectively, have an almost identical exon–intron organization.[11,12] *F5* is localized to human chromosome 1q21–25.[13] The gene spans approximately 80 kilobase (kb) pairs of DNA and consists of 25 exons and 24 introns (FIGURE 12.1). The exons range in size from 72 to 286 base pairs (bp) with the exception of exon 13, which spans 2,820 bp. The introns range in size from 448 bp to 11.4 kb. The length of *F5* mRNA is approximately 7 kb.[14–16] At the present time, there is no evidence for alternative splicing of *F5* transcripts, and the mechanisms

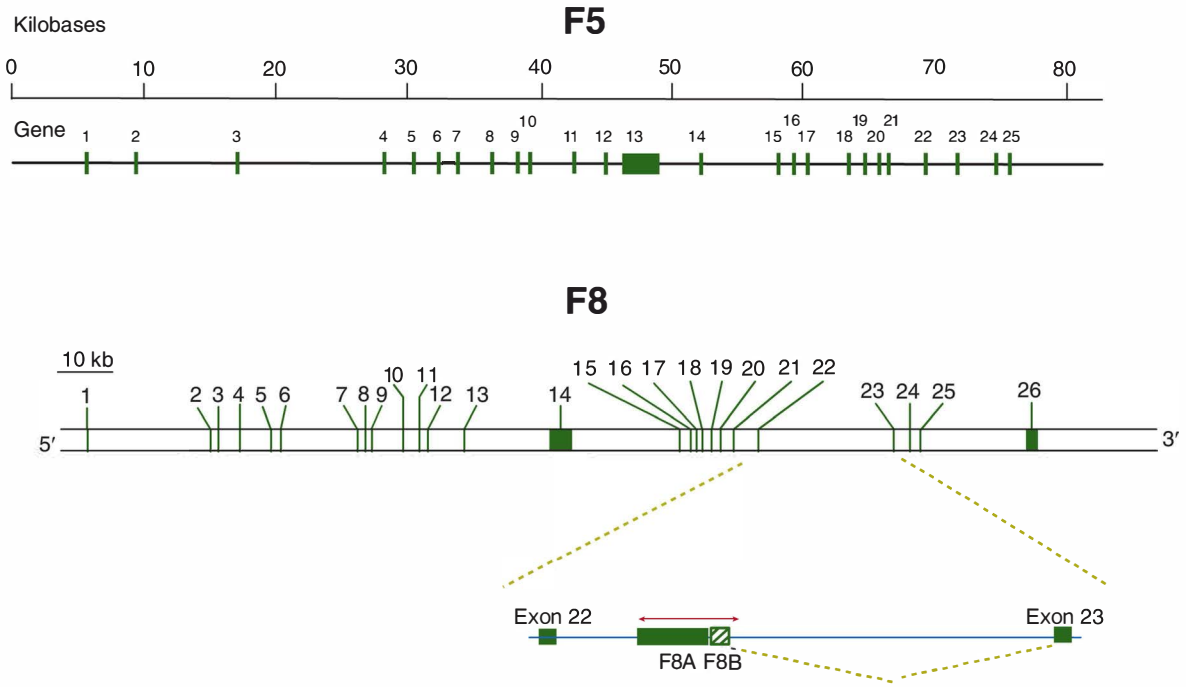

FIGURE 12.1 Features of the factor V and factor VIII encoding genes. The top line shows the scale of *F5* genomic sequence. The second line shows the intron–exon organization of *F5* with the exons being represented by *green boxes*. For *F8*, the bar represents the scale, and the bottom of the figure shows the intron–exon organization with exons represented by *green boxes*. The genomic region between exons 22 and 23 is enlarged to show the direction of transcription of *F8A* and *F8B* (see text).

responsible for the control of transcription and translation remain unknown. A rich report of this gene and the surrounding genomic region is available at NCBI (http://www.ncbi.nlm.nih.gov/gene/2153).

F8 is localized on human X chromosome (Xq28). The gene is 186 kb long (~0.1% of the DNA of the X chromosome) and contains 26 exons and 25 introns (FIGURE 12.1). The exon length varies from 69 to 262 bp except for exon 14 that is 3,106 bp and the last exon 26 that has 1,958 bp. There are some large intervening sequences including IVS22 that is 32 kb long. *F8* mRNA is approximately 9 kb, of which the coding sequence covers 7,053 nucleotides. In the gene, a CpG island within IVS22 is associated with two additional transcripts. One transcript of 1.8 kb is produced abundantly in a wide variety of cells. The orientation of this transcript is opposite to that of factor VIII and contains no intervening sequence.[17] This cDNA of 1.7 kb, termed factor VIII–associated gene A (*F8A*), is conserved in the mouse.[18] The second transcript of 2.5 kb, named factor VIII-associated gene B (*F8B*), is transcribed in the same direction as factor VIII, and after a short exon that may encode for eight amino acids, it utilizes exons 23 to 26 of the *F8* gene[19] (FIGURE 12.1). The two transcripts *F8A* and *F8B* originate within 122 bases from each other. The sequences of *F8A* and *F8B* along with a few kilobases of surrounding DNA are also present in two other areas of the X chromosome approximately 400 kb telomeric to *F8*.[17,20] The function of these transcripts and their potential protein products is unknown. Transgenic mice with a deletion of the *F8B* gene showed particular eye abnormalities, suggesting that migration of neural crest cells might have been perturbed during eye development.[21] For a detailed report and graphical view of *F8* and its genomic context, see http://www.ncbi.nlm.nih.gov/gene/2157.

Features of Factor V and Factor VIII Proteins

F5 and *F8* encode large precursor proteins of 2,224 and 2,351 amino acids, respectively. At the *N*-terminal, both precursors have a signal peptide, of 19 and 28 amino acids, respectively, that is cleaved upon translocation in the lumen of the endoplasmic reticulum (ER). Factors V and VIII share a common organization of three structural domains that occur in the same order A1-A2-B-A3-C1-C2 (FIGURES 12.2 and 12.3) and a high degree of amino acid identity (about 40%) over the entire length except for the B domains where there is no similarity. The B domain is encoded by an unusually large single exon spanning 3.1 and 2.8 kb in FVIII and FV, respectively. In general, the B-domain sequence is about 900 amino acids in length and rich in flexible amino acids (e.g., serine, threonine, glycine, and proline) and *N*- and *O*-glycosylation sites. A unique feature of both B domains is their unusual number of *N*-linked oligosaccharides. The factor VIII and factor V B-domains have 18 and 25 *N*-linked glycosylation sites, respectively. In the human factor V B-domain, two tandem repeats of a 17-amino acid sequence and 31 tandem repeats of a nine–amino acid sequence are present (FIGURE 12.2). The consensus sequences for these two types of repeats are SQDTGSPSXMPRPWEDXP and [T,N,P]LSPDLSQT. The significance of the tandem repeats structures that are present in the B domain of factor V, but not factor VIII, remains to be determined.

The three A-type domains present in factor V and factor VIII are approximately 330 amino acids in length, and are

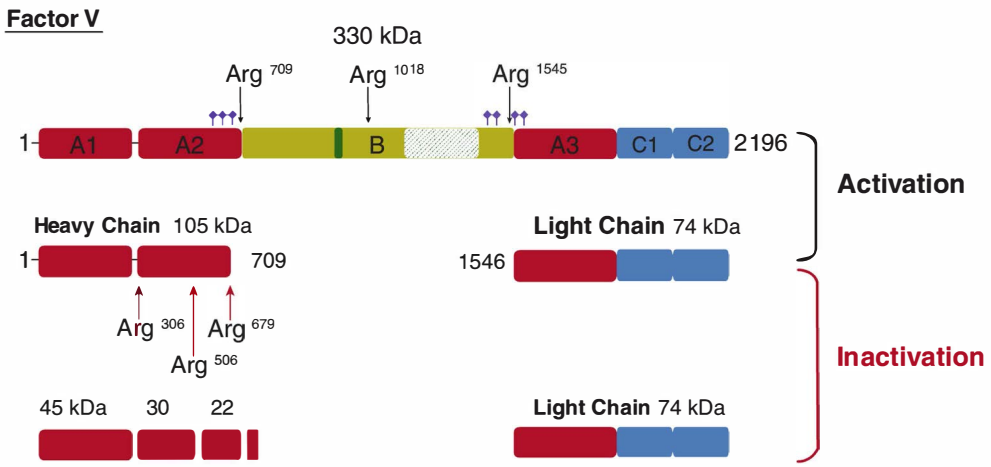

FIGURE 12.2 Domain structure and proteolytic activation/inactivation of human factor V. The structural domains of the single-chain factor V are depicted in the top line by the labeled *boxes*: (i) a triplicated A domain of approximately 330 amino acids; (ii) a unique B domain of 890 amino acids; and (iii) a duplicated C domain of approximately 150 amino acids. The tandem repeats of 2 × 17 amino acids are represented by the *green box* and the 9 × 31 amino acids by the *dashed green box*. The location of potential disulfide bonds and asparagine-linked glycosylation sites is not shown for simplicity (see Accession number P12259 at UniprotKB: http://www.uniprot.org/uniprot/). The *violet diamonds* indicate the location of putative sulfotyrosines. The thrombin cleavage sites are indicated by the *black arrows* at the top of the figure. The location of the APC cleavage sites are indicated by *red arrows* at the bottom of the scheme. The apparent molecular mass of the intermediates and final products following activation by thrombin and inactivation by APC are indicated. The heavy chain and light chain of thrombin-activated factor V (Va) form a calcium-dependent heterodimer. The numbering refers to the amino acid sequence devoid of the signal sequence.

about 30% identical to the triplicated A-type domains in the copper-binding proteins ceruloplasmin and hephaestin and to the single A domain of ferroxidase.[9,10,16,22] The C-type domains in factor V and factor VIII are approximately 150 amino acids in length and are homologous with discoidin 1, a lectin that mediates cell adhesion and migration in the single-cell organism *Dictyostelium discoideum*. Discoidin 1 domains are found in a growing family of proteins implicated in cell adhesion and/or developmental processes.[23,24]

In addition to these domains, in factor VIII there are three acidic amino acid–rich regions (a1, a2, a3) that reside at the junction of the A1/A2 (a1: residues 336 to 372), A2/B (a2: residues 711 to 740), and B/A3 (a3: residues 1649 to 1689) domains (FIGURE 12.3). Moreover, both factor V and factor VIII have been shown to bind copper and calcium ions.[25,26]

Within the secretory pathway, factor VIII is processed to a heterodimer of the heavy-chain fragment of variable size (apparent molecular weight ~90 to 200 kDa)[7,8] in a metal-dependent association with the light chain of 80 kDa (FIGURE 12.3). The A1, A2, and B domains occur in the heavy chain whereas the A3, C1, and C2 domains occur in the light chain. In plasma, human factor VIII is present at a concentration of approximately 1 nM (150 ng/mL) and is stabilized by association with a 50-fold molar subunit excess of von Willebrand factor (vWF). Human factor V circulates in the plasma as single-chain glycoprotein of high apparent molecular weight (~330 kDa) (FIGURE 12.2). Its concentration is approximately 30 nM (10 μg/mL).

The analysis of homologies of the primary sequences of factors V and factors VIII from different species suggests that these genes evolved from an ancestral ferroxidase gene by triplication of the A domain, insertion of the B domain, and addition of the C domains to the primordial cofactor gene. Subsequently, the factor V and factor VIII genes possibly evolved by duplication and divergence of amino acid residues within the B domain, although the high number of *N*-glycosylation sites were preserved, while amino acid sequences within the A and C domains were conserved.

Biosynthesis of Factor V and Factor VIII

Factor V Expression

The main site of factor V biosynthesis is the liver. Human megakaryocytes also have been shown to contain factor V mRNA and to express factor V[27] but it is believed that most or all of platelet factor V originates from the plasma pool by endocytosis.[28,29] As uptake of factor V by megakaryocytes has not been demonstrated, the origin of platelet factor V in humans remains controversial.[30] However, total factor V is distributed into two pools: 20% is contained in platelet granules whereas the remaining 80% is in the plasma compartment. The storage of factor V within platelets appears to be important because, when platelets aggregate to form the primary hemostatic plug, they also provide both a surface for assembly of the *prothrombinase* complex as well as high local concentrations of released platelet factor V. In addition, residual platelet factor V supports thrombin generation in patients with severe factor V deficiency and mild bleeding symptoms.[31] The synthesis of factor V by several other cell types, including bovine aortic endothelial cells, bovine vascular smooth muscle cells, and human mesangial cells, has also been reported, although the physiologic importance of synthesis at these sites remains unknown.

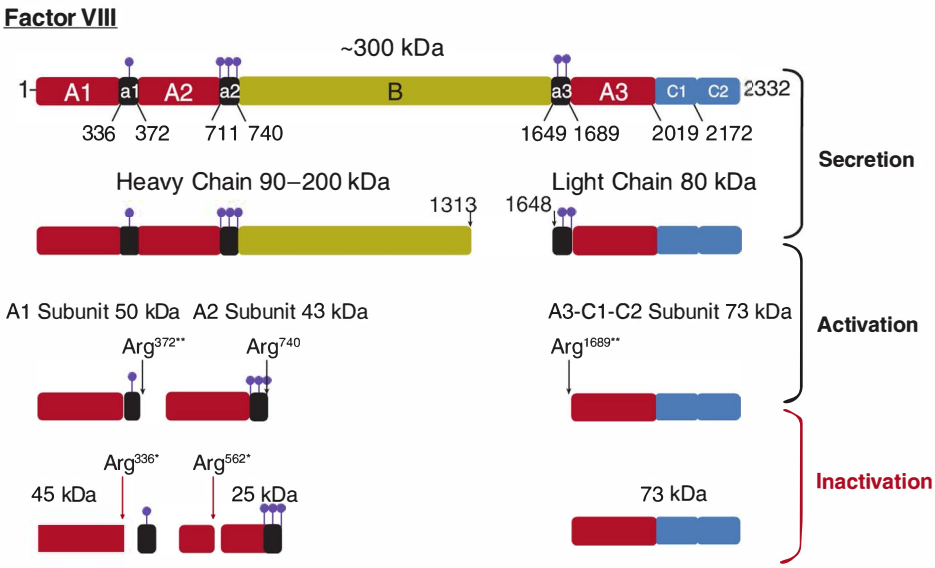

FIGURE 12.3 Domain organization and proteolytic activation/inactivation of human factor VIII. The structural domains of the full-length factor VIII are depicted in the *top line* by the labeled *boxes*: (i) a triplicated A domain of about 330 amino acids, (ii) a unique B domain of 980 amino acids, and (iii) a duplicated C domain of 150 amino acids. The *black boxes* represent regions enriched in acidic amino acids. The ball-stick symbol (*violet*) represents the positions of sulfotyrosine residues that were experimentally determined (residues 346, 718, 719, 723, 1664, 1680). The location of free cysteine residues, disulfide bonds, and asparagine-linked glycosylation sites is not shown (see Accession number P00451 at UniprotKB Database: http://www.uniprot.org/uniprot/). Within the Golgi compartment in the cell, factor VIII is cleaved at two sites within the B domain to generate heavy-chain polypeptides of variable size (90 to 200 kDa) and the 80-kDa light chain. The cleavage sites for activation by thrombin (*black arrows*) and inactivation by APC (*red arrows*) are shown at the point of the processed products. The apparent molecular mass (kDa) of the intermediates and final products are indicated. The two cleavages required for thrombin activation (**) and the sites of proteolytic inactivation by APC (*) are indicated. The numbering refers to the amino acid sequence devoid of the signal sequence.

Factor VIII Expression

Although the natural cell type that produces factor VIII has not been definitively identified, liver transplantation studies in factor VIII-deficient dogs[32] and several hemophiliac patients[33] strongly implicate the liver and/or the reticuloendothelial system as primary sites of factor VIII synthesis. Initial immunochemical localization by light microscopic[34] or electron microscopic[35] examination detected the factor VIII antigen in hepatocytes. However, RNA hybridization analysis detected factor VIII mRNA in hepatocytes as well as in many other cells and tissues.[36] More recent analysis of factor VIII mRNA by quantitative reverse transcription polymerase chain reaction identified highest levels in liver, followed by kidney.[37] Factor VIII mRNA and protein were concentrated in hepatic sinusoidal endothelial or Kupffer cells, with significantly less in hepatocytes.[37] In addition, isolated sinusoidal endothelial cells were shown to produce factor VIII.[38] Also a part of factor VIII is contained in α granules of platelets together with factor V.[39] Since there are no known natural established cell lines that express factor VIII, it has not been possible to study the biosynthesis of factor VIII in its native host cell.

Trafficking and Modification within the Cell

Factor V and factor VIII are abundantly modified glycoproteins secreted into the blood. The factor VIII biosynthetic pathway was proposed based on analysis of factor VIII expression in transfected cell lines, such as Chinese hamster ovary cells (FIGURE 12.4). On synthesis, factor VIII is translocated into the lumen of the ER where the signal peptide is cleaved and the protein is subjected to *N*-linked core glycosylation (FIGURE 12.4 steps 1 to 3, see also Chapter 5 "Cell Biology, Protein Processing, and Cell Signaling"). A significant portion of newly synthesized factor VIII is retained in the ER through interactions with two protein chaperone systems designed to prevent the exit of unfolded proteins from the ER. First, factor VIII is bound to BiP, the most abundant ER protein[40] (FIGURE 12.4, step 4). BiP expression is induced by glucose deprivation, inhibition of *N*-linked glycosylation, or the presence of malfolded protein within the ER. In addition, high-level factor VIII expression can also induce transcription of the BiP gene indicating the induction of the unfolded protein response (for details, see Chapter 5).[41] The level of BiP in the cell inversely correlates with the efficiency of factor VIII secretion.[42,43] BiP exhibits a peptide-dependent adenosine triphosphatase activity. Factor VIII dissociation from BiP and secretion requires an unusually high level of intracellular adenosine triphosphate (ATP).[44] Because factor VIII interacts with BiP, and factor V does not, it was possible to identify a primary BiP-binding site by analysis of the secretion of factor VIII and factor V chimeric proteins. This study identified a hydrophobic beta-sheet within the factor VIII A1 domain that resides adjacent to a proposed ligand, Cys310, for binding copper ion that was also recently confirmed by the crystal structure of FVIII (see further FIGURE 12.6).[26,45,46] Exposed hydrophobic residues are

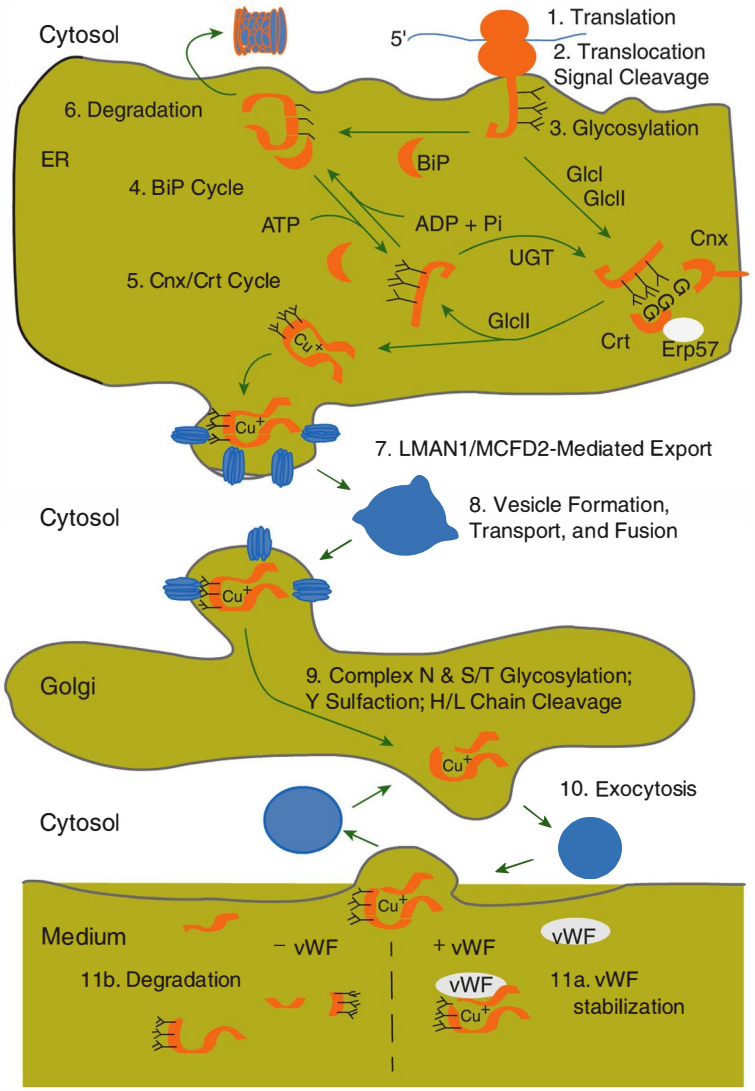

FIGURE 12.4 Synthesis, processing, and secretion of factor VIII in mammalian cells. The figure depicts the pathway of biosynthesis of factor VIII from the primary translation product that is translocated into the lumen of the ER to the medium as determined by expression in culture cells. For detail in the description see text under "Trafficking and modification within the cell."

preferred sites of BiP binding. Substitution of phenylalanine at residue 309 with serine within the hydrophobic sheet increased the secretion efficiency of factor VIII several-fold and this correlated with a reduced requirement for ATP for secretion.[45] These studies suggest that BiP may have a role in copper ion binding to factor VIII. Finally, a portion of factor VIII forms high molecular weight aggregates immediately after synthesis.[47] These aggregates require ATP for disassembly and secretion.[47]

The second chaperone system that retains factor VIII in the ER recognizes the structure on *N*-linked oligosaccharides on factor VIII. Rapid trimming of the two outermost glucose residues of the *N*-linked glycans (*N*-acetylglucosamine$_2$-mannose$_9$-glucose$_3$) prepares protein-bound *N*-glycans for association with the two homologous ER lectins calnexin (CNX) and calreticulin (CRT) and exposure to the glycoprotein-specific oxidoreductase ERp57 to catalyze proper disulfide bond rearrangement (see Chapter 5).[48,49] Release from CNX/CRT depends on glucosidase II cleavage of the innermost glucose residue. Although the modalities of misfolded protein domain recognition and ER retention are not known,[50,51] the enzyme UDP-glucose:glycoprotein glucosyltransferase (UGT) and the CNX/CRT chaperone system are thought to play central roles.[52,53] Current models[52–56,57] propose that UGT reglucosylates non-native polypeptides thereby preventing their release from the CNX/CRT chaperone system and their exit from the ER. Factor VIII interacts with both CNX and CRT, although their roles in factor trafficking within the ER are not known.[58]

Formation of disulfide bonds by oxidation of a pair of cysteine residues is another crucial modification for proteins destined to be secreted and contributes to the stabilization of the structure. Factor VIII contains eight disulfide bonds and factor V has seven putative disulfide bonds deduced by similarity. The enzyme PDI1 plays the predominant function as catalyst of oxidative folding in the ER. Interestingly, it has been recently reported that treatment with antioxidants improves secretion of factor VIII from cultured cells suggesting that folding of complex multidomain proteins can generate oxidative stress.[59]

Improperly folded proteins are selectively extracted from the ER and directed for degradation by the cytosolic proteasome in a process called ER-associated degradation (*ERAD*, step 6 in FIGURE 12.4). A significant portion of factor VIII within the ER never transits to the Golgi compartment, but rather is

degraded through ERAD (see Chapter 5). Factor VIII within the ER is retrotranslocated and degraded by the cytosolic 26S proteasomal machinery. Recently, *E*R *d*egradation *e*nhancing *m*annosidase-like (EDEMs) proteins were shown to recognize oligosaccharide structures trimmed by ER mannosidase I and mediate their transfer to the cytosol for ERAD.[60]

Finally, studies on combined deficiency of factors V and VIII indicate that oligosaccharides are also important for trafficking of factor VIII and V from the ER to the Golgi compartment through interaction with the cargo receptor complex LMAN1/MCFD2 (FIGURE 12.4, step 7). The sum of these findings supports the notion that oligosaccharide processing plays a central role in directing factor VIII trafficking within the secretory pathway.

The portion of factor VIII that is secretion competent transits to the Golgi apparatus, where the majority of factor VIII is processed at two sites within the B domain after residues 1313 and 1648 to generate the heavy chains (90 to 200 kDa) and the light chain (80 kDa) (FIGURES 12.3 and 12.4). Also within the Golgi apparatus, factor VIII is further processed by (a) modification of the asparagine-linked high mannose-containing oligosaccharides to complex types, (b) addition of carbohydrate to multiple serine and threonine residues within the B domain (*O*-glycosylation), and (c) addition of sulfate to six tyrosine residues within the heavy and the light chains[61] (FIGURE 12.4, step 9).

Factor VIII is finally secreted by exocytosis (FIGURE 12.4, step 10). In the plasma, vWF stabilizes factor VIII through noncovalent association. *In vitro* studies demonstrate that vWF can alter intracellular transport and secretion of factor VIII from the cell. vWF promotes the association of the light and heavy chains of factor VIII upon secretion from the cell and results in stable accumulation of factor VIII activity in the conditioned medium of factor VIII-producing cultured mammalian cells[62,63] (FIGURE 12.4, step 11a). In the absence of vWF in the conditioned medium, the factor VIII heavy and light chains are secreted into the medium as dissociated chains that are subsequently degraded (FIGURE 12.4, step 11b).

In vitro reconstitution experiments demonstrated that vWF can directly promote reassembly of isolated heavy and light chains of factor VIII,[62,64] suggesting a possible role of vWF in facilitating factor VIII assembly. The effect of vWF in promoting factor VIII heavy and light chain assembly and stable secretion in cell culture systems may reflect the role of vWF in regulating levels of factor VIII activity *in vivo*.[65–68] However, it is not known whether vWF also regulates factor VIII protein synthesis and/or secretion *in vivo*.[69] At present, there are no natural cell types that are known to express both factor VIII and vWF.[70] It is proposed that a portion of factor VIII synthesized is coexpressed with vWF from an endogenous endothelial bed and secreted as a complex upon stimulation,[71] although this has not been directly demonstrated *in vivo*.

Metal Ions in Factor V and Factor VIII

Both factors V and VIII bind calcium and copper ions and ion-dependent interactions appear vital for both their structure and function. The recently reported three-dimensional (3-D) structures of these factors identified the position of the high-affinity ion-binding sites and provided new interpretations on the role of ions in factor V and VIII structure and function. Adams et al.[72] solved the structure of bovine factor Vai (A1/A3-C1-C2) (FIGURE 12.5). The two A domains sit on a platform formed by the two C domains, which are aligned in an edge-to-edge fashion, a feature that was found to be present also in the crystal structure of a recombinant single-chain B-domain–deleted human factor VIII (FIGURE 12.6B) and in an intermediate-resolution crystallographic structure of a recombinant form of factor VIII consisting of a heterodimer of the A1-A2 and A3-C1-C2 subunits.[73]

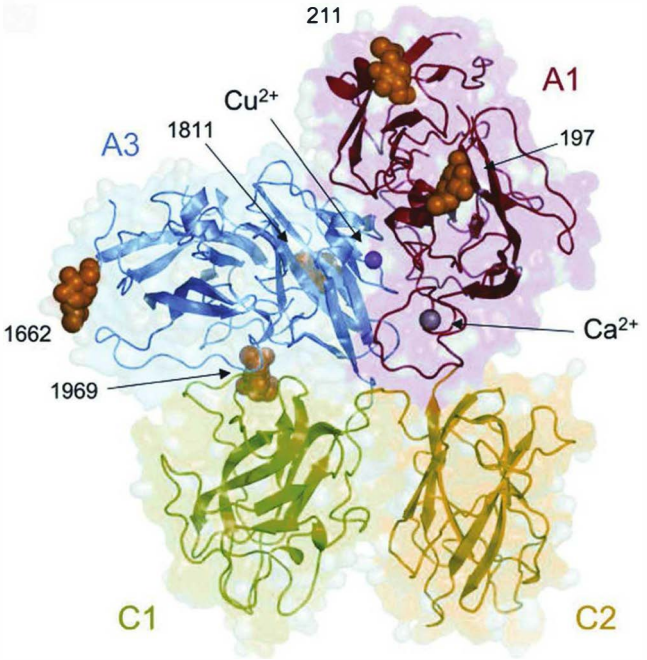

FIGURE 12.5 The 3-D structure of bovine factor Va_i. Domain arrangement in a ribbon representation of bovine factor Va_i indicating the positions of the metal ions within the A1 and A3 domains (Ca^{2+}: *gray* and Cu^{2+}: *pink*) and of five *N*-linked chains (*orange*) at residues N197, N211, N1811, N1662, and N1969. The van der Waals representation in the background shows the surface contour of the protein. The C domains are side-by-side and predict a role in membrane binding (see text). (Adapted from Adams TE, et al. The crystal structure of activated protein C-inactivated bovine factor Va: implications for cofactor function. *PNAS*. 2004;101:8918–1923. A high-affinity calcium-binding site and a copper-binding site were identified in factor Vai. Chain association is required for factor V function and is dependent on a divalent cation. Although calcium ion was believed to bridge the heavy and light chains,[74] the structure revealed that the high-affinity calcium-binding site is located entirely in the A1 domain[74] (FIGURE 12.5). The side chains of both Asp111 and Asp112, along with the main-chain carboxyl oxygens of Lys93 and Glu108, coordinate the calcium ion. The structural studies clearly indicate that chain association cannot directly be attributed to the coordination of calcium but rather calcium may play a role in the maintenance of the A1-C3 domain interface.

The role of copper ion in factor V has always been uncertain. A single copper ion-binding site is located in the A3 domain of bovine factor Va_i with ligands His1802, His1804, and Asp1844

arranged in a trigonal planar coordination geometry.[72] Recently, Song et al.[74] used recombinant factor V mutants to demonstrate that Asp111 in the heavy chain was important for the metal ion binding and for interactions between the heavy and light chains of the active cofactor. However, the structure of factor Vai suggested that copper ion provides additional stabilization of the A1-A3 interface rather than directly linking the two domains.

The crystal structures of factor VIII revealed one calcium-binding site and two copper-binding sites. The position of the calcium-binding site in the A1 domain confirms the region in the A1 domain identified in factor V as a calcium-binding site. In the structure of factor VIII, the calcium is liganded by the carboxyl groups of Glu110, Asp116, Asp125, and Asp126 and the backbone carbonyl of Glu122 and Lys107 as observed for factor V[74] (FIGURE 12.6C). It is noteworthy that mutations of these residues (Asp125Ala and Asp126His) were associated with mild/moderate hemophilia A, whereas mutations at the remaining residues (Glu110Val, Asp116Tyr, Glu110Val, Lys107Thr, and Glu122Lys) were related with severe hemophilia A (http://hgdb.org.uk/). Recent mutational data further support the existence of this calcium-binding site in both factors Va and VIIIa.[74] The calcium ion is unlikely to play a role in directly bridging the light and heavy chains but could be involved in the maintenance of the interface between C2 and A1 domains in a given conformation. In addition, the intermediate-resolution x-ray crystal structure predicts a second calcium-binding site within the A2 domain utilizing residues Asp538 and Asp542.[73]

While previous results indicated a role of calcium in promoting the active conformation of factor VIII, copper ion was primarily involved in enhancing intersubunit affinity.[75] The two copper-binding sites are within the A1 and A3 domains (FIGURE 12.6B). In the A3 domain, the site is composed of His1954, Cys2000, and His2005 and is dispensable for cofactor function.[76] However, a His1954Leu mutation associated with mild hemophilia A has been reported (http://hgdb.org.uk/). The second site in the A1 domain (composed of ligands His267-Cys310-His315) is essential for cofactor function (FIGURE 12.6C). Electron paramagnetic spectroscopy suggests that cupric ion (Cu^{+}) occupies this site.[26] The mutation of Cys310Ser destroyed factor VIII activity and yielded secreted heavy and light chains that were not associated, supporting a requirement for this copper ion-binding site in heavy and light chain association. Interestingly, mutations of Cys310Phe and His267Pro have been reported in patients with severe hemophilia A, suggesting the

importance of this second copper-binding site (http://hgdb.org.uk/). However, this second copper site in the A1 domain localizes near the interface of the A1 and A3 domains rather than at the interface suggesting that a role for copper in enhancing interchain affinity is indirect.

Copper alone is insufficient to generate cofactor activity but in the presence of calcium does marginally increase the specific activity of factor VIII.[64,77] Recombining purified factor VIII chains in buffers containing Ca^{2+} or Mn^{2+} yields active factor VIII.[62,64] These ions do not contribute to the interchain affinity but rather promote cofactor activity by modulating the conformation of the heterodimer.[75]

FUNCTION AND REGULATION OF FACTOR V AND FACTOR VIII

Cofactor Activities of Factor VIII and Factor V

Factor VIII acts to increase the rate of conversion of factor X to factor Xa by the protease factor IXa. The K_m for factor X activation in the presence of factor IXa and calcium is decreased several orders of magnitude by phospholipid due to concentration of enzyme and substrate on the plane of the phospholipid surface (Table 12.1). Factor VIIIa dramatically increases the V_{max} of factor X activation by factor IXa by 100,000-fold[78] and consequently the catalytic efficiency (Table 12.1). Factor VIIIa accelerates the proteolysis of factor X by interaction with both factor X and factor IXa on a phospholipid surface to facilitate a conformational change in the active site of factor IXa that favors catalysis.[79]

In a similar manner, factor Va enhances the activation of prothrombin to thrombin by the serine proteinase factor Xa in the presence of calcium ions and a procoagulant phospholipid surface.[3] As shown in Table 12.1, the acceleration of prothrombin activation by phospholipids results from a 1000-fold decrease in the K_m for prothrombin.[80,81] The major contribution of factor Va is a 3,000-fold increase in the V_{max} for prothrombin activation[80–82] (Table 12.1). The observed increase in V_{max} is due, in part, to the fact that factor Va acts as a receptor for factor Xa resulting in an increased concentration of factor Xa at the membrane surface. Overall, the main effect of factor Va is to enhance the catalytic efficiency of prothrombin activation probably by properly orienting factor Xa and prothrombin.

Table 12.1

The effect of cofactors on the rate of activation of factor X and prothrombin

Components	K_m	V_{max}	Catalytic Efficiency[a]
Factor X Activation			
IXa	300	0.002[b]	1
IXa, Ca^{2+}	181	0.011	8
IXa, Ca^{2+}, PL	0.06	0.002	5.8×10^3
IXa, Ca^{2+}, PL, VIIIa	0.06	500	1×10^9
Prothrombin Activation			
Xa	130	0.061[c]	1
Xa, Ca^{2+}	84	0.68	1.7
Xa, Ca^{2+}, PL	0.06	2.30	8.3×10^3

Regulation of Factor VIII Cofactor Activity

Activation

The secreted heterodimer factor VIII is activated by limited proteolysis (for review, see Ref.[83]). Upon treatment of intact factor VIII with thrombin, there is a rapid >30-fold increase and subsequent first-order decay of procoagulant activity. Significant data has also characterized the activation of factor VIII by factor Xa, and other observations suggest that Factor XIa[84] and VIIa[85] can also catalyze this reaction. The physiologic activator(s) of factor VIII has (have) not been rigorously determined. Thrombin is the best characterized activator of factor VIII and maximal activation by thrombin is greater than that observed with factor Xa[86].

Thrombin cleaves peptide bonds after Arg372, Arg740, and Arg1689. Procofactor activation coincides with proteolysis of both the heavy and light chains of factor VIII as depicted in FIGURE 12.3. Cleavage within the heavy chain at Arg740 generates a 90-kDa polypeptide that is subsequently cleaved at Arg372 to generate polypeptides of approximately 50 and 43 kDa.[87] These polypeptides are designated as the A1 (residues 1 to 372) and A2 (residues 373 to 740) subunits, respectively, owing to their domainal derivations (FIGURE 12.3). Concomitantly, the 80-kDa light chain is cleaved at Arg1689 to generate a 73-kDa polypeptide[88] designated as the A3-C1-C2 subunit (residues 1690 to 2332). The cleavage of selected bonds is likely to lead to the appropriate structural changes that impact cofactor function. Significant data support that thrombin anion-binding exosites I and II are involved in recognition of factor VIII.[89,90,176,177] The corresponding binding sites on FVIII are thought to be the regions rich in acidic amino acids that contain the posttranslational modified amino acid tyrosine sulfate and border each of the cleavage sites[91] (FIGURE 12.3). The tyrosine-sulfate residues appear to enhance thrombin cleavage at adjacent sites, but do not affect factor Xa cleavage.[92] These observations suggest that thrombin may utilize tyrosine-sulfate residues to facilitate interaction and/or cleavage. In support of this contention are data showing that a mutation at a tyrosine sulfation site (Tyr346 to Cys) yielded a factor VIII that was defective in activation by thrombin[93] and is associated to mild hemophilia A. However, conflicting data show that mutations of individual Tyr residues to Ala in the acidic region designated as a2 resulted in little, if any, effect on rates of thrombin-catalyzed cleavage or activation of factor VIII.[94] Thus the contribution of sulfated Tyr residues to the activation mechanism may be restricted to selected regions in the procofactor.

Numerous studies have correlated the appearance of the 50-, 43-, and 73-kDa polypeptides with peak factor VIII activity.[87,95,96] Other studies examined the role of the individual cleavage sites in the expression of FVIIa cofactor activity. Mutagenesis studies showed that cleavage after residue 740 was not required for cofactor activity.[97,98] In contrast, mutation at either Arg372 or Arg1689

yielded molecules that were not cleaved by thrombin at the mutated site and were not susceptible to thrombin activation.[97] The importance of cleavage at residues 372 and 1689 for factor VIII activation was demonstrated *in vivo* by the identification of hemophilia A patients having missense mutations that prevent cleavage at either Arg372 or Arg1689.[99–102] These findings indicate that activation requires cleavage at both residues 372 and 1689, but does not appear to require a specific sequential order for cleavage at these sites. Cleavage at Arg1689 releases factor VIII from the inhibitory influence of vWF[103] and appears to additionally increase the activity of factor VIIIa.[104,105] Cleavage at Arg372 is essential to expose a functional factor IXa-interactive site(s) in the A2 domain that is cryptic in the unactivated molecule.[106]

Examination of apparent rates of thrombin cleavage at the three sites in factor VIII shows that Arg740 > Arg1689 > Arg372. Thus, the step essential to forming cofactor activity, cleavage at Arg372 to liberate the A1 and A2 subunits, is rate limiting. Cleavage at Arg^{740} and Arg^{1689} appears to facilitate cleavage within the heavy chain as mutations at these sites slows subsequent cleavage at Arg^{372}. However, the different magnitude of the effects produced by Arg1689Gln or Arg740Gln mutations on the reduction of the rate of cleavage of the light chain indicates that the docking of Arg740 represents the preferred pathway.[107,108]

Factor VIIIa is a heterotrimer of A1, A2, and A3-C1-C2 subunits[105,109,110] (FIGURE 12.3). The A1 and A3-C1-C2 subunits retain the metal ion linkage and can be isolated as a stable A1/A3-C1-C2 dimer. Conversely, the A2 subunit is associated with the A1/A3-C1-C2 dimer in a primarily electrostatic interaction and readily dissociates from the dimer at physiologic pH and ionic strength (see below).

In an attempt to probe individual residues that contribute side chain hydrogen-bonding interactions to the association of A2 subunit in the cofactor, Wakabayashi et al. mutated 30 polar or charged residues to Ala at the borders of the A2 and A1, and A2 and A3 domains that were spatially separated by <2.8 Å.[111,112] Results from that study showed that a number of the point mutations exhibited more rapid decay rates (5- to 40-fold) in factor VIIIa activity, hence showed reduced affinity for A2 subunit, suggesting a role for these residues in A2 subunit retention in the heterotrimer. Recent results have shown that replacing acidic residues such as E272, D519, E665, and E1984 with Ala or Val to yield hydrophobic interactions at the interfaces yielded factor VIII variants with as much as eightfold increases in the stability of factor VIIIa, as judged by reduced rates of activity decay.[113] Furthermore, these mutations appeared to have an additive effect in that variants where more than one acidic residue was replaced with Ala or Val showed further increases in cofactor stability.[112]

Aside from identification of cleavage sites, the structural alterations that transform "procofactor" factor VIII into active cofactor, factor VIIIa, are not well characterized. Circular dichroism spectral analysis indicates that purified factor VIIIa shows significant reduction in random coil and increase in beta-sheet structures compared with factor VIII;[114] however, it is unclear what contribution the B domain makes to these gross conformational differences. Zero-length cross-linking studies suggest formation of a new salt bridge between the *N*-terminal half of A2 subunit and the *C*-terminal region of A1 subunit following thrombin cleavage.[115] Furthermore, new hydrogen-bonding interactions involving A2 domain appear to form following conversion of the procofactor to the active cofactor.[111] Taken together, these results suggest that activation of factor VIII resulting in limited proteolytic cleavage is accompanied by changes in the protein conformation.

Finally, the cellular surface profoundly affects the procoagulant activity of factor VIII. Negatively charged phospholipids are usually confined to the inner leaflet of cellular membranes and are exposed upon cellular lysis at sites of injury.

Formation of the Xase Complex

Interaction with Factor IXa

The proteolytically activated form of factor VIII, factor VIIIa, serves as a cofactor for the serine protease factor IXa in the conversion of factor X to factor Xa. This complex of enzyme and cofactor, assembled on an anionic phospholipid surface, is referred to as the intrinsic factor Xase. The phospholipid surface is primarily involved in reducing molecular interactions to a 2-D space, thereby markedly decreasing the K_m for factor X. The role of surface also appears to contribute to the K_{cat} effect.[116] The association of factor VIIIa and factor IXa is complex and not fully understood. This interaction has been studied by homology modeling, analysis of naturally occurring hemophilia A and B mutations, mutagenesis, cross-linking, and inhibition with synthetic peptides. All these studies came to the conclusion that the interaction sites are localized in the A2 domain (residues 558 to 569, residues 484 to 509, residue Asp527, and residues 708 to 715) and the A3 domain (residues 1811 to 1818).[114,117,118,119,120,121–124] The molecular model of factor VIII[46], although not the activated form, mapped the potential factor IXa binding sites on the A2 domain at residues 558 to 665 and the region around Asp712 and in the A3 domain in the region of residues 1811 to 1818. All these regions appear on the model to be solvent exposed and thus likely accessible to binding factor IXa (see further FIGURE 12.7).

Interaction with Factor X

Little information is available on the interaction of factor VIIIa with factor X, the substrate for factor Xase complex. Analyses employing solid-phase binding assays[125] and fluorescence anisotropy[126] localized a factor X interactive site to the acidic *C*-terminal region (residues 337 to 372) of the A1 subunit. The affinity of this association was determined to be 1 to 3 μM; however, these experiments were performed in the absence of phospholipid vesicles, which may contribute to the affinity of the interaction. Zero-length cross-linking studies revealed that the site of interaction on factor X was in the serine protease-forming domain of the heavy chain but was not in that portion of the sequence representing the activation peptide.[127] Factor VIIIa reduces the K_m of factor Xase complex for factor X by several-fold,[128,129] suggesting a direct or indirect contribution to substrate affinity. Interestingly, deletion of the *C*-terminal region of A1 following proteolysis at Arg336 by factor Xa or APC (see below) resulted in an approximately fivefold increase in the K_m for factor X.[130] This increase in K_m from approximately 40 to 200 nM could potentially depress factor Xase complex activity in plasma since the latter K_m value is approximately twice the plasma concentration of factor X. Furthermore, evidence indicates that factor X increases the affinity of factor IXa for factor VIIIa by approximately 10-fold.[131] Evaluation of a functional K_d for the factor VIIIa–factor IXa interaction as measured by rates of factor Xa generation yields a value of approximately 70 pM. One interpretation of these data is that the enhanced affinity for the binary interactions reflects interdependent associations involving the three proteins: cofactor, enzyme, and substrate.

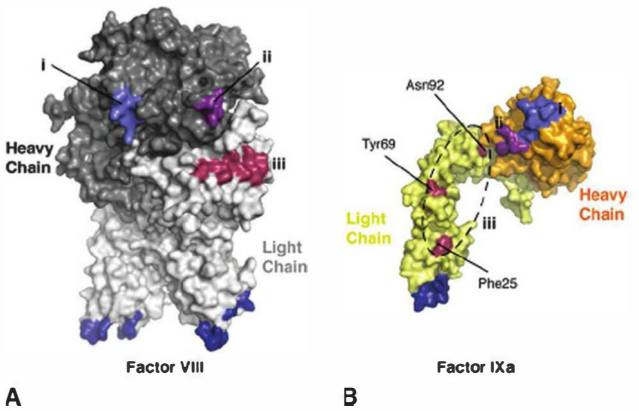

FIGURE 12.7 Binding interface between factor VIII and factor IXa. Models of the binding interface of factor VIII **(A)** and factor IXa **(B)**. The crystal structure of factor VIII shown in Fig. 12.6 and the structure of the porcine factor IXa backbone were used to construct a model of the factor IXa-factor VIIIa complex, the following constraints derived from previous studies: (i) residues 558 to 565 of factor VIII interact with the 330–339 helix of factor IXa (both in *light blue*), (ii) residues 707 to 712 of factor VIIIa bind to factor IXa residues 301 to 303 (*purple*), and (iii) residues 1811 to 1819 of factor VIII interact with the light chain of factor IXa (*red*). Phe25 in the Gla domain of factor IXa is juxtaposed with the light chain, and the area that interacts with residues 1811 to 1819 is highlighted with a *dashed line*. The putative phospholipids–binding sites in the C1 and C2 domains of factor VIII and the Gla domain of factor IXa that forms noncovalent interactions with the phosphoserine of the phospholipid bilayer are indicated (*dark blue*). [Adapted from Ngo JC, et al. Crystal structure of human factor VIII: implications for the formation of the factor IXa-factor VIIIa complex. *Structure* 2008;16:597–606. Use with permission © 2008 by Elsevier Ltd].

From the above studies, it appears that all three A domains of factor VIII participate in interprotein interactions essential for the efficient conversion of substrate to product. Although progress has been made in the identification and initial characterization of intermolecular binding sites, the mechanism by which factor VIIIa modulates the active site of factor IXa to greatly stimulate factor Xa generation is not known. Fluorescence studies using active site-modified factor IXa have yielded insights into the factor VIIIa–factor IXa interaction. Fluorescence energy transfer studies show that binding of factor VIIIa does not markedly alter the distance separating the active site of factor IXa and the phospholipid surface.[79] However, binding factor VIIIa did alter the emission intensity and anisotropy of the fluorescent probes used to modify the factor IXa, indicating a change in probe environment. Duffy et al.[117] showed that the fluorescence anisotropy of active site-labeled factor IXa was increased in the presence of factor VIII and that a further incremental increase was observed upon thrombin activation of factor VIII. While both the A1/A3-C1-C2 dimer and the isolated A2 subunit somewhat increased anisotropy of a similarly labeled factor IXa molecule, factor VIIIa-like increases in anisotropy values required reconstitution of the cofactor from the isolated subunits.[132] Interestingly, in the absence of factor VIIIa, substrate factor X shows little effect on the anisotropy of the labeled factor IXa.[133] However, inclusion of factor X produced a maximal increase in the factor VIIIa-dependent anisotropy. These results indicate that a primary role of factor VIIIa is to alter the conformation around the active site of factor IXa and its orientation relative to substrate factor X.

Interaction with Phospholipids

Phospholipids interact with substrates, enzymes, and cofactors to play a critical role in the assembly and functional activity of the coagulation protease complexes. Negatively charged phospholipids are required for factor VIIIa-mediated enhancement of the activation of factor X.[78,134,135] *In vivo*, negatively charged phospholipids are likely provided by activated platelets and damaged endothelial cells. Factor VIII and factor V bind phosphatidylserine (PS) by both hydrophobic and electrostatic interactions.[136–141] However, factor V does not efficiently compete with binding of factor VIII to phospholipid vesicles composed of 15% phosphatidyl-L-serine.[134] Under equilibrium conditions, factor VIII can bind phospholipid vesicles containing 15% to 25% PS with an apparent K_d of 2 to 4 nM.[117,134,142] Saturation occurs between 170 and 385 moles of phospholipid per mole of factor VIII,[134] although the process involves both rapid and slow interactions.[143] Factor VIII binding to phospholipid involves stereoselective recognition of the O-phospho-L-serine moiety of PS.[142] Since the composition of PS exposed on the platelet membrane surface can increase from 2% to 13% after stimulation,[144] the increase in PS content could account for the ability for factor VIII to specifically bind the surface of thrombin-activated platelets.

Addition of negatively charged phospholipids to the factor VIII–vWF complex dissociates factor VIII from vWF.[145,146] Interestingly, thrombin-treated factor VIII does not bind vWF with high affinity[147–149] but binds phospholipid with a 10-fold increased affinity compared with that of the procofactor, factor VIII.[150] This effect is thought to result from a conformational change within the C2 domain following activation, based upon the capacity of the anti-C2 monoclonal antibody, ESH8, to lock the conformation of C2 into the low-affinity form. The phospholipid-binding site(s) within factor VIII appears primarily localized to the light chain,[151,152] and antibody inhibition studies suggest that binding is likely modulated by the C2 domain.[153]

A high-resolution x-ray structure (1.5 Å) of the factor VIII C2 domain was determined.[154] It predicts a β-sandwich core (40 × 30 Å) with two pairs of hydrophobic residues extending from adjacent loops that contribute to phospholipid binding. The two hydrophobic spikes comprising Met2199/Phe2200 and Leu2251/Leu2252 are proposed to penetrate the lipid bilayer and associate with the aliphatic hydrocarbon chains. On the other hand, a ring of basic residues (Arg2215, Arg2220, Lys2227, and Lys2249) localized above the hydrophobic residues contributes electrostatic interactions. A number of point mutations resulting in hemophilia A that map to the C2 domain tend to cluster at the protein core region rather than at putative membrane–binding sites. One explanation proposed for this observation[155] is that the binding energy reflects the additive nature of several side chains at the membrane interface. For this reason, single-point mutations within this flexible region may be tolerated. Conversely, mutations within the protein core of the C2 domain

could disrupt folding and interfere with secretion, thereby producing loss of function.

The intermediate-resolution x-ray crystal structures of factor VIII indicate that the C1 and C2 domains are aligned such that both domains may interact with the phospholipid surface.[46,73] A similar alignment was noted for factor Vai.[72] Recent results comparing isolated factor VIII C2 domain with a C1 C2 protein showed enhanced affinity of the latter in platelet binding suggesting direct and/or indirect roles for C1 in this interaction.[156] In a recent report, Wakabayashi et al.[157] demonstrated that a factor VIII variant lacking the entire C2 domain possessed a marked (~15-fold) reduction in affinity for phospholipid membranes, supporting a direct role for the C1 domain in this interaction. Furthermore, deletion of C2 did not appear to grossly alter the rate of procofactor activation by thrombin, the affinity of factor VIIIa for factor IXa, the K_m of Xase for substrate factor X, or k_{cat} for factor Xa generation. However, this deletion did significantly destabilize the cofactor, such that when combined with several modest defects in various intermolecular interactions, it resulted in a significant reduction in the thrombin-generating capacity. Overall, these observations show pronounced membrane-dependent cofactor activity in the absence of C2 domain, yet indicate this domain was essential in contributing to maximal cofactor function.

Modeling of the Factor Xase Complex

The crystal structure of factor IXa shows it to be an elongated molecule analogous to a tulip with the γ-carboxyglutamic acid (Gla)-rich, epidermal growth factor-like (EGF), and serine protease domains representing the bulb, stem, and flower, respectively[158] (FIGURE 12.7B). The Gla domain binds the protease to the phospholipid surface, whereas the active site is located high above the membrane surface (>70 Å).[79,125] The A3-C1-C2 subunit of factor VIIIa associates with the phospholipid surface via residues in the C1 and C2 domains. Thus, it is reasonable to speculate the high-affinity binding sites in factors VIIIa and IXa involve a surface proximal interaction between the A3 domain of factor VIIIa and the Gla–EGF domains of factor IXa. Furthermore, the A2 subunit directly modulates the active site of factor IXa.[159] Therefore, a surface distal, weaker-affinity interaction likely occurs between the A2 subunit and the serine protease domain. Based upon biochemical and mutational results described above for interactive regions in factors VIII and IXa, Ngo et al.[46] proposed a molecular model of the factor Xase complex using the crystal structure of IXa and VIII. FIGURE 12.7 shows the structures of factor VIII and IXa with interprotein interactive sites highlighted. A membrane-bound model of factor Xase is illustrated in FIGURE 12.8 and visualizes a putative complex of the two proteins. Unfortunately, this model does not consider what changes occur upon activation of factor VIII to factor VIIIa. Furthermore, interactions of specific residues within these structures are not identified. This latter information will require results obtained following cocrystallization of the cofactor and proteinase. However, the 3-D model does provide a basis for predictions of intra- and intermolecular interactions.

Inactivation

Factor Xase has been regarded as "self-damping,"[160] and the labile nature of this complex reflects the decay of factor VIIIa. The affinity of A2 subunit for the A1/A3-C1-C2 dimer (K_d ~ 260 nM)[161,162] greatly exceeds the concentration of factor VIII in plasma (~1 nM). Thus, one would predict that activation of factor VIII would be followed by immediate and near complete dissociation of A2 subunit. The dissociation rate

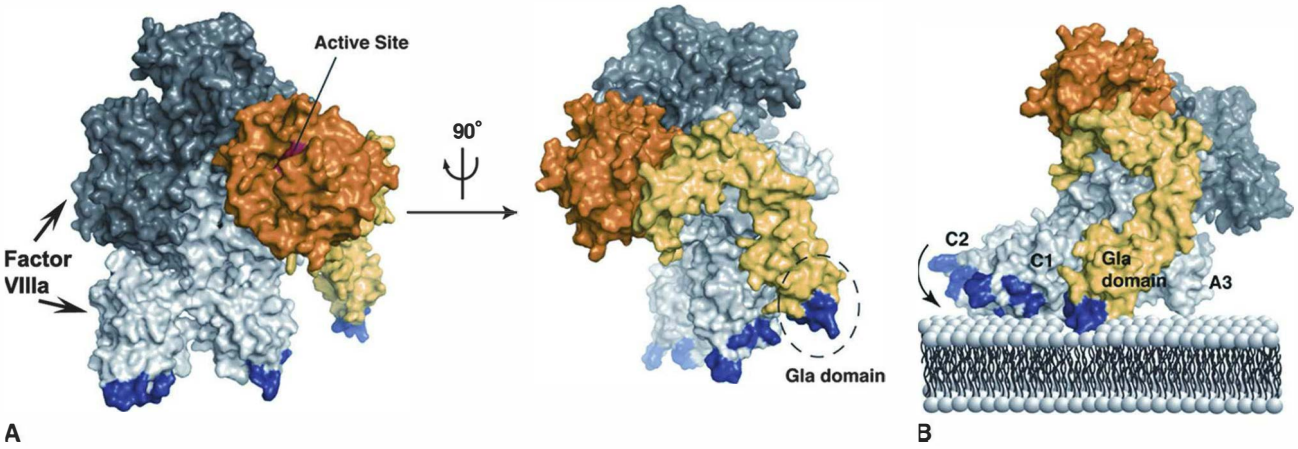

FIGURE 12.8 Model of the factor VIIIa–factor IXa complex. **(A)** Front and scale views of the complex of factor VIIIa (*dark gray*: heavy chain; *light gray*: light chain) and factor IXa (*orange*: heavy chain; *light green*: light chain). Four putative membrane–binding sites, including the bases of C1 and C2 domains, the A3 domain loop of factor VIIIa, and the Gla domain of factor IXa are shown in *blue*. The active site of factor IXa is indicated (*red*). **(B)** View of the possible interaction of the factor VIIIa–factor IXa complex with phospholipids membrane surfaces. The model suggests that upon binding with factor IXa, factor VIII orients in a bent position and C2 domain undergoes a conformation change to align its membrane-binding site with the Gla domain to interact with the membrane simultaneously. The active site of factor IXa faces the solution. (Adapted from Ngo JC, et al. Crystal structure of human factor VIII: implications for the formation of the factor IXa-factor VIIIa complex. *Structure* 2008;16:597–606. Use with permission © 2008 by Elsevier Ltd).

constant for loss of A2 subunit in human factor VIIIa (~0.35/minutes) is markedly faster than that observed with porcine factor VIIIa (~0.12/minutes), indicative of a higher affinity interaction in the latter.[162] Indeed, reconstitution of factor VIIIa using a porcine A2 subunit plus human A1/A3-C1-C2 yielded a hybrid factor VIIIa molecule possessing threefold higher specific activity than factor VIIIa reconstituted from the human subunits.

However, an effect opposing dissociation of subunits is the capacity for factor IXa to stabilize the labile factor VIIIa heterotrimer. Lollar et al.[163] determined that at low factor VIIIa (<1 unit/mL) and factor IXa (5 nM) and in the presence of phospholipid, porcine factor VIIIa was stabilized from spontaneous decay. It was subsequently determined that factor IXa transiently enhances the reconstitution of factor VIIIa from isolated subunits by a mechanism consistent with reducing the intersubunit dissociation rate constant.[164] One mechanism by which factor IXa stabilizes factor VIIIa may involve interaction of the enzyme with sites on the A2 subunit and A3 domain to in effect tether the labile complex. However, prolonged reaction of factor VIIIa with factor IXa results in proteolysis in the A1 subunit and subsequent inactivation of the cofactor. Sequence analysis revealed that factor IXa cleaves the A1 subunit at Arg336,[165,166] thereby altering interaction of A1 with the A2 subunit to yield a low-activity conformation. A secondary, slow reacting site at Arg1719 was also identified; however, cleavage at this site is not inactivating.[167] This factor VIII–directed proteolytic activity coupled with the interfactor VIIIa subunit stabilizing activity provides factor IXa mechanisms for regulating its own activity by modulating the activity of its cofactor. Thus a situation of "reciprocal regulation" appears to exist and may influence the activity of intrinsic factor Xase.

APC is a potent anticoagulant and its importance as a regulator of blood coagulation is apparent from predisposition to thrombosis in individuals with protein C deficiency (see Ref. [168] for review). The anticoagulant effect is phospholipid and Ca^{2+} dependent and results from the selective inactivation of factor Va and factor VIIIa. Cleavage of factor VIIIa occurs at Arg562,[121] bisecting the A2 subunit and Arg336[87,121] preceding the *C*-terminal acidic region of the A1 subunit (FIGURE 12.3). The former cleavage occurs within a factor IXa interactive site and effects the factor VIIIa-dependent modulation of the factor IXa active site, as judged by fluorescence anisotropy.[126] The latter cleavage likely influences the affinity of the A1/A3-C1-C2 dimer for A2 subunit as well as affects the interaction of factor VIIIa with substrate factor X. APC-catalyzed cleavage appears to show a preferred pathway. The human enzyme cleaves the A1 subunit initially.[169] The rate of cleavage at Arg336 is approximately 25-fold faster than at Arg562, and cleavage at either site is independent of the other.[170] Factor IXa selectively protects cleavage of factor VIIIa at Arg562; however, this effect is abrogated by inclusion of protein S,[171] a cofactor for APC. APC-catalyzed inactivation of factor VIIIa may be secondary to its inactivation by subunit dissociation. Comparison of rates of cofactor inactivation attributable to APC action suggests factor Va is the primary substrate, since the majority of factor VIIIa activity lost was not the result of proteolysis.[169] Furthermore, studies using a reconstituted coagulation model show greater degradation of factor Va compared with factor VIIIa by the APC pathway.[172]

APC resistance is one of the major causes of hereditary thrombophilia that results from an Arg to Gln mutation in the APC cleavage site in factor V at residue 506.[4,173,174] The APC-resistant phenotype was first reported as a poor anticoagulant response to APC in an activated partial thromboplastin time assay (called the APC resistance ratio).[173] It is possible that APC resistant mutations in factor VIII may also lead to hereditary thrombophilia. Analysis of mutant factor VIII protein demonstrated that cleavage at either Arg336 or Arg562 only partially inactivated factor VIII and that resistance to cleavage at both Arg336 and Arg562 was necessary to detect a poor anticoagulant response in an activated partial thromboplastin time assay.[175] These results show that a single mutation in either factor APC cleavage site to yield cleavage resistance would not be detected as a poor anticoagulant response *in vitro*. In addition, a search did not identify any mutations at Arg336 or Arg562 in factor VIII in 125 patients with venous thrombosis.[176] The sum of these studies indicates that it is unlikely mutations in factor VIII APC cleavage sites will result in thrombophilia.

Factor Xa also catalyzes inactivating cleavages in factor VIIIa, and since this protease is a product of factor Xase, it suggests a potential to participate in its down-regulation. Factor Xa cleaves factor VIIIa at Arg336[87] and Lys36[177] in the A1 subunit. Loss of activity due to cleavage at the latter site is less well understood than cleavage at Arg336, but appears to result in an altered conformation of this subunit affecting interaction with A2 subunit.[177] The interaction of protease with the factor VIII substrate appears to require residues in the C2 domain[178] and the *C*-terminal region of A1 subunit.[177] Binding to the latter site may make use of a heparin-binding exosite[177] recently identified in factor Xa.[179] Overall, the relative contributions of spontaneous A2 subunit dissociation and proteolysis mediated by APC, factor Xa, or factor IXa, in limiting factor VIIIa *in vivo* remain unclear.

Regulatory Role of vWF

The plasma levels of factor VIII and vWF are maintained at a fairly constant ratio of 1 molecule of factor VIII to 50–100 vWF subunits. For example, patients with type 1 von Willebrand disease who have a 50% reduction in vWF have a corresponding 50% reduction in factor VIII. Infusion of vWF into vWF-deficient patients elicits an immediate rise in circulating levels of factor VIII. Studies of clearance kinetics upon infusion of factor VIII/vWF complex or pure factor VIII clearly established the stabilizing influence of vWF on factor VIII in the circulation.

In addition to increasing factor VIII survival, vWF plays a critical role in directly regulating factor VIII activity.[180] vWF prevents factor VIII binding to phospholipids[145] and activated platelets,[181] and inhibits factor VIII from activation by factor Xa[182] and inactivation by APC.[121,183,184] Furthermore, vWF appears to protect factor VIII from imidoacetate-induced degradation by blocking loss of bound calcium in the procofactor.[185] On the other hand, vWF does not interfere with activation by thrombin,[147,186] and actually serves as a cofactor in facilitating the thrombin-catalyzed cleavage of factor VIII light chain, thereby enhancing rates of factor VIIIa dissociation from vWF.[187] It is likely that vWF mediates its inhibitory effects on factor VIII activity by preventing factor VIII interaction with phospholipids, a reaction required for both factor Xa and APC-mediated cleavage of factor VIII. However, there is evidence that binding sites for vWF and APC in the factor VIII C2 domain may overlap,[184] supporting a mechanism of inhibition by direct competition. It is proposed that vWF binding to platelet receptor glycoprotein Ib (GPIb) brings factor VIII to the vicinity of

platelets adhering to damaged endothelium.[181] After proteolytic activation of factor VIII, factor VIIIa is released from vWF permitting its interaction with the platelet surface.

Recently, a reciprocal effect, that of factor VIII regulating vWF, has been observed. Proteolytic cleavage of large vWF multimers by the metalloproteinase, ADAMTS13 is important for normal hemostasis. Failure to process these multimers due to deficiency or defect in the proteinase results in the generation of microthrombi, a characteristic feature of thrombotic thrombocytopenic purpura. Factor VIII serves as a cofactor in the proteolytic cleavage of vWF, increasing the rate of ADAMTS13-catalyzed cleavage at the Tyr1605-Met1606 bond in vWF by approximately 10-fold.[188] The a3 segment of factor VIII that forms a primary binding site of vWF appears critical for this interaction.

The interaction of factor VIII with vWF is mediated by a major factor VIII–binding site within the first 272 amino acids of the mature vWF molecule[189–191] with residues 78 to 96, residues around 53, and the amino-terminus providing crucial roles.[189,192–195] Moreover, processing of vWF propeptide in the Golgi, essential for multimerization, is required for generation of high-affinity factor VIII–binding sites.

High-affinity binding to vWF requires both the amino-terminal and carboxy-terminal ends of the factor VIII light chain.[124,196,197] A vWF-binding site on factor VIII was localized to residues 1673 to 1684 (a3), a region removed by thrombin cleavage at residues 1689 (see FIGURE 12.3). Phospholipid and vWF compete for binding to factor VIII.[142,145,146] The two hydrophobic spikes (Met2199/Phe2200 and Leu2251/Leu2252) participate in binding to phospholipid membranes and also contribute to the binding of vWF. Furthermore, an isolated C1-C2 fragment demonstrated higher affinity for vWF than isolated C2.[198] Taken together, these data suggest a complex intermolecular interaction that occurs over an extended interface involving the amino-terminal region of vWF and both ends of the factor VIII light chain.

In the circulation, factor VIII(a) catabolism is mediated by low-density lipoprotein receptor–related protein (LRP), a hepatic clearance receptor. The association of factor VIII with vWF reduces the binding of factor VIII to LRP by >90% contributing to reduce its clearance. Both factor VIII and vWF bind to macrophages with subsequent rapid uptake and degradation of the internalized protein.[199] Chemical inactivation of macrophages resulted in a doubling of factor VIII levels in vWF-null mice. These results suggest a prominent role for macrophages in the clearance of the factor VIII/vWF complex.

Regulation of Factor V Cofactor Activity

Activation

As a single-chain protein, factor V expresses very little, if any, procoagulant activity.[82] Procoagulant activity is expressed following limited proteolysis at discrete sites in the molecule. Thrombin is considered the physiologic activator of factor V. Thrombin cleaves three peptide bonds at Arg709, Arg1018, and Arg1545 within the B domain of factor V (FIGURE 12.2). Thrombin-activated factor V is a calcium-dependent heterodimer consisting of an *N*-terminal heavy chain (A1-A2) of 105 kDa and a light chain (A3-C1-C2) of 74 kDa.[200–202] The heavily glycosylated B domain is not necessary for procoagulant activity and is released during activation by thrombin.[201–203] The use of snake venom proteases and factor V mutants has provided important insights into the functions of the individual thrombin cleavage sites.[204–207] Thrombin cleavage at Arg709 is kinetically favored over cleavage at Arg1018 and Arg1545. Thrombin cleavage at Arg709 results in little or no increase in cofactor activity.[183,204–206] Cleavage at both Arg709 and Arg1018 releases the amino-terminal portion of the B domain resulting in further partial activation of the cofactor.[204,206] Cleavage at Arg1545 and release of the carboxyl-terminal fragment of the B domain from the light-chain fragment is required for maximal activation.[204–207] Cleavage at Arg709 and Arg1018 is necessary for maximal rates of factor V activation by thrombin.[204,205] Factor V mutants, in which cleavage at Arg709 and/or Arg1018 are blocked, are resistant to thrombin cleavage at Arg1545. In contrast, these mutants can be fully activated by the snake venom protease RVV-V, which cleaves factor V at Arg1018 and Arg1545.[204,205,207] These observations indicate that release of the B domain from the heavy chain is not absolutely required for maximal expression of procoagulant activity.

Thrombin cleavage of factor V at Arg709 and Arg1545 requires interactions with anion-binding exosite I on thrombin.[90] Factor V residues Glu666-Glu672 have been shown by crystal structure to bind to exosite 1 on thrombin, with the aromatic side chain of Phe668 inserting into a hydrophobic pocket.[208] Modeling experiments indicate that the sequence between this binding site and Arg709 of factor V wraps around thrombin in productive thrombin-factor V complexes that cover a large surface area to engage the active site. An acidic region in factor V, Asp695-Tyr698, is also required for efficient thrombin cleavage at Arg709.[209] The sequence of this peptide (DYDYQ) contains the consensus sequence for tyrosine sulfation and is the likely site of sulfation in the factor Va heavy chain.[210] Tyrosine sulfation of factor V is required for efficient thrombin cleavage at both Arg709 and Arg1545.[88] The factor V B domain contains a similar acidic region Glu1508-Tyr1515, which is the likely site of sulfation in the factor V B domain.[88,210] This peptide (EDDYAEIDY) may also play a role in binding to exosite 1 and is required for efficient cleavage by α-thrombin and formation of the factor Va light chain.[211] Consistent with this hypothesis, deletion of the entire factor V B-domain (amino acids 710 to 1545) results in a molecule that is resistant to thrombin cleavage and activation.[212] In contrast, factor V molecules with deletions of amino acid residues 811 to 1491 or 709 to 1476 were efficiently cleaved by thrombin and fully activated.[204,213–215]

Characterization of the B-domain deletion mutant lacking amino acid residues 811 to 1492 and mutated in thrombin cleavage sites Arg709 and Arg1545 indicated that removal of this portion of the B domain leads to constitutive but partially active single-chain cofactor; however, cleavage at Arg1545 is essential for complete activation of factor V.[204] Consistent with this observation, thrombin cleavage at Arg1545 appears to be required for optimal factor Xa–binding affinity.[206,207] These results suggest the presence of the B domain in factor V is necessary to inhibit procoagulant activity prior to proteolytic processing. Recent truncation analyses identified a discrete region of the B domain that stabilizes the profactor state.[216] The interaction between factor Va and prothrombin is mediated by the heavy chain of the cofactor, and this interaction is independent of calcium ions.[217] Factor V can also be activated by factor Xa.[205,218] After several studies by different groups, data of Orfeo et al.[219] concluded that direct activation of factor V by factor Xa at physiologically

relevant concentrations does not appear to be a significant contributor to factor Va formation.[219]

Several other enzymes (factor XIa, calpain, monocyte-derived cathepsin G, plasmin, neutrophil elastase snake venom protease NN) also can activate factor V. In contrast to the activators discussed above, these enzymes produce complex proteolytic cleavage pattern and/or can only partially activate factor V. Recent studies indicate that factor XIa is capable of activating factor V at plasma concentrations during the preincubation phase of a PTT assay.[84]

Formation of the Prothrombinase Complex

Formation of the prothrombinase complex requires the presence of a membrane surface to which the individual components bind and subsequently assemble into a functional complex. Activated platelets, platelet microparticles, and damaged vascular cells provide this surface *in vivo* (for a review, see Ref. [220]). The interaction of factor V with cellular surfaces appears to be mediated, at least in part, by binding to acidic phospholipids (e.g., PS). These phospholipids are normally sequestered in the inner leaflet of the cellular membrane but become exposed following platelet activation and microparticle formation.

The primary membrane-binding sites for factor V are contained within the light-chain fragment (A3-C1-C2). Structural data indicate that membrane-binding sites for PS membranes in the C1 and C2 are each composed of a common distorted jelly-roll β-barrel structure with three variable loops, or "spikes," located at the membrane-binding surface.[72,221] The C1 and C2 domains in factor Va are aligned in an edge-to-edge orientation, making it possible for the variable loops in both domains to interact with a membrane surface.[72] In contrast, the factor V A3 domain, which was also proposed to interact with phospholipids membranes, rests on top of the platform formed by the C1 and C2 domains.[72]

Factor Va interacts with factor Xa in the presence of calcium ions on a phospholipid membrane surface to accelerate the conversion of prothrombin to thrombin. The affinity of factor Xa for phospholipids increases when factor Va is bound to a membrane surface containing acidic phospholipids. Binding of factor Xa to factor Va allosterically alters the active site of factor Xa and, in addition, repositions the active site of the enzyme to the proper distance above the membrane for prothrombin activation.[222] The binding of factor Xa to factor Va also results in modulation of the binding of prothrombin to substrate-binding exosites distinct from the active site of factor Xa. Further studies also suggested that PS may allosterically regulate interactions between factor Va and factor Xa.[223]

More recently, mutagenesis studies localized a key factor Xa-binding surface to residues Arg501, Arg 510, Arg 511, Asp513, Asp577, and Asp578 in the factor Va A2 domain.[224] Discrete regions within the factor Va heavy chain also regulate the activation of prothrombin by the prothrombinase complex, including residues 334 to 335,[225,226] residues 659 to 663,[227] and residues 695 to 698.[226–228]

Prothrombin does not bind to factor V, indicating that the cofactor must be activated before it binds prothrombin.[229] Sedimentation equilibrium analysis revealed that the factor Va heavy chain and prothrombin form a 1:1 complex with a dissociation constant of 10 μM.[217] Proteolysis of the factor Va heavy chain by APC results in the loss of its ability to bind prothrombin.[229] A prothrombin-binding site was localized to an acid peptide containing residues 697 to 709 at the carboxyl terminus of the factor Va heavy chain.[207,209] A pentapeptide from this region, spanning Asp695 to Gl699, preferentially interferes with the initial cleavage of prothrombin at Arg320 by prothrombinase, shifting activation of prothrombin through prethrombin 2 rather than meizothrombin.[228] The binding of prothrombin to factor Va appears to involve proexosite 1 in the catalytic domain of prothrombin[230,231] as well as the kringle 1 and kringle 2 domains.[232]

The ability of factor Va to bind to factor Xa is lost when factor Va is proteolytically cleaved by APC. Conversely, APC cleavage of factor Va at Arg506 decreases the affinity of the cofactor for factor Xa,[233] whereas APC cleavage at Arg306 leads to a total loss of factor Xa binding.[234]

Inactivation

Activation of the protein C pathway leads to inactivation of factor Va and down-regulation of the *prothrombinase* complex. APC is a vitamin K–dependent serine protease that inactivates factor Va by limited proteolysis of the factor Va heavy chain. Efficient inactivation of factor Va requires a protein cofactor, protein S, and a phospholipid or platelet membrane surface. An APC-binding site on the factor Va heavy chain includes residues 311 to 325, which overlap with a binding site for factor Xa.[235] APC cleaves human factor Va heavy chain at Arg306, Arg506, and Arg679 (FIGURE 12.2). There is an additional APC cleavage site present at Lys994 in the B domain of human factor V (not shown in FIGURE 12.2).[236] Binding sites for APC have been localized to the factor Va light chain.

Characterization of factor V_{Leiden} has helped to define the roles of the APC cleavage sites at Arg306 and Arg506. Factor V_{Leiden} lacks the APC cleavage site at Arg506 due to substitution of glutamine at this position (R506Q). An initial rapid phase of factor Va inactivation correlates with APC cleavage at Arg506 and is followed by a slower phase that results in complete inactivation of the cofactor.[233] APC cleavage at Arg506 results in a partial loss of cofactor activity because of a 50-fold decrease in the affinity of the cofactor for factor Xa.[233] The second, slow phase of inactivation seen during inactivation of factor Va and FVa_{Leiden} correlates with APC cleavage at Arg306. APC cleavage at Arg306 releases the heavy-chain fragment corresponding to the A2 domain (amino acids 307 to 709), generating an A1/A3C1C2 heterodimer that expresses no cofactor activity.[237] The role of APC cleavage at Arg679 has not been completely defined. APC cleavage at Arg679 occurs more slowly than APC cleavage at Arg506 or Arg306 and appears to play a minor role in the inactivation of normal factor Va.[233,238]

Rapid cleavage of factor Va by APC at Arg306 is completely membrane dependent.[234] APC cleavage of factor Va at Arg506 can occur in the absence of phospholipid membranes;[236] however, the membranes do enhance the rate of this cleavage. In contrast, the slow cleavage of factor Va at Arg679 does not appear to be enhanced on the membrane surface.[233,236]

Protein S is a vitamin K–dependent plasma protein that acts as a cofactor promoting inactivation of factor Va by APC. Protein S selectively promotes APC cleavage of factor Va at Arg306 while having no effect on the rate of APC cleavage at Arg506.[239]

Formation of the *prothrombinase* complex by addition of factor Xa protects factor Va from inactivation by APC. Rosing et al.[239] demonstrated that factor Xa selectively inhibits APC cleavage at Arg506 while having no effect on the rate of APC cleavage at Arg306. These findings suggest that the binding sites

for factor Xa and APC overlap. The inhibitory effects of factor Xa can be partially overcome in the presence of protein S because of the enhanced rate of APC cleavage at Arg306.[239] More recently, Norstrøm et al.[240] confirmed the protective effect of factor Xa at Arg506, but found that APC cleavage at Arg306 was actually stimulated in the presence of factor Xa. In addition, protein S can counteract the protective effect of factor Xa against cleavage at Arg506.[240] In the presence of both factor Xa and protein S, inactivation of factor Va and FVa_{Leiden} can proceed at similar rates because the contribution of APC cleavage at Arg506 to inactivation of the cofactor is minimal under these conditions.[239] These observations may explain the relatively mild prothrombotic risk associated with the FV_{Leiden} mutation.

Prothrombin also protects factor Va from inactivation by APC.[241,242] Prothrombin impairs cleavages at both Arg306 and Arg506, and this inhibition was seen in the presence and absence of protein S.[241] In particular, cleavage at Arg306 was more pronounced in the presence of protein S, indicating that prothrombin impaired APC function as well as the cofactor function of protein S.[241] The gla domain of prothrombin linked to kringle domains 1 and 2 is necessary for the ability of prothrombin to protect factor Va from APC cleavage; once activated, thrombin is not protective.[242]

GENETICS AND PATHOLOGY

Factor V–Associated Diseases

Some mutations in factor V have been reported to lead to a bleeding disorder (parahemophilia) whereas others increase the risk of developing thrombosis (APC-resistance) with no mutations or polymorphisms at the factor V thrombin cleavage sites.

Deficiency of Factor V: Parahemophilia

Congenital factor V deficiency, also called parahemophilia, is a rare disorder that has an estimated incidence of 1 in 10^6. More than 200 cases have been reported in the literature.[243] Parahemophilia is characterized by low levels of functional factor V activity in plasma and platelets and is inherited in an autosomal recessive manner. Clinical manifestations include ecchymoses, epistaxis, oral bleeding, menorrhagia, and bleeding following surgery or trauma. Rare patients also have had thromboembolic events, including deep and superficial venous thromboses, pulmonary embolism, stroke, and myocardial infarction.[244] Most patients with congenital factor V deficiency have low antigenic levels of factor V; however, approximately 17% of patients were found to have a discrepancy between their functional and antigenic levels.[245] Plasma factor V levels have not correlated well with the hemorrhagic tendency, and several authors have suggested that the severity of bleeding symptoms may be more closely correlated with platelet than with plasma factor V levels.[246,247] The molecular basis for factor V deficiency has been established in 120 patients (see Table 12.2). Factor $V_{New\ Brunswick}$ (A221V) is a missense mutation in the factor V heavy chain that results in the expression of a factor V molecule with reduced specific activity caused by an increased rate of dissociation of the heavy and light chains of factor Va.[248,249] Several missense or splicing mutations impair secretion of factor V.[250–252] Five patients had severe factor V deficiency caused by homozygous nonsense or frameshift mutations in the B domain.[253–255] These mutations predict the synthesis of truncated factor V molecules lacking a portion of the B domain and all of the light chain. In contrast, factor V–deficient mice generated by homologous recombination have a phenotype characterized by fatal hemorrhage and an incomplete block in embryogenesis.[256] Transgenic rescue of factor V–deficient mice indicates that factor V levels of <0.1% are sufficient for survival.[257] Survival of patients with homozygous nonsense mutations may be explained by ribosomal slippage and trace expression of factor V.[257,258]

Table 12.2

Pathogenic *F5* mutations causing factor V deficiency[a]

Nucleotide substitution: missense codon	52
Nucleotide substitution: nonsense codon	19
Nucleotide substitution: splicing error	10
Small deletions (up to 20 bp)	28
Small insertions (up to 20 bp)	7
Gross deletions	2
Other rearrangements	2

APC-Resistant Factor V and Risk of Thrombosis

As mentioned above, one of the genetic risk factors for thrombosis is factor V_{Leiden} that is partially resistant to inactivation by APC due to a Gln substitution at the APC cleavage site Arg^{506}. Patients who are heterozygous for this mutation have a three- to eightfold increased risk of developing thrombosis whereas the risk for homozygous individuals is 50- to 80-fold higher compared to normal individuals.

Factor VIII-Associated Disease: Hemophilia A

Unlike factor V, no factor VIII mutation has been described so far that is linked to a prothrombotic state. Although APC resistance is strongly correlated with enhanced risk to develop thrombosis, no mutations at the corresponding APC inactivation sites have been observed in factor VIII in patients affected by venous thrombosis. However, high levels of factor VIII are associated with an increased risk of venous thrombosis. To date, no genetic variations in the *F8* gene have been identified that could account for this phenotype.

The *F8* gene is located on the human X chromosome and therefore hemophilia A is a classic example of X-linked recessive inheritance. It occurs almost exclusively in males for they only have one X chromosome; females with one abnormal copy of the *F8* gene are carriers because the other X chromosome contains a normal copy of the gene. The frequency of the disorder is 1 in 5,000 to 10,000 male births and there is no particular ethnic group that has unusually lower or higher incidence of the disease. Severe hemophilia A was in the past a genetically lethal disease in which affected males produced few offspring. Therefore, nearly one-third of the mutant alleles would be lost in each generation. Haldane in 1935 predicted that in order to maintain a constant frequency in the population about one-third of cases would be the result of novel mutations. The prediction was proven to be correct since a large number of different mutations

exist in the *F8* gene and many patients carry a *de novo* mutation not present in the X chromosome of their mothers. One notable exception to the Haldane prediction is the case of the common inversion within the *F8* gene (see below).

The severity and frequency of bleeding in the patients correlate with the level of factor VIII activity in plasma.[259] About 50% to 60% of patients have severe hemophilia A with factor VIII activity <2% of normal; these patients have frequent spontaneous bleeding into joints, muscles, and internal organs. Moderately severe hemophilia A occurs in about 25% to 30% of patients; the factor VIII activity is 2% to 10% of normal and there is bleeding after minor trauma. Mild hemophilia occurs in 15% to 20% of patients and is associated with factor VIII activity of 20% to 30% where bleeding occurs only after significant trauma or surgery. Individuals with factor VIII activity >30% do not have symptoms of hemophilia A. Of particular interest for understanding the mechanism of factor VIII action is a category of patients with considerable amount of factor VIII protein in their plasma (at least 30% of normal) but the protein is nonfunctional. Approximately, 5% of patients belong to this category termed CRM (cross-reacting material) positive.[260] CRM reduced is another category in which the factor VIII antigen and activity are equally reduced.

F8 Gene Defects

The *F8* gene from more than 4,500 hemophilia A patients has been examined for molecular defects using a variety of methods. The human genome database (HGMD: www.hgmd.org) provides a comprehensive list of the *F8* mutations. Another database was created and is updated to 2007 (HAMSTeRS http://hadb.org.uk/ and [261]). In the HAMSTeRS database more than a thousand mutations have been classified. For each mutation, the degree of severity of the disease and for some also the levels of factorVIII antigen and/or activity present in the plasma of the corresponding patient are reported. In Table 12.3 the gene defects are classified according to the type of mutation. The point mutations are further divided into missense, nonsense, and nucleotide substitutions that cause splicing errors. Missense mutations are the most represented both in the point mutation category and in the overall mutations reported in Table 12.3.

Table 12.3

Pathogenic *F8* mutations causing hemophilia A summary of unique mutations (regardless of recurrence)

Nucleotide substitution: missense codon	583
Nucleotide substitution: nonsense codon (stop)	131
Nucleotide substitution: splicing error	95
Small deletions (up to 50 bp)	197
Small insertions (up to 50 bp)	80
Gross deletions	135

Source: The Haemophilia A Mutation, Structure, Test and Resource (HAMSTeRS) http://hadb.org.uk/. Latest available summary January 1, 2007.
Data refer only to exons 1–26 of *F8* gene.
Permission to use obtained by Geoffrey Kemball-Cook.

The missense mutations are spread throughout the gene with only four mutations in the B domain.

Hemophilia A also originates from gross DNA rearrangements, known as common partial inversions of *F8* gene. The most common cause of severe hemophilia A is a partial inversion up to and including exon 22 of the *F8* gene. In 1993, two studies found that approximately 40% of patients with severe hemophilia A had a partial inversion of *F8* gene.[262,263] A second inversion was identified in intron 1 of *F8*.[264] The mechanism of inversion is intrachromosomal or intrachromatid recombination between homologous regions. For the first inversion, the involved regions include the *F8A* gene in intron 22 and one or two other homologous regions located more than 400 kb 5' (telomeric) to *F8*. For intron 1, the inversion is mediated by a 1041 bp duplication that maps within intron 1 and approximately 140 kb telomerically near the VBP1 gene. Other rearrangements such as duplications, chromosomal translocation, and insertion of retrotransposons (LINE elements) or other mobile elements (*Alu* sequences) were reported in a few cases of hemophilia A.

Aside from the common intron 22 inversion, the frequencies of the different types of genetic defects in severe and mild to moderate hemophilia are shown in FIGURE 12.9 which refer to tables and references updated to August 2007 [http://hadb.org.uk/WebPages/Database/Download]. The number of genetic defects that are taken into consideration is rather large being 984 and 417 for severe and for mild to moderate hemophilia A, respectively. For severe hemophilia A, other than the intron 22 inversion, the largest class of genetic defects is represented by small deletions (<50 bp) that amount to 29% of all the classified mutations. Missense mutations are the second largest class (25%), whereas large deletions (>50 bp) and nonsense (stop) have a similar frequency (14% to 13%), and splice mutations are the least abundant class (6%). Interestingly, in mild to moderate hemophilia A, the missense mutations constitute the predominant class (80%).

The splice site mutations in FIGURE 12.9 include mostly nucleotide substitutions. Donor or acceptor splicing sites are affected, new sites are created, or cryptic splicing sites are activated. These mutations are distributed in all the introns with only one reported mutation in introns 8, 21, and 25 out of 101 total mutations. A few rare mutations (5 out of 101) are within exons or at the intron/exon boundaries. These mutations may affect enhancers or silencers of splicing sites and may cause abnormal pre-mRNA splicing.[265] Nonsense mutations comprise 13% of the mutations associated with severe hemophilia A. These mutations cause premature translation termination of the polypeptide chain and may also reduce the *F8* mRNA level through nonsense-mediated mRNA decay (NMD). Small deletions or insertions predominantly result in frameshift. Together, they constitute 409 unrelated mutations out of 984 severe hemophilia A mutations and represent the largest class of mutations (42%) (FIGURE 12.9A). Moreover, 150 out of 304 small deletions and 98 out of 140 insertions were found as expected in the large exon 14.

Missense Mutations and Factor VIII Protein

Missense mutations reported in Table 12.3 result in amino acid substitutions in the mature protein and are important for understanding the function of the protein and the pathophysiology of the disease. Amino acid substitutions can affect the local protein structure and have only mild effects on the folding/stability/function of the molecule. Alternatively, some amino acid replacements can have both local effects and

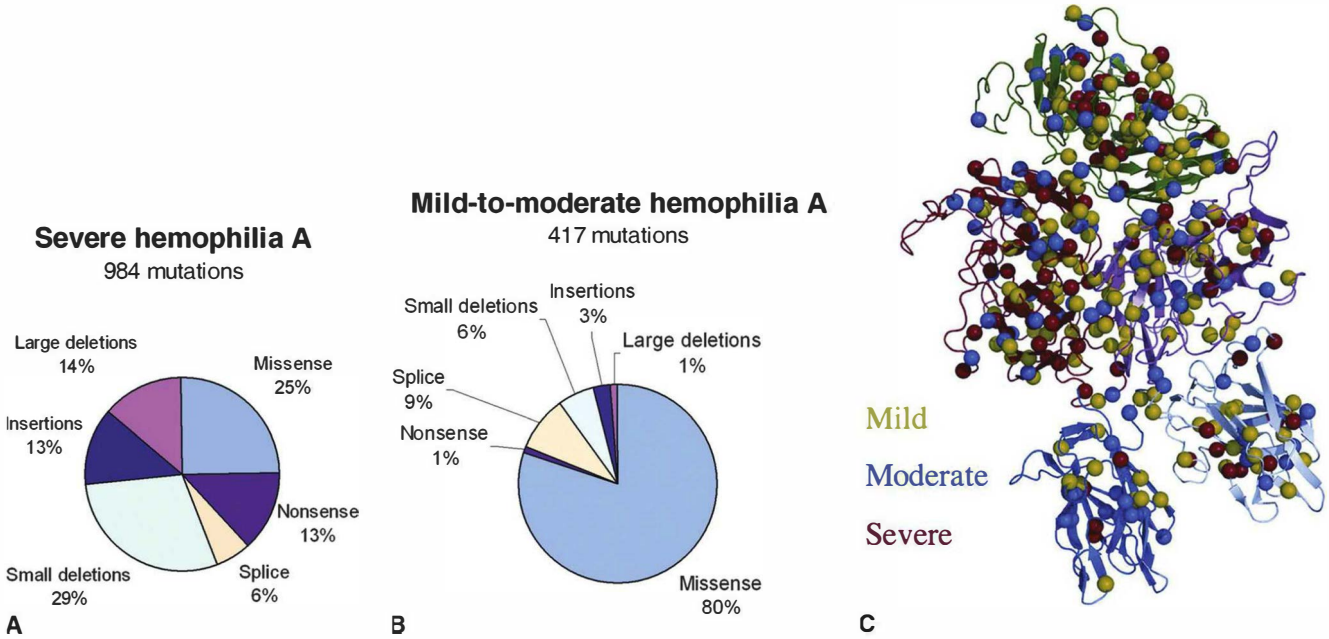

FIGURE 12.9 Factor VIII gene defects in severe and mild to moderate hemophilia A. The frequency of gene defects in severe **(A)** and mild to moderate hemophilia A **(B)**, excluding the intron 22 inversion, was elaborated from data deposited in the HAMSTeRS database (updated August 2007). Only data for which a classification of the degree of severity was reported were taken into consideration. Missense mutations refer to the amino acid number of protein devoid of the signal peptide. Where a range from severe to mild of symptoms was reported, the missense mutation was assigned to severe. Small deletions (50 bp or less), large deletion (>50 bp), insertions (all reported insertions), and splice mutations (all reported splice mutations). **(C)** Missense mutations in the factor VIII structure related to hemophilia A. The structural domains of the protein are shown and the amino acid substitutions are depicted with different colors depending on the severity of the disease/symptoms as defined by criteria of the HAMSTeRS Database (http://hadb.org.uk/). long-range effects that may affect folding and cause instability/dysfunction of the entire molecule. Expression level, secretion efficiency, and/or half-life in the plasma can also be affected. Moreover, amino acid substitutions can occur at critical sites, for example, thrombin cleavage sites or sites of interaction with the substrate or other proteins. For example: (a) mutations in patients with CRM-positive hemophilia A that affect thrombin cleavage (mutations R372H, R372C, and S373L, abolish cleavage in the heavy chain[99,102,266] and mutations R1689C and R1689H abolish thrombin cleavage in the light chain[101,267]); (b) Y1680F substitution at the site of tyrosine sulfation that is required for high-affinity vWF interaction, observed in patients with moderate CRM-reduced hemophilia A,[268] decreases binding affinity to vWF presumably because the Phe residue cannot be sulfated;[92,269] (c) two other CRM-positive mutations, I566T and M1722T, produce severe hemophilia A by creating new *N*-glycosylation sites N564 and N1770, respectively, in the A2 and A3 domains[270] where factor VIII is present at normal levels in plasma, but is inactive. When the plasma from either patient is deglycosylated, factor VIII activity is restored to a significant degree. The glycosylation in the I566T mutant factor VIII causes steric hindrance for interaction with factor IXa.[271]

In a recent study, the missense mutations associated to hemophilia A were mapped onto the 3-D structure of the B domain–deleted factor VIII heterodimer[73] (FIGURE 12.9C). Hemophilia A-associated missense mutations appear to be distributed uniformly along the entire polypeptide chain, regardless of either severity of the symptoms or the structural domain of the protein.

Hypotheses regarding how the amino acid changes affect the structure, function, and secretion of the protein can be tested by expression of the mutant factor VIII in cultured cells. Not only do these studies provide insight into the amino acids and contacts essential for cofactor function[271–273] but this knowledge can also be used to engineer FVIII variants that have improved clinical utility for therapy of hemophilia A[274] (for a review, see Ref. [275]). An elegant example of this type of approach is a recent demonstration that altering contacts at the A1–C2 interface by introducing a disulfide bond or by filling a cavity with a bulky hydrophobic group increases interchain affinity and functionally enhances factor VIII stability.[276]

Combined Factor V and VIII Deficiency (F5F8D)

Combined factors V and VIII deficiency (F5F8D) is an autosomal recessive disease that was described in 1954 by Oeri et al.[277] Patients with this disorder exhibit factor V and factor VIII antigen levels in the range of 5% to 30% that correlates with the

activity measurements. Bleeding is similar to that observed in other coagulation factor deficiencies. The levels of all other plasma proteins that have been measured appear normal in these patients, including those of the homologous copper ion–binding protein ceruloplasmin. Although there have been several reports of individuals who simultaneously inherited mutations in both the factor VIII and factor V gene,[278] this is rare (~$1/10^{10}$).

Homozygosity mapping and positional cloning approaches were used to identify the defective genes in F5F8D. Essentially, all individuals with F5F8D have mutations in *LMAN1* (lectin, mannose-specific, also known as *ERGIC-53*) (~70% of the families)[279] or *MCFD2* (multiple coagulation factor deficiency gene 2)(~30% of the families).[280] At least 32 mutations in *LMAN1* have been reported throughout all 13 exons of the gene.[281,282] The mutations would be expected to result in a complete loss of function of the protein. In contrast, 16 mutations have been reported in *MCFD2*, the majority being splice site or missense mutations and would be expected to produce protein products. The diversity of the mutations suggests that F5F8D evolved through multiple independent genetic events. Interestingly, some mutations are uniquely associated with selective populations, such as two mutations in *LMAN1* account for all Jewish F5F8D patients. One mutation is most common in Sephardic Jews while the other mutation is unique to Middle Eastern Jews,[279] suggesting that in some populations, founder mutations may account for all or the majority of individuals with F5F8D.

LMAN1 encodes a 53-kDa type-1 transmembrane protein of the ER–Golgi intermediate compartment (hence, ERGIC-53) that has a luminal carbohydrate recognition domain that selectively binds mannose in a Ca^{2+}-dependent manner. LMAN1 forms homohexamers in the cell that cycle between the ER and the Golgi compartment.[283,284] *MCFD2* encodes a 16-kDa monomeric lumenal protein that has two EF-hand domains that bind Ca^{2+}. MCFD2 interacts with LMAN1 in a Ca^{2+}-dependent manner, and missense mutations that disrupt Ca^{2+} binding in MCFD2 disrupt LMAN1 interaction and cause F5F8D.[285] Analysis of factor VIII functional and physical interaction with LMAN1/MCFD2 suggests that the oligosaccharides within the B domain are the most important feature for LMAN1/MCFD2 interaction.[286,287] Most data support the hypothesis that factor V and factor VIII have evolved to utilize LMAN1/MCFD2 to facilitate their trafficking from the ER to the Golgi complex. Although there are several reports that describe alternative cargo for the LMAN1/MCFD2 trafficking complex, more definitive studies are required to substantiate these findings.[285]

CHAPTER

13 Structure and Function of von Willebrand Factor

SANDRA L. HABERICHTER AND ROBERT R. MONTGOMERY

von Willebrand disease (vWD) is the most common hereditary bleeding disorder with a prevalence estimated by some to be 1% or greater.[1,2] Numerous studies have demonstrated the autosomal inheritance pattern for vWD (FIGURE 13.1). vWD is caused by decreased levels or defective function of von Willebrand factor (vWF) protein. vWF is a large, multimeric glycoprotein that functions to bind platelets at the site of vascular injury, to promote platelet–platelet interaction, and to serve as the carrier protein for coagulation factor VIII (FVIII). vWF is synthesized as a precursor protein comprised of a large propeptide (vWFpp) and even larger mature vWF protein (refer to Table 13.1 for terminology).

MOLECULAR AND STRUCTURAL BIOLOGY

Over the past 20 years, investigators have gained much insight into the structure and function of vWF through the delineation of its molecular and cellular biology. Such studies have helped us develop assays for laboratory diagnosis and understand the clinical manifestations, , the classification of vWD and its variants, and the rationale for therapy.

Molecular Biology

The coding sequence for human vWF was identified in a cDNA library derived from endothelial mRNA by several independent groups in 1985.[3,4–6] This cDNA sequencing demonstrated an 8.7-kb mRNA with an open reading frame that encodes a 2,813–amino-acid protein, including a signal peptide of 22 amino acids, a large propolypeptide of 741 amino acids, and a mature vWF molecule containing 2,050 amino acids. FIGURE 13.2 demonstrates the relationship of this cDNA to the vWF protein. Using the current numbering system, the initiating methionine codon is defined at nucleotide number one, and this methionine is also identified as amino acid number one. Analysis of the protein structure suggested areas of internal homology that have been termed A, B, C, and D domains.[7,8] The A repeats have sequence similarity to complement Factor B, type VI collagen, chicken cartilage matrix protein, and the "I-domain"–containing integrin α-subunit (Mac-1, VLA2, LFA, p 150, 95).[9,10] Areas of the C repeat are similar to segments of procollagen and thrombospondin.[11] Several functions of vWF have been mapped to specific domains. The D′ and D3 domains are important in FVIII binding, and the D3 domain is also essential for multimerization. The A1 domain contains the site for glycoprotein GPIbα binding. vWF binding to collagen occurs through interaction with the A1 and A3 domains. The C1 domain contains an RGDS sequence that allows vWF to bind glycoprotein GPIIb/IIIa. The site for proteolysis by the vWF-cleaving protease, ADAMTS13, is located within the A2 domain.[12]

After the coding sequence for vWF was identified, the entire human vWF gene has been cloned and much of its structure defined. The gene is about 178 kb long and contains 51 introns.[13] The localization and sequence of the intron–exon boundaries of these 51 introns have been determined. The gene for vWF has been localized to the short arm of chromosome 12, although a pseudogene, representing approximately the middle third of the vWF gene, has been identified and mapped to chromosome 22.[14,15] The presence of this pseudogene can cause problems in determining the genetic structure of some of the vWD variants, but various strategies have been developed to avoid this problem.[16] This pseudogene has about 98% homology to its corresponding portion of the authentic vWF gene on chromosome 12.[14]

Various genetic alterations of the vWF gene have been reported and include deletions, insertions, point mutations, alternative splice junctions, and premature transcription termination sites. Many of the molecular mutations reported are included in exon 28.[17] This exon encodes the region of vWF that interacts with platelet glycoprotein Ib (GPIb) and encodes the portion of the vWF protein containing the important *N*-terminal multimerization site(s)[7] and an important site where a metalloprotease cleaves vWF between Y1605 and M1606.[18] Most of the type 2A and 2B mutations have been localized within exon 28.[17] Type 2N mutations are clustered within the D′ and D3 domains of vWF.[19–23] Although a number of patients with type 1 vWD do not appear to have identifiable mutations in the vWF coding region, mutations that have been identified in type 1 vWD do not appear to cluster in any one domain, but are located throughout the vWF protein.[24–26]

Within intron 40, there are repetitive elements of variable length that have been termed VNTR (variable number of tandem repeats) or STR (short tandem repeats).[27,28] These repetitive elements can be amplified to define the allelic inheritance for unusual genetic phenotypes. These STRs may also be helpful for intrauterine diagnosis using amniocytes or chorionic villi cells with subsequent gene amplification of segments of the vWF gene using the polymerase chain reaction. Caution in amplifying this region must be exercised because of instability of this locus.[29]

von Willebrand Factor Promoter

Significant progress has been made in defining the upstream regulatory elements that control vWF expression. Several consensus sequences for *cis*-acting elements have been identified in the immediate upstream promoter region and first exon including

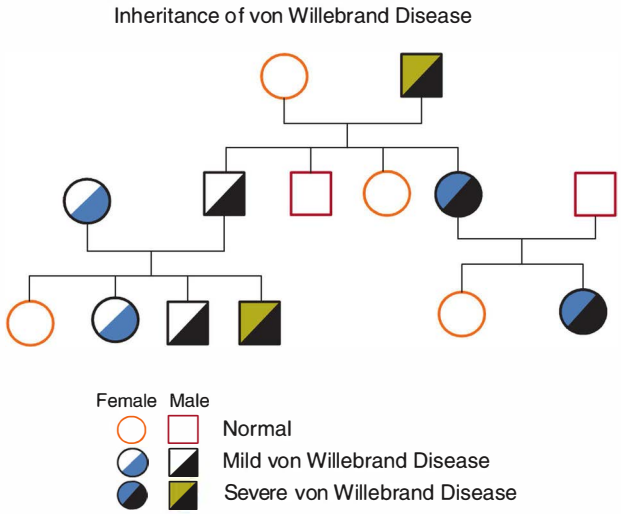

FIGURE 13.1 The autosomal inheritance of von Willebrand disease (vWD) is illustrated in this figure. Because low von Willebrand factor (vWF) has a frequency of 1% to 2%, some of these individuals are asymptomatic. Those with symptoms are said to have mild type 1 vWD. Patients with type 3 vWD are homozygous and inherit null alleles from each parent. (Used by permission, Montgomery RR.)

two GATA-binding consensus sequences.[30] The endothelial cell–specific expression appears to be regulated by a repressor–derepressor mechanism and includes both an NF1-binding site and an Oct-1-binding site.[30–34] A more complex mode of transcriptional regulation through vascular bed–specific signaling pathways has been recently defined. A 2,200 base pair 5′ flanking sequence together with the first intron and exon direct expression to microvascular endothelial cells of skeletal muscle and heart.[35] Recently, cell type–specific regulation of vWF expression by the E4BP4 transcriptional repressor has been identified.[36] Within the heart, a cardiomyocyte-dependent signaling pathway through platelet-derived growth factor (PDGF) has been defined.[37] Several single-nucleotide polymorphisms at nucleotides -1793, -1234, -1185, and -1051 have been associated with plasma vWF:Ag levels.[38,39] Thus, vWF gene is regulated by both cell-specific elements as well as the environment in which these cells are growing.[31,40]

Biochemistry

Numerous laboratories have purified normal human vWF, and there is general agreement concerning its structure and function relationships.[41–47] It is composed of a series of high molecular weight multimers that range between approximately 600,000 (vWF dimer) and 20 million Da. Using low-concentration agarose gels (0.65% to 1%), these multimers can be resolved, with the lowest band representing the dimer. Using high-concentration agarose gels (2% to 3%), each of these individual multimers can be resolved into several additional bands that are thought to result from subunits that have undergone partial proteolytic cleavage or contain variable amounts of modified carbohydrate.

When the disulfide bonds are reduced, a single predominant band is seen on polyacrylamide gel electrophoresis with an apparent molecular weight estimated to be approximately 220,000, plus some smaller bands caused by proteolytic degradation.[48] The complete protein sequence has been determined

Table 13.1

Terminology

vWD	The autosomally inherited bleeding disorder with a reduced amount or function of vWF
vWF	The glycoprotein that is abnormal or present in reduced amounts in patients with vWD
vWF:Ag	vWF antigen, the detection and quantitation of vWF by immunoassay
vWF:Rco	Ristocetin cofactor, the detection or quantitation of vWF using the antibiotic ristocetin, which induces vWF binding to platelets
vWF multimers	The multiple molecular forms of vWF comprising *C*-terminal–linked dimers assembled through subsequent *N*-terminal multimerization to produce high molecular weight vWF multimers
vWFpp	The large propeptide of vWF normally cleaved from pro-vWF during intracellular processing to produce a free vWFpp molecule (also previously called VW AgII) and mature vWF
FVIII	Factor VIII, the protein that is abnormal or reduced in patients with hemophilia A; vWF serves as an FVIII carrier protein in plasma, and, therefore, if vWF is reduced or its binding to FVII is abnormal, patients with vWD have reduced FVIII levels
Ag	Factor VIII coagulant antigen, factor VIII antigen is measured by immunoassay

vWD, von Willebrand disease; vWF, von Willebrand factor.

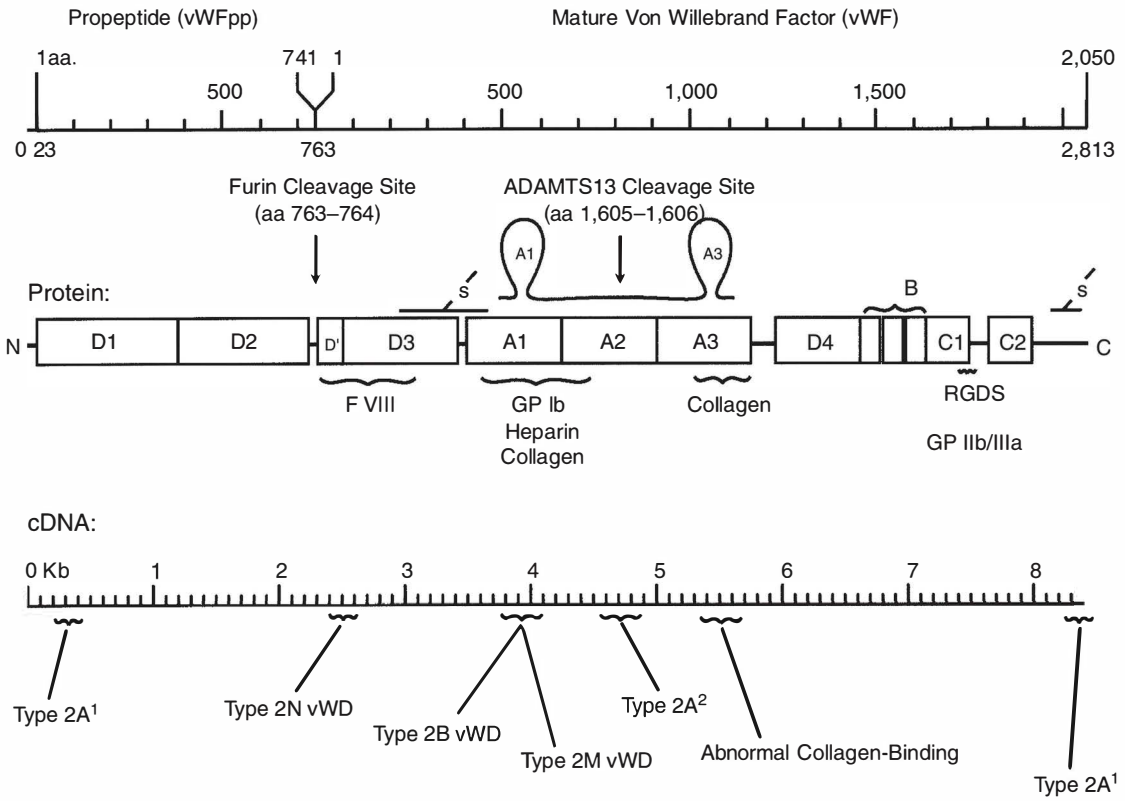

FIGURE 13.2 The von Willebrand factor (vWF) protein is initially synthesized as a 2,813–amino acid pro-vWF molecule whose synthesis is directed by an 8.5-kb RNA. The pre-pro-vWF is composed of a 22–amino acid signal peptide, a 741–amino acid propeptide (vWFpp), and a 2,050–amino acid mature vWF monomer. The pro-vWF is composed of A, B, C, and D repeats. Various functional domains have been identified and contain the sites of interaction with factor VIII, platelet glycoprotein GPIb, GPIIb/IIIa, collagen, and heparin. On the basis of these functional domains, various genetic mutations have been mapped to discrete regions of the cDNA as illustrated. Two protease domains are illustrated: furin cleavage site (cleaves the vWFpp from vWF) and ADAMTS13 cleavage site that cleaves the A2 domain. This ADAMTS13 cleavage is increased by some vWF mutations that cause type 2A vWD caused by increased vWF proteolysis. Cleavage by ADAMTS13 is absent in patients with thrombotic thrombocytopenic purpura (TTP) either because of a deficiency of the enzyme (hereditary TTP) or an autoantibody that blocks its cleavage of vWF (acquired or sporadic TTP). Type 2 mutations are generally located in specific regions along the vWF protein. Types 2A, 2B, and 2M are primarily located within exon 28 that encodes for the A1 and A2 regions of vWF. The two different types of 2A are those that have increased proteolysis 2A[2] and those with abnormal multimer synthesis 2A[1]. Mutations with abnormal collagen binding are clustered in the region encoding the A3 domain. (Used by permission, Montgomery RR.)

and is identical to the protein sequence derived from the cDNA sequence with a molecular weight of 225,663 for just the amino acid sequence of the mature vWF.[3–5,49] The carbohydrate component is estimated to add approximately 10% to 15% to the molecular mass; thus, the true molecular weight of the monomer is approximately 255,000, and its migration in polyacrylamide gel underestimates its true molecular weight.

The vWF multimers are extraordinarily large; the biggest are considerably larger than some virus particles. Electron microscopy of the vWF molecule after rotary shadowing reveals a flexible filamentous structure with irregularly spaced nodules that have been reported from several groups.[50,51,52] These filaments are approximately 20 to 30 Å wide and as long as 11,500 Å, with an average length of 4,780 Å; for comparison, fibrinogen is 475 Å long. Under native conditions, these long filamentous strands are presumed to be wound together in a compact molecule. During activation, shear stress, or other *in vivo* modifications, portions of the vWF may be unwound, allowing exposure of multiple interactive sites that may participate in platelet adhesion. Decreasing the size of the multimers by partial reduction of disulfide bonds results in a dramatic decrease in the platelet-agglutinating activity.[50,53,54]

This molecular weight-dependent heterogeneity of vWF is important when one compares the results of assays based on immunologic and platelet-agglutinating activities. Although immunoassays recognize large and small multimers, estimates of vWF activity using the ristocetin cofactor (vWF R:Co) assay predominantly measure the function of high molecular weight multimers.[54,55,56,57] In contrast, estimates of vWF activity using botrocetin-induced platelet binding correlate better with the immunoassays but may not represent functional activity *in vivo*.[58] Individuals with hereditary conditions such as type 2A

vWD, in which there is a reduction in multimeric size, often have more severe bleeding symptoms than individuals with a similar reduction in protein concentration but normal multimeric size (type 1 vWD); thus, *in vivo*, multimeric size may correlate with function.[55]

CELL BIOLOGY

Although vWF is synthesized both in the megakaryocyte and the endothelial cell, most of our understanding of cellular biosynthesis is derived from the endothelial cell because of the ease of *in vitro* endothelial cell culture.[59,60] Studies on megakaryocytes are limited.[61] Studies using transformed cell lines, and inference from the study of platelets, suggest that platelet vWF production is similar to that in endothelial cells. One difference has been seen in dogs whose platelets have been shown by several laboratories to lack vWF,[62] although one report identified vWF in canine platelets.[63]

Cellular Processing

Endothelial cells and platelets store vWF in secretory granules that are termed Weibel-Palade bodies (endothelial cells) and α-granules (megakaryocytes and platelets).[60,64,65] These secretory granules can be induced to release their contents by a variety of agonists such as calcium ionophore A23187, thrombin, adenosine diphosphate (ADP)/epinephrine (platelets), and histamine (endothelial cells).[66–68] *In vivo*, the vasopressin derivative desmopressin acetate (DDAVP) can induce the release of vWF into plasma.[69] The cell from which it is released is presumably the endothelial cell, as evidenced by a lack of reduction in platelet vWF after DDAVP therapy and a loss of Weibel-Palade body vWF on immunostained tissue sections obtained after DDAVP administration.[70] Much of our understanding of these endothelial cell events comes from expression studies in model cell lines and is summarized in the following paragraphs.[45,46,71,72]

vWF is synthesized as a 2,813–amino acid pre-pro-vWF molecule and contains a 22–amino acid signal peptide, 741–amino acid propeptide, and 2,050–amino acid mature vWF protein (FIGURE 13.3). vWF is subjected to extensive intracellular modifications. In the endoplasmic reticulum (ER), the signal peptide is removed, disulfide bonds are formed, and protein folding occurs. vWF is a cysteine-rich protein, containing 234 cysteine residues. While early studies indicated these cysteines were all involved in disulfide bonds, more recent studies using more sensitive techniques suggest that there may be a number of reactive free sulfhydryls in plasma vWF.[73,74] Although a number of disulfide linkages have been mapped, the majority of disulfide mapping in vWF has not been accomplished.[75–77] The process of protein folding and disulfide bonding has to be remarkably complicated given the large number of cysteines in vWF. The pro-vWF forms *C*-terminal dimers in the ER. This results in a pro-vWF *C*-terminal–linked dimer, the protomeric species that later forms larger vWF multimers. This dimerization is dependent upon the last 151 amino acids of the mature vWF protein.[78,79] These *C*-terminal sequences may serve a role in retaining monomers in the ER until they are either dimerized or degraded. The *N*-terminal portion of vWF is less important for dimerization and the large vWF propeptide is not required for dimerization to occur.[80–82]

Upon transport through the Golgi compartments, vWF undergoes carbohydrate modification. The mature vWF subunit is heavily glycosylated with 10 *O*-linked and 12 *N*-linked oligosaccharides.[49,83,84] This glycosylation accounts for approximately 18% to 19% of the total protein mass. Sulfation of the vWF molecule has also been demonstrated.[85] In the Golgi, the *C*-terminal–linked pro-vWF dimers form *N*-terminal–linked multimers that may exceed 20 million Da in size. The vWF propeptide (vWFpp), a protein initially described in plasma as VW AgII, is also proteolytically cleaved in the *trans*-Golgi. Processing of pro-vWF into vWFpp and the mature vWF is carried out by a paired amino acid–cleaving enzyme (PACE), or furin, that cleaves the propeptide from the mature vWF.[86,87] The site of propeptide cleavage is targeted by the sequence motif Arg-Xxx-Arg/Lys-Arg at the *C*-terminal end of the propeptide.[87] Because patients with hereditary persistence of pro-vWF have normal multimers, cleavage of the propeptide does not appear to be a prerequisite for multimerization or secretion.[88] The cleavage of propeptide appears to be essentially completed in the Golgi, prior to regulated storage.[80,89,90] Both portions of the molecule, the high molecular weight multimerized vWF and the cleaved propeptide, are stored in the Weibel-Palade body secretory granule.

vWF Multimerization and Regulated Storage

The assembly of vWF into *N*-linked multimers is a complex process involving interchain disulfide bonds. The first interchain disulfide bonds are formed during dimerization and involve cysteine residues located in the *C*-terminus region. Multimerization of *C*-terminal dimers involves cysteine residues located in the *N*-terminus region (D′ and D3 domains).[45,91] *C*-terminal dimerization is independent of multimerization. Although both processes involve the formation of disulfide bonds, *C*-terminal dimerization of vWF is completed in the ER, while *N*-terminal multimerization is carried out in the Golgi. The two processes are compartmentalized implying different enzymes or mechanisms regulate these steps. In the ER, neutral pH and the presence of necessary oxidoreductase enzymes such as protein disulfide isomerase promote disulfide bonding.[92,93] The acidic pH and lack of chaperones in the Golgi provide a desolate environment for disulfide bonding. However, ER-to-Golgi transport vesicles are unlikely to be able to accommodate the very large vWF multimers; thus, the formation of the large multimers is delayed until transport to the Golgi is complete. Initial glycosylation of the vWF protein and a low pH in the *trans*-Golgi network have been shown to be important for normal multimerization of vWF.[46] The acidic pH in the *trans*-Golgi network appears to be of particular importance for multimer formation. The assembly of functional vWF multimers from purified vWF subunits can be triggered *in vitro* under low pH conditions, similar to the pH in the Golgi.[73] The large propeptide plays an essential role in the vWF multimerization process. Deletion of either of the D1 or D2 propeptide domains, or the entire propeptide, results in a complete loss of normal vWF multimerization.[82,94] When the propeptide and the "mature" vWF molecule (propeptide-deleted) were expressed as two separate gene constructs, normal multimerization was observed indicating the propeptide can function *in trans* to facilitate multimerization.[82] The propeptide may facilitate vWF multimerization through areas of the propeptide that contain vicinal

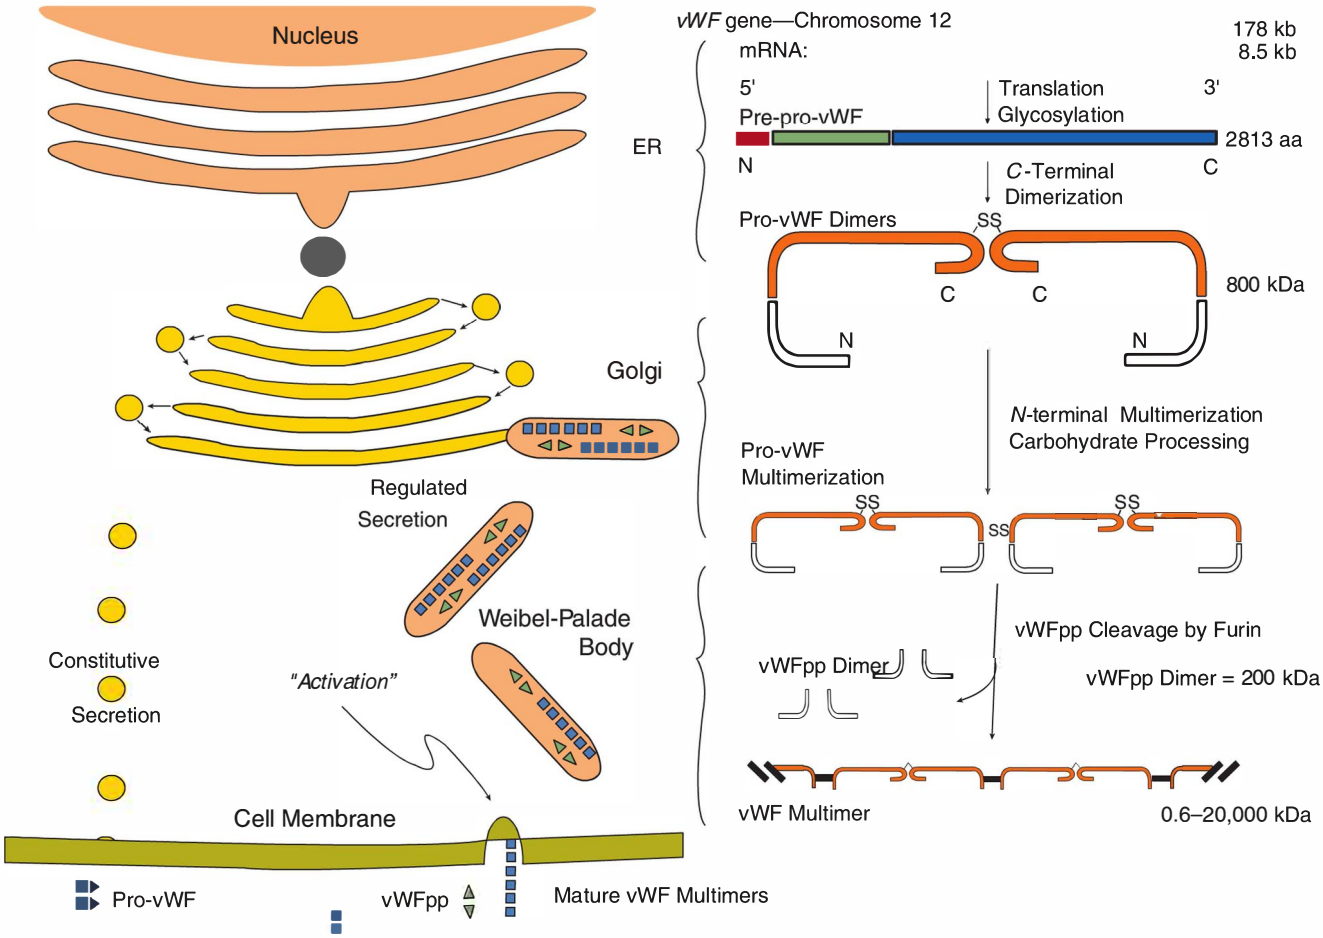

FIGURE 13.3 The sites of cellular biosynthesis are represented schematically in this illustration of endothelial cell biosynthesis. The von Willebrand factor (vWF) protomer is synthesized as a pre-pro-vWF dimer that is a *C*-terminal disulfide-bonded dimer within the endoplasmic reticulum (ER). The 22–amino acid signal peptide is then cleaved. The carbohydrate is then processed into complex sugars within the Golgi compartment. *N*-Linked multimerization by virtue of the self-association of the vWF propeptide (vWFpp) occurs in the acidic compartment of the late-Golgi, and the vWFpp is cleaved from the mature vWF by furin. A pH-dependent association between vWFpp and vWF enables the packaging of both proteins into storage granules termed Weibel-Palade bodies. After activation of the endothelial cell, the regulated secretion of these proteins occurs, but at the neutral pH in plasma, there is no longer an association of vWFpp with vWF. A similar pathway is assumed to occur in megakaryocytes, but the α-granule contains more different types of proteins. In the absence of vWF, the Weibel-Palade body is not formed, but the α-granule is still present. (Used by permission, Montgomery RR.)

cysteine motifs similar to disulfide isomerase.[95] The propeptide was shown to act as an oxidoreductase, thus promoting the multimerization of vWF in the Golgi apparatus.[96] Additional studies identified two amino acids in the D3 domain, Cys-1099 and Cys-1142, that participate in this process.[76]

Both vWF and vWFpp are stored for regulated secretion in Weibel-Palade bodies (endothelial cells) and alpha-granules (megakaryocytes/platelets). The Weibel-Palade body was first described nearly 50 years ago by Weibel and Palade.[97] Weibel-Palade bodies are large cigar-shaped granules that are the hallmark of endothelial cells. This secretory organelle is used for the storage of vWF (amongst other proteins) in endothelial cells and can be very rapidly triggered to release its contents.[98,99] Weibel-Palade bodies store components that are important to hemostasis, inflammation, and angiogenesis. vWF is the main component protein within Weibel-Palade bodies and plays an important role in the biogenesis of this organelle as discussed below.

The large vWF propeptide also plays a critical role in the regulated storage of vWF. vWF expression studies utilizing the AtT-20 and HEK293 cell lines have examined the regulated storage of vWF.[80,94,100,101,102] After the propeptide is furin cleaved in the Golgi, the propeptide and vWF remain noncovalently associated and are trafficked to regulated storage in a propeptide-dependent process. Expression studies have shown that deletion of either of the D domains abolishes the sorting of vWF to storage granules.[94] When the entire propeptide is deleted (Δpro), regulated storage of the "mature" vWF protein is also abolished. In contrast, the propeptide sorts to endogenous storage granules when it is expressed alone in AtT-20 cells. When the vWF propeptide and mature vWF (propeptide-deleted vWF or Δpro) are expressed together as two separate gene constructs, normal

granular storage of vWF is reestablished.[80,103] The propeptide contains the necessary sequence or conformation for sorting to storage granules and secondarily cotraffics mature vWF multimers through noncovalent association.[80] The nature of the noncovalent association between propeptide and mature vWF has been further defined. Two amino acids, arginine 416 within the propeptide and threonine 869 in the mature vWF protein are essential for noncovalent association and regulated storage of vWF.[104] The putative sorting signal for the propeptide may been located in the D2 domain. By using a series of propeptide truncation cDNA constructs (FIGURE 13.4), the sorting signal has be localized within amino acids 387 to 545 of the propeptide. The sorting signal within the vWF propeptide has been used to traffick an unrelated, nonsecretory granule protein (C3α) to the regulated storage pathway in AtT-20 cells and endothelial cells.[90]

Although the propeptide plays a critical role in both the multimerization and storage of vWF, the two events are clearly independent. Expression of vWF with disrupted vicinal cysteine motifs demonstrated a lack of vWF multimerization but maintenance of vWF regulated storage.[95] This was further demonstrated by expression studies utilizing human and canine vWF cDNA constructs. The canine propeptide was able to facilitate multimerization of human propeptide-deleted vWF (Δpro) but could not traffic the human vWF to regulated storage.[80] In a study utilizing the cross-species storage difference, a large number of human/canine chimeric constructs were expressed and examined for multimerization and regulated storage. No correlation was found between vWF multimerization and granular trafficking.[104] In many cases, normally multimerized vWF was not stored in granules and conversely, several vWF species that did not form multimers were trafficked to storage granules. A number of vWF mutations have been identified in vWD patients that disrupt vWF multimerization but did not affect the regulated storage of vWF.[101,105] There have been few patient mutations reported that maintain normal vWF multimerization but eliminate regulated storage and secretion.[102,106,107]

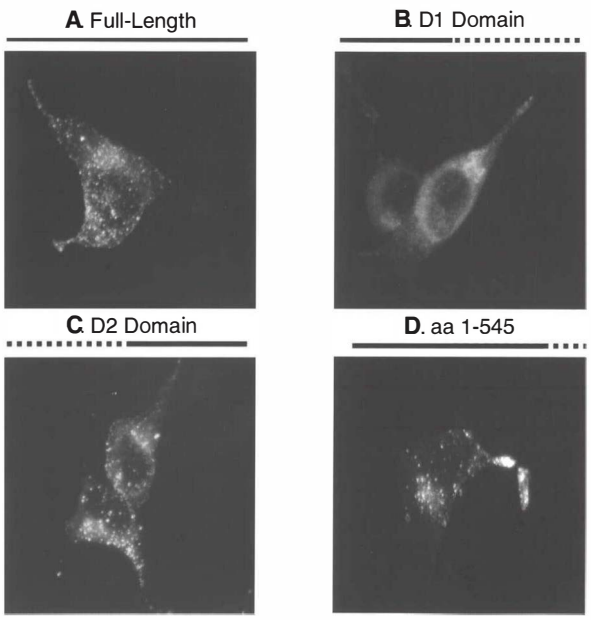

FIGURE 13.4 At T-20 cells were transiently transfected with von Willebrand factor (vWF) propeptide truncation expression plasmids, immunofluorescently stained, and examined by confocal microscopy. **A:** Cells expressing full-length propeptide demonstrate a granular staining pattern. **B:** Cells expressing only the D1 domain (amino acids 1 to 386) of the propeptide demonstrate a diffuse staining pattern with no granules detected. **C:** Cells expressing only the D2 domain (amino acids 386 to 763) of the propeptide demonstrate a granular staining pattern similar to full-length propeptide. **D:** Granular staining of a propeptide consisting of amino acids 1 to 545. The putative vWF propeptide sorting signal lies in the D2 domain within the region of amino acids 387 to 545. (Used by permission, Montgomery RR and Haberichter SL.)

The regulated storage of vWF in endothelial cell Weibel-Palade bodies and platelet alpha-granules is important physiologically. Patients with type 1 vWD are often treated with the vasopressin analog DDAVP (1-desamino-8-D-arginine-vasopressin). Administration of DDAVP results in a rapid increase in plasma vWF levels resulting from release of vWF from Weibel-Palade bodies.[108,109] vWF plays an essential role in the formation of Weibel-Palade bodies in endothelial cells. In the vWF-deficient mouse (e.g., type 3 vWD), no Weibel-Palade bodies can be detected in endothelial cells and the membrane protein P-selectin is routed to lysosomes.[110] Similarly, cultured endothelial cells harvested from type 3 vWD dogs demonstrated a lack of Weibel-Palade bodies.[111] Expression studies using the endothelium from the type 3 vWD dogs have demonstrated that expression of vWF protein is necessary for the formation of Weibel-Palade bodies that contain the membrane protein, P-selectin (FIGURE 13.5).[111] Both propeptide and mature vWF are necessary for formation of Weibel-Palade bodies: neither the propeptide nor mature vWF (Δpro) were sufficient for granule formation. Expression studies using *C*-terminal truncations of vWF showed that a vWF construct consisting of vWFpp through the vWF A1 domain stored vWF as tubules that correlated with the elongation of Weibel-Palade bodies.[112] More recently, vWF tubule assembly has been demonstrated *in vitro* using only purified vWFpp and D–D3 domains of vWF, narrowing the required domains for Weibel-Palade body formation to the vWF D1–D3 domains.[113] These studies also indicated that vWF may serve an active role in the recruitment of the leukocyte receptor, P-selectin to the Weibel-Palade body membrane.[114] While vWF is believed to be the most abundant protein in the Weibel-Palade body, additional components include P-selectin, the tetraspanin CD63, IL-8, osteoprotegerin, α1,3-fucosyltransferase VI, endothelin-1, eotaxin, and t-PA.[115–120,121,122,123] Although the site of synthesis of FVIII is unclear, FVIII can be stored together in a Weibel-Palade body when expressed with vWF.[124] Thus, vWF-dependent Weibel-Palade body biogenesis has significant biologic implications.

Although there are many similarities between endothelial cell Weibel-Palade bodies and platelet alpha-granules, there also several differences. While the hallmark characteristic of the endothelial cell Weibel-Palade body is its elongated, cigar shape, alpha-granules are not elongated. While both granules contain vWF and P-selectin, the alpha-granule contains several proteins not found in Weibel-Palade bodies such as fibrinogen, coagulation factor V (FV), platelet factor 4, thrombospondin-1, and fibronectin.[125] Unlike endothelial cell Weibel-Palade bodies, platelets do not require the synthesis of vWF to form the alpha-granule. In vWF-deficient mice[110] or dogs (Haberichter,

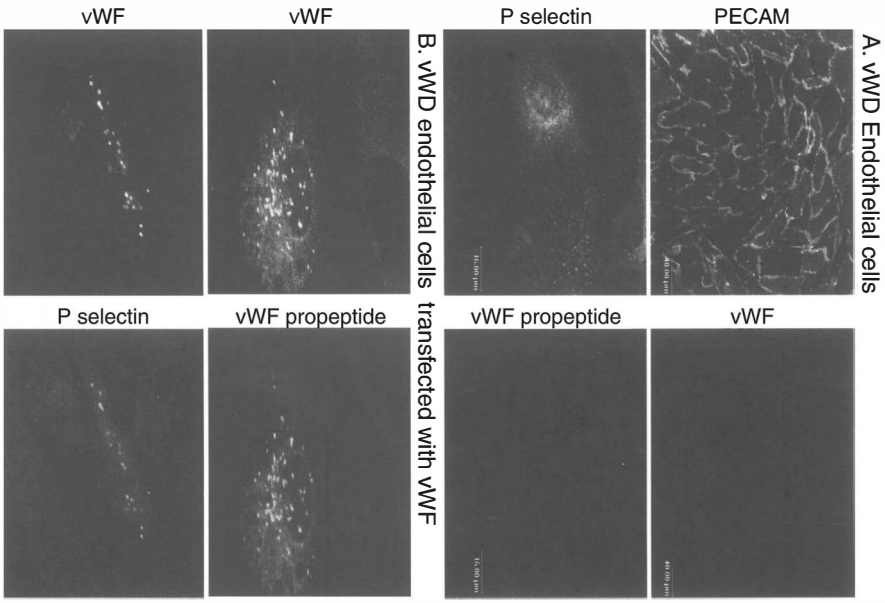

FIGURE 13.5 **A:** Endothelial cells were harvested from the aortas of dogs with type 3 von Willebrand disease (vWD), cultured, immunofluorescently stained, and examined by confocal microscopy. The cells were platelet/endothelial cell adhesion molecule (PECAM) (CD31)-positive, indicating that a homogenous population of endothelial cells had been cultured as shown. The cells were also found to be vWF-negative as shown. Staining for P-selectin was faint and diffuse with many small granules, most likely lysosomes. The vWF propeptide could not be detected in these cells. Therefore, no apparent Weibel-Palade bodies were detected in the canine vWD aortic endothelial cells. **B:** The canine vWD aortic endothelial cells were transiently transfected with a vWF expression plasmid. Immunostaining of cells expressing vWF demonstrated a granular distribution of vWF and vWF propeptide as shown. Dual staining for vWF and P-selectin revealed that the vWF was colocalized with P-selectin in granules. Therefore, in the absence of vWF, no Weibel-Palade bodies are formed in endothelial cells. However, vWF expression induces the formation of Weibel-Palade bodies, and the Weibel-Palade body distribution of endogenous P-selectin is reestablished. (Used by permission, Montgomery RR and Haberichter SL.)

unpublished data), P-selectin-containing alpha-granules are still present in platelets and megakaryocytes. Therefore, vWF is required for the biogenesis of the Weibel-Palade body but not the alpha-granule.

On appropriate agonist stimulation, endothelial cells and platelets release both vWF and the propeptide from Weibel-Palade bodies and α-granules, respectively. The cleaved propeptide remains associated with vWF under acidic conditions similar to those observed in the late *trans*-Golgi network and Weibel-Palade bodies, but dissociates from vWF when exposed to the higher pH found in plasma. The propeptide self-associates as a noncovalent dimer in plasma.[126] vWF can be secreted both luminally into plasma and abluminally into the subendothelial cell matrix.[71] Although the propeptide is also secreted, its extracellular function has not been delineated.

Proteolysis and Clearance of vWF

Once secreted, vWF multimers circulate in plasma at a concentration of approximately 10 μg/mL with a half-life of about 12 hours. The free propeptide circulates in normal human plasma at a concentration of about 1 μg/mL with a half-life of 2 to 3 hours. Little is known regarding the mechanisms underlying the normal clearance of vWF from circulation.[127] Increased clearance from the circulation has been identified as one mechanism causing type 1 vWD (type 1C).[128,129,130] In these patients, vWF has a significantly decreased half-life. Mutations in vWF have been associated with this phenotype including R1205H, C1130G/F/R, C1149R, W1144G, S2179F, and C2671Y.[128,129,131,132] In these patients, clearance was not dependent on multimer size as all multimers, small and large, disappeared quickly. Patients with this phenotype can be identified by an increased ratio of steady-state plasma vWFpp to vWF:Ag (FIGURE 13.6).[129] The characteristic elements of the type 1C phenotype include a substantially reduced vWF:Ag, reduced vWF half-life, diminished vWF multimer satellite bands, an apparently enhanced DDAVP response, *vWF* gene mutation, and increased vWFpp/vWF:Ag ratio.[131] An experimental model has been developed to examine clearance of human vWF from mouse circulation.[133] These studies supported the role of the D′-D3 domains in regulation of clearance. Carbohydrate modification and ABO blood group may also be important in vWF clearance.[134–137] The relevance of this mechanism to the normal clearance of vWF is not known.

There is a marked effect of ABO blood type on the vWF antigen (vWF:Ag) levels seen in normal individuals.[138,139] A study of more than 1,300 normal blood donors revealed that patients with group A, B, and AB have a much greater mean vWF:Ag plasma concentration than blood group O individuals. The A, B, and H antigen (the unmodified H antigen is present in persons with blood group O) has also been identified in vWF. The primary effect of this posttranslational carbohydrate modification appears to result in altered vWF

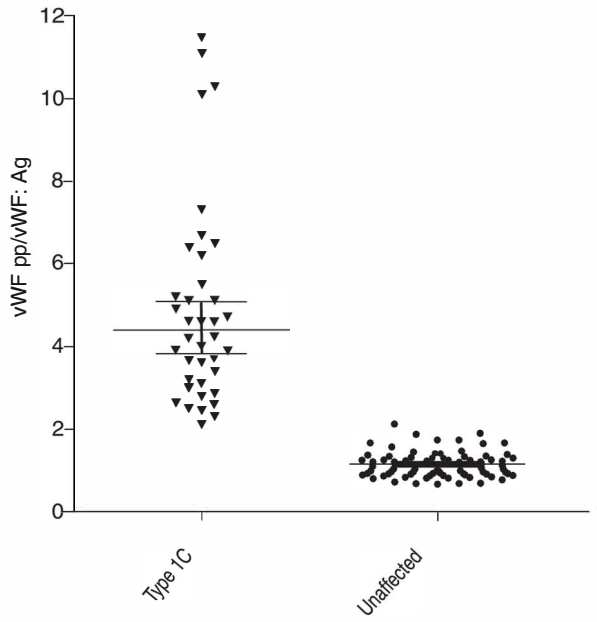

FIGURE 13.6 Steady-state plasma vWFpp/vWF:Ag in type 1C vWD. In patients with increased vWF clearance, plasma levels of vWF:Ag are markedly reduced while steady-state plasma levels of vWFpp are not reduced. Shown here are vWFpp/vWF:Ag ratios for a number of type 1C vWD patients with vWF mutations including R1205H, C1130F/G/R/Y, W1144G, and S2179F. The mean vWFpp/vWF:Ag in these patients was 4.9, in contrast to unaffected family members and normal controls with a vWFpp/vWF:Ag ratio of 1.2. The steady-state vWFpp/vWF:Ag ratio is useful in identifying vWD patients with reduced vWF survival. (Used by permission, Haberichter SL.)

survival *in vivo*. A study by Gallinaro et al. demonstrated a moderately reduced half-life of vWF in type O individuals.[135] Type O individuals have an increased ratio of vWFpp/vWF:Ag (1.33 ± 0.28 for type O and 1.03 ± 0.21 for non-O) supporting a reduced vWF survival in these individuals (Habericher, *unpublished data*). Table 13.2 lists the normal ranges for the different blood types reported in one study.[138] The effect of ABO blood type on vWF is now recognized as a disease-modifying gene for vWD.

Degradation of vWF is accomplished by the vWF-cleaving protease, ADAMTS13, a member of the "*a d*isintigrin-like *a*nd *m*etalloprotease with *t*hrombo*s*pondin repeats."[140,141–143] vWF is proteolytically processed by ADAMTS13 by cleavage of the Tyr[1605]–Met[1606] bond located within the A2 domain.[144,145] vWF is resistant to ADAMTS13 cleavage under static conditions but is rapidly cleaved when subjected to high shear stress. The high shear conditions most likely expose the cleavage site. vWF released from endothelial cell Weibel-Palade bodies consists of ultralarge vWF multimers. If the ultralarge vWF multimers are released directly into plasma, platelets can spontaneously aggregate resulting in thrombosis.[146,147] The ultralarge multimers form long string-like structures that remain tethered to the endothelial cell surface by interaction of the vWF with the membrane protein, P-selectin.[148] ADAMTS13 cleaves the tethered ultralarge vWF multimers rapidly under flow conditions.[149,150] Recently, the binding of platelet GPIbα to the vWF A1 domain was shown to stimulate the cleavage of the adjacent A2 domain by ADAMTS13.[151] A number of mutations in ADAMTS13 have been identified that affect its synthesis or function and cause a congenital form of thrombotic thrombocytopenic purpura (TTP).[143,152] In contrast, a number of mutations have been identified in vWF that increase the susceptibility of vWF to proteolysis by ADAMTS13 resulting in a loss of high molecular weight multimers in patient plasma and defective platelet binding (type 2A vWD).[18,153] The role of ADAMTS13 in normal degradation of vWF multimers is not well defined.

vWF is subjected to extensive posttranslational modifications, and mutations in the vWF gene can affect its intracellular processing. In the ER, protein misfolding (perhaps a result of aberrant disulfide bonding) can lead to intracellular retention and degradation resulting in reduced vWF secretion and low plasma vWF levels. Defective vWF multimerization results in reduced platelet binding as seen in type 2A vWD. Aberrant processing of carbohydrates may affect vWF function or its clearance from plasma. Defects in any of the many vWF intracellular processing steps may result in vWF intracellular retention, lack of secretion, defective regulated storage and secretion, increased clearance or degradation, or a functionally defective protein.

vWF FUNCTION

vWF serves several functional roles in hemostasis related to the initiation of hemostasis. During vascular injury, vWF first adheres to exposed subendothelial matrix proteins, including various types of collagens.[66,54] This tethered vWF then recruits circulating platelets in order to initiate platelet adhesion by

Table 13.2

Influence of ABO blood group on von Willebrand factor: values in volunteer blood donors

ABO Type	*N*	Geometric Values	Geometric Mean ± 2 SD
O	456	74.8	(35.61 ± 57.0)
A	340	105.9	(48.02 ± 33.9)
B	196	116.9	(56.82 ± 41.0)
AB	109	123.3	(63.82 ± 38.2)

The groups were statistically significantly different from each other as follows: O vs. A, B, AB, $P < 0.01$; A vs. AB, $P < 0.01$; B vs. A, $P < 0.05$.

binding to the GPIb receptor found on platelets.[155,156] After the adhesion event, platelets become activated and platelet aggregation ensues, primarily by use of fibrinogen binding. vWF also supports platelet aggregation through binding to glycoprotein IIb/IIIa, but usually when fibrinogen levels are low, or the local concentration of vWF is high.[157,158] vWF also serves as the carrier protein for coagulation factor VIII (FVIII), protecting it from proteolytic degradation in plasma.[159] It has been suggested that since FVIII will ultimately participate in clot formation by binding to the activated platelet's exposed phosphatidylserine, vWF may play a role in the delivery of the necessary FVIII to the site of clot formation.

Interaction with Platelets

vWF is known to bind to subendothelium, perhaps in part due to its interaction with collagen.[160–162] Thus, in the normal hemostatic system, an intact endothelium precludes the interaction between matrix-bound vWF and platelets. After vessel injury, however, this bound vWF can be induced to interact with the GPIb receptor on platelets.[163] *In vitro*, this interaction with platelets can be mimicked in platelet-rich plasma by the addition of the antibiotic ristocetin, by the venom protein botrocetin, or by subjecting the platelets to high shear stress, all of which promote the binding of vWF to GPIb platelet.[158,164,165] vWF can also bind to a second receptor on platelets, the GPIIb/IIIa complex.[157,166,167] The GPIIb/IIIa receptor normally is the physiologic binding site for fibrinogen during *in vitro* aggregation, but in the absence of fibrinogen or after the local concentration of vWF is increased (platelet or endothelial cell secretion), vWF also may promote this platelet aggregation process.[164] Although the physiologic stimuli for the interaction of vWF with platelets are not fully defined, vWF may undergo a conformational change caused either by interaction with subendothelial matrix or by shear stress.[163,168,169] As described in more detail below, shear-induced platelet aggregation or adhesion can be inhibited by monoclonal antibodies directed against both GPIb and GPIIb/IIIa, suggesting that both receptors are physiologically relevant.[168,170–177]

Effects of Ristocetin on Binding of vWF to Platelets

The interaction of vWF with platelets is the biologic event that reflects a major interaction of vWF with the hemostatic system. Much of our knowledge about the normal interaction of vWF with platelets is derived from several assays that identify a functional abnormality in blood from patients with vWD: ristocetin-induced (or botrocetin-induced) platelet aggregation and agglutination, *ex vivo* interaction of platelets with blood vessel segments from which the endothelium has been denuded, and shear-induced platelet adhesion or aggregation.

Ristocetin, an antibiotic introduced into clinical practice in the late 1950s was observed to produce thrombocytopenia in recipients and was therefore withdrawn from clinical use. Approximately 10 years later, ristocetin was shown to aggregate normal platelets *in vitro* but to cause little or no aggregation of platelets from patients with vWD.[178,179] This observation permitted the development of a quantitative assay, the ristocetin cofactor assay.[180] If fixed platelets, which lack metabolic activity, are used, the response to ristocetin is termed *ristocetin-induced platelet agglutination*.[181] When ristocetin is used with metabolically active platelets in platelet-rich plasma, however, the overall response is termed *ristocetin-induced platelet aggregation* (*RIPA*). vWF binding to platelets induced either by ristocetin (GPIb) or thrombin (GPIIb/IIIa) is agonist dependent. Modified vWF molecules such as type 2B vWF, or normal vWF in which the negatively charged sialic acid residues are removed (asialo vWF), can bind directly to platelets even without any agonist activation.[182–184] In contrast, vWF protein harboring the D1472H polymorphism commonly found in African Americans has reduced ristocetin-induced platelet binding thought to be a result of decreased ristocetin binding to vWF, rather than a true type 2M defect.[185]

vWF Interactions Under High Shear Stress

To simulate more closely the conditions *in vivo* and to permit the differentiation between initial platelet adhesion to a surface in the subsequent platelet–platelet aggregation, a number of research models have been developed to study the effects of shear stress. Early studies on shear stress used the wall of an inverted rabbit aorta that demonstrated the adherence of isolated platelets and subsequent platelet aggregate formation under the control of vWF and fibrinogen.[186,187] The participation of vWF in this process was highly dependent on high shear forces (1,300 to 5,200/second).[188,189] A number of laboratories developed techniques to define the interaction between vWF and GPIbα, the necessary initial step that tethers platelets to damaged vascular surfaces.[190,191] The immobilization of plasma vWF onto exposed subendothelial surfaces is thought to be the predominant mechanism that initiates platelet response in areas of vascular injury exposed to elevated shear forces. Shear forces in the circulation uncoil globular vWF proteins while they are bound transiently to vascular surfaces.[192] The binding of GPIbα to the A1 domain of vWF is the main interaction that can tether platelets to a surface, even under conditions of high flow velocity.[193–195] Furthermore, the stable attachment of platelets requires the synergistic binding of integrins $\alpha_2\beta_1$ and $\alpha_{IIb}\beta_3$ to their respective substrates. The initial binding of platelets to vWF tethered to exposed subendothelial matrix proteins slows the rolling of platelets so that other platelet receptors such as $\alpha_2\beta_1$ can further immobilize the platelet. Under abnormally elevated shear conditions (>5,000/second), vWF is thought to participate in the binding to $\alpha_{IIb}\beta_3$ in addition to GPIbα.[165,196,197] Subsequent studies have demonstrated a role for vWF, fibrinogen and possibly fibronectin, and CD40 ligand in the support of thrombus development.[110,190,191,198–200] Under physiologic arterial shear rates, vWF is responsible for the immobilization of platelets on the surface. Irreversible attachment of these platelets to the surface requires both vWF and fibrinogen and involves both receptors GPIbα and $\alpha_{IIb}\beta_3$.

Interaction with Platelet Glycoprotein Ib

The primary platelet receptor for vWF is GPIb. The GPIb complex on the platelet surface is comprised of at least four proteins: GPIbα, GPIbβ, GPIX, and GPV.[201–205] The site of interaction on the GPIb complex is GPIbα, but GPIbα is not trafficked to the platelet surface unless the other components of the complex are present. Within vWF, the site for

interaction with GPIb is the A1 domain. Although the sites for interaction with GPIb are within the A1 loop, the sites for ristocetin interaction are just outside the A1 loop. The interaction of platelet GPIb and the vWF A1 domain is particularly important as this interaction supports activation-independent platelet tethering even under conditions of elevated flow velocities. This bond has a fast dissociation rate and is considered "selectin-like."[206] *In vivo*, the stimulus for platelet adhesion to vWF is recognized to be shear. Under shear, vWF is unraveled and the binding sites for platelet GPIb are exposed, initiating the immobilization of circulating platelets.[207,208] Platelets tethered to the vessel wall through vWF–GPIb interaction move slowly in the direction of flow. This slow motion allows the interaction of other platelet receptors to the vessel wall, such as the interaction of the activated integrin GPIIb/IIa with collagen receptors.

There are three types of mutations in vWF that impact the binding of vWF to GPIb including "gain-of-function" mutations that cause type 2B vWD, "loss-of-function" mutations that cause type 2M vWD, and gain of function mutations within GPIbα that cause platelet-type of pseudo-vWD.[58,209–213] The crystal structure for the vWF A1 domain has been solved and both type 2B and 2M mutations are found to cluster together.[214,215] More recently, it has been reported that the A1 loop of vWF has an active conformational state that allows it to easily bind to GPIb.[216–219] This "activated" vWF can be identified using a llama-derived antibody fragment that only binds to the A1 loop when vWF is in an active conformation. This "activated" vWF conformation is identified in TTP, type 2B vWD, and antiphospholipid syndrome.[216,217,219]

Interaction with Platelet Glycoprotein IIb/IIIa (Integrin $\alpha_{IIb}\beta_3$)

In vitro, if one uses washed platelets and purified vWF, platelet agonists such as ADP and thrombin can induce the binding of vWF to GPIIb/IIIa.[166,167] This binding is blocked by monoclonal antibodies to GPIIb/IIIa but not by antibodies to GPIb.[126,164] In the presence of normal concentrations of fibrinogen, however, fibrinogen, not vWF, binds to this receptor.[164] This may be in part a result of the fibrinogen concentration being much greater than the concentration of vWF (3 mg/mL vs. 10 μg/mL). In clinical conditions in which fibrinogen is reduced in concentration, vWF can be demonstrated to bind to this receptor and may partially support platelet aggregation in patients congenitally deficient in fibrinogen (afibrinogenemia).[220] *In vivo*, at local sites at which platelets and endothelial cells may participate in hemostasis, secretion of vWF from α-granules and Weibel-Palade bodies may increase dramatically the local concentration of vWF and facilitate vWF interaction with GPIIb/IIIa. In studies on shear-induced platelet aggregation both in a cone viscometer as well as in flow chambers, vWF appears to participate with both the GPIb receptor and the GPIIb/IIIa receptor.[221,222]

Identification of the specific sites of interaction between vWF and platelets has been greatly facilitated by both the delineation of vWF genetic structure and by using specific vWF fragments, synthetic peptides, and recombinant proteins. A crucial interaction site for GPIIb/IIIa is the Arg-Gly-Asp (RGD) sequence at amino acid positions 1744 to 1746 on the *C*-terminal end of the vWF subunit.[223,224] Initial studies indicated that the GPIb binding site for vWF was localized to a disulfide-bonded loop at amino acids 463 to 921 of vWF, which is encoded by exon 28 of the vWF gene.[225,226]

Subendothelial Binding

Types I, III, and VI collagen are known to support platelet adhesion and aggregation.[227] Several putative collagen-binding proteins have been identified on platelets including integrin $\alpha 2\beta 1$, GPVI, and GPIV.[228–232] However, only $\alpha 2\beta 1$ and GPVI have a clear role in collagen-mediated platelet binding. Platelets can also bind to fibrinogen/fibrin, fibronectin, thrombospondin, and laminin.[207] The relative importance of each remains unclear. vWF plays a unique role in platelet adhesion under flow conditions. The mechanism of vWF interaction with components of the blood vessel wall has been extensively studied. Endothelial cells not only secrete vWF but also deposit vWF on the abluminal surface in close association with the internal elastic lamina.[233,234] vWF binds to type VI collagen via the A1 domain, while the A3 domain does not appear to play any role in this interaction.[235] vWF also binds to types I and III collagen and these interactions have been localized to the A1 and A3 domains of vWF.[236] Several mutations have been identified in the A3 domain that result in defective collagen binding to types I and III collagen including S1731T, W1745C, S1783A, and H1786D.[237–240] While vWF binding to type VI collagen appears to occur at low shear rates, the relative contributions of vWF binding to types I, III, and VI collagen *in vivo* have yet to be determined.[240,241] vWF binding to collagen is dependent upon multimer size—only the largest molecular weight multimers bind efficiently. Therefore, the vWF–collagen binding assay may be used to identify lack of high molecular weight multimers as found in types 2A and 2B vWD. Another subendothelial component that may function as a binding site for vWF is the elastin-associated microfibril; extracts of this material cause platelets to aggregate in the presence of vWF, which requires the presence of platelet GPIb receptor.[242,243] Further studies are necessary to fully delineate the various interactions of vWF required for normal hemostatic function.

Interaction with Factor VIII

Antihemophilic factor, Factor VIII, circulates in plasma associated with vWF; this led investigators to conclude that vWF and Factor VIII were the same molecules.[244–249] Other investigators established that these were two independent molecules that circulated together in plasma as an associated complex.[245–249] While the initial name for vWF was factor VIII–related antigen, this is now an outdated and incorrect term (see Table 13.1).

Early studies on patients with vWD demonstrated a reduced level of FVIII.[250–252] When cryoprecipitate was infused into patients with vWD, there was a modest initial increase in FVIII that increased to even higher levels over several hours and then slowly declined. This contrasts sharply with the pattern seen in patients with hemophilia infused with the same product, who have a rapid increase in FVIII with a normal 12-hour half-life.[159,252] Furthermore, early studies demonstrated that after cryoprecipitate or plasma prepared from patients with hemophilia containing no FVIII was infused into patients with vWD, it resulted in a paradoxic increase in plasma FVIII in the patient's plasma.[251–253] Our current understanding is that these two proteins associate

through a noncovalent interaction.[254,255] The infused vWF associates with the endogenously produced FVIII to protect this FVIII from rapid degradation and removal, normalizing the short half-life of the endogenously produced FVIII.[256,257]

Factor VIII is synthesized as a large precursor protein containing repeated domains A1-A2-B-A3-C1-C2. Factor VIII circulates in plasma as a heterodimer of heavy chain A1-A2-B, and light chain A3-C1-C2, in complex with vWF.[258] The binding site on FVIII for vWF was initially localized to the carboxyl terminus of the light chain. Together, the acidic region of the FVIII light chain and the C2 domain form a high-affinity binding site for vWF.[259] Mutations have been identified in hemophilia A patients that affect FVIII binding to vWF including Y1680F, S2119Y, R2150H, and P2300S.[260–262] Within vWF, the binding site for FVIII has been localized to the *N*-terminus region of vWF within the D′-D3 domains.[263] A number of mutations have been identified in type 2N vWD patients with reduced FVIII binding including R760C, R763G, Y795C, Q1053H, C788R/Y, C804F, D879N, C1060R, and C1225G.[264]

It is generally assumed that vWF is synthesized in endothelial cells and megakaryocytes[7,41,43,265] and that FVIII is synthesized in hepatocytes, although expression of FVIII in murine sinusoidal and human microvascular lung endothelial cells has been reported.[266–269] When the drug DDAVP is administered, vWF is released from endothelial cells, and FVIII is found to increase in parallel to the vWF, although the source of this released FVIII remains controversial. It has been demonstrated that if FVIII is produced in a cell that also synthesizes and stores vWF (AtT-20 cells or endothelial cells), FVIII follows vWF into storage granules.[270] In addition, patients with severe hemophilia A who are administered recombinant FVIII for prolonged periods have no increase in their FVIII after administration of DDAVP.[271] Furthermore, the patient with severe vWD who is given only vWF, which results in normalization of FVIII, has been found to have no change in plasma FVIII after the administration of DDAVP. Thus, FVIII and vWF must both be endogenously synthesized for FVIII to be released from storage sites. A study by Lollar and coworkers demonstrates that sinusoidal endothelial cells synthesize and store FVIII together with vWF in *ex vivo* cultured cells.[269] Understanding the mechanism of vWF and FVIII association may be important for the most appropriate transfection strategy in the gene therapy of hemophilia A. The functional reason for the association of FVIII with vWF is not entirely clear, but one could theorize that vWF binding and delivery of FVIII to the phospholipid surface of platelets might be coordinated *in vivo*. Recent studies have demonstrated the potential for targeting FVIII expression to megakaryocytes and platelets for efficient delivery of FVIII to the site of platelet plug formation.[272,273]

Animal Models of vWD

Several animal species have been found to have vWD similar to the human disorder (canine and porcine). A "knockout" mouse model of vWD has also been developed.[110] Porcine vWD has been identified for more than 20 years.[274] This model was used to study both liver and bone marrow transplantation as a means of correcting endothelial (liver) or platelet vWF (bone marrow). Bone marrow corrected the platelet vWF but resulted in only a minimal increase in plasma vWF. Bleeding symptoms decreased and there was partial correction of the bleeding time. Liver transplantation caused a near normalization of plasma vWF levels and a normalization of the bleeding time. Such studies suggest that plasma vWF is primarily derived from endothelial cell vWF synthesis, but that platelet vWF also provides some benefit even if it is not accompanied by an increase in plasma vWF.[275] Canine models of vWD are also available as either type 2 or type 1 vWD.[63,276,277] Such models will be useful in studying gene therapy of vWD. The canine type 2 models are important for studying the variant forms, which are not present in the porcine model. Studies on the porcine and murine model of vWD suggested a potential role for vWF in the development of atherosclerosis and endocarditis.[278] Studies on human vWD have not yet identified a similar protection from atherosclerosis.[279]

CHAPTER

14

Structure and Function of Vitamin K–Dependent Coagulant and Anticoagulant Proteins

KANAGASABAI VADIVEL, AMY E. SCHMIDT, VICTOR J. MARDER, SRIRAM KRISHNASWAMY, AND S. PAUL BAJAJ

Physiologic coagulation is initiated when, upon vascular damage, blood comes into contact with tissue factor (TF) expressed by cells in the extravascular compartment.[1,2,3–7] TF exposed at the injury site complexes with factor VIIa (FVIIa, ~100 pM) as well as with factor VII (FVII, ~10 nM).[8,9] The FVIIa/TF complex activates both factors X (FX) and IX (FIX), leading to thrombin (IIa) generation and fibrin formation (FIGURE 14.1). In positive feedback loops, factor Xa (FXa), factor IXa (FIXa), and FVIIa/TF generate additional FVIIa/TF from FVII/TF.[10–15] Similarly, factor XIa (FXIa), formed by the activation of FXI by thrombin, produces additional FIXa for sustained coagulation.[16,17,18,19,20] FXa initially formed by FVIIa/TF generates small amounts of thrombin, which activates platelets as well as factor V (FV) and factor VIII (FVIII).[21] FIXa and FVIIIa assembled on the surface of the activated platelets convert additional FX to FXa, which complexes with FVa to further augment thrombin generation.[21] In addition to the four procoagulant proteins (FVII, FIX, FX, and FII), three other vitamin K–dependent (VKD) proteins, protein C (PC), protein Z (PZ), and protein S (PS), control the process by acting as anticoagulants. Activated PC (APC) generated by the action of thrombin/thrombomodulin complex inactivates FVa and FVIIIa,[22,23] PZ serves as a cofactor for inhibition of FXa by the protein Z–dependent inhibitor (PZI),[24] and PS serves as a cofactor for inactivation of FVa and FVIIIa by APC.[25,26,27] Other VKD proteins have been described, including osteocalcin (bone metabolism),[28] periostin (matrix homeostasis), and Gas6 (endothelial homeostasis),[29,30] plus others of unknown function.[31] This chapter focuses on the structural and functional aspects of the VKD proteins involved in hemostasis and thrombosis.

MOLECULAR ORGANIZATION OF THE VKD PROTEINS

Domain Organization

Zymogen FVII, FIX, FII, PZ, and PS circulate as single-chain molecules, whereas FX and PC circulate as two-chain molecules.[32,33–39] FVII, FIX, FX, and PC have similar structural architecture, in which an *N*-terminal γ-carboxyglutamic acid (Gla)-rich domain is followed by two epidermal growth factor (EGF)-like domains and a *C*-terminal serine protease domain (FIGURE 14.2).[40–45] PZ has similar domain organization, but it contains a pseudoprotease domain without catalytic activity at the *C*-terminus.[37,38] PS consists of six domains, an *N*-terminal Gla domain, a thrombin-sensitive region (TSR), four EGF-like domains, and a sex hormone globulin binding domain.[46–48] Prothrombin (FII) has a distinct domain architecture, in which the *N*-terminal Gla domain and the *C*-terminal protease domain are linked by the two kringle domains.[49]

Zymogen Activation

The VKD zymogens are synthesized in the liver and secreted into the blood; the molecular mass and plasma concentrations are shown in Table 14.1 (see also Chapter 9).

FVII consists of an *N*-terminus Gla domain (residues 1 to 38), a short hydrophobic segment (residues 39 to 45) followed by two EGF-like domains (residues 47 to 84 and 31 to 85), and a *C*-terminus latent protease domain (residues 153 to 406)[12,34,50] (FIGURE 14.2A). FXa, FIXa, and the FVIIa/TF complex activate FVII by cleaving a single peptide bond between Arg152 and Ile153 located in the connecting region between the EGF2 and the protease domain,[15,51–53] leading to a two-chain molecule (FIGURE 14.3A), a light chain of 152 residues, and a heavy chain of 254 residues linked by a single disulfide bond between Cys-135 and Cys-262.

FIX consists of *N*-terminus Gla domain (residues 1 to 40), a short hydrophobic segment (residues 41 to 46), two EGF-like domains (residues 47 to 84 [EGF1] and 85 to 127 [EGF2]), an activation peptide region (residues 146 to 180), and a latent serine protease module (residues 181 to 415) (FIGURE 14.2A).[33,54,55] Activation of FIX requires two peptide bond cleavages, one at Arg145–Ala146 and Arg180 and one at Val-181, releasing a 35-residue activation peptide (FIGURE 14.3A).[32,56] The resulting FIXa consists of a light chain containing Gla, EGF1, and EGF2 domains (residues 1 to 145) and a heavy chain containing the protease domain (181 to 415) held together by a single disulphide bond.

FX consists of a light chain (amino acids 1 to 139) and a heavy chain (amino acids 143 to 448) held together by a single disulfide bond between Cys-132 and Cys-c302 (FIGURE 14.2A).[35] The release of a 52-residue activation peptide after cleavage at Arg194–Ile195 (by FVIIa/TF, FIXa/FVIIIa, or Russell's viper venom protease) in the heavy chain leads to the generation of FXa (FIGURE 14.3A).[57] The light chain of FXa contains *N*-terminus Gla domain (residues 1 to 39), a hydrophobic stack of residues (residues 40 to 45), EGF1 domain (residues 46 to 84), and EGF2 domain (residues 85 to 128), and the heavy chain contains the protease domain (residues 195 to 448).

Prothrombin (FII) is the most abundant VKD protein in plasma and circulates as a single-chain molecule consisting of an

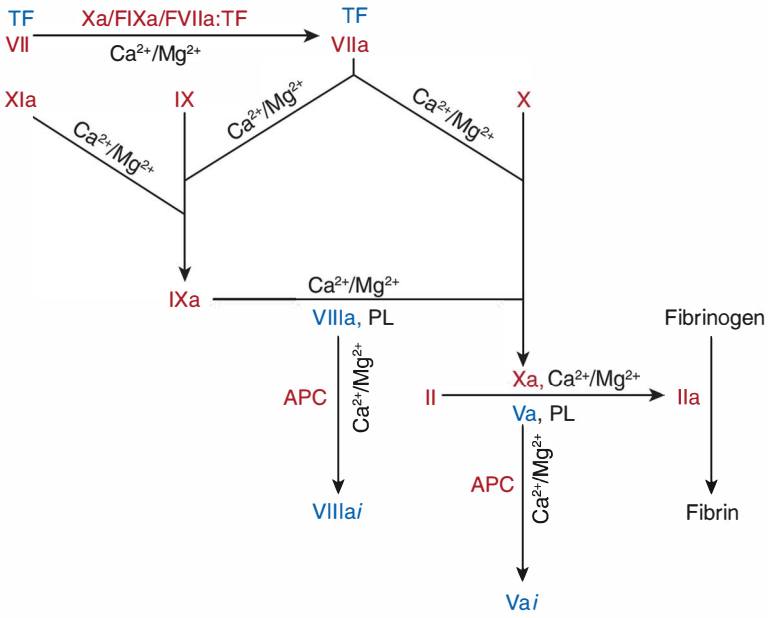

FIGURE 14.1 The role of VKD coagulant and anticoagulant proteins in hemostasis. The FVIIa/TF (extrinsic tenase complex) converts zymogens FX and FIX into their respective active FXa and FIXa forms. In positive feedback loops **(top left)**, FXa, FIXa, and FVIIa/TF activate FVII/TF. FIXa bound to FVIIIa (intrinsic tenase complex) activates FX to FXa on the phospholipid (PL) surfaces, FXa then binding to FVa (prothrombinase complex) to convert prothrombin (II) to thrombin (IIa). APC inactivates FVa (to FV*ai*) and FVIIIa (to FVIII*ai*). Activation of PC to APC by the IIa/-thrombomodulin complex and that of FXI to FXIa by IIa are not shown. Under physiologic conditions, all activation and inactivation processes involving VKD enzymes are Ca^{2+}/Mg^{2+} dependent. Although Ca^{2+} alone can function in these reactions, free Mg^{2+} can substitute for Ca^{2+}. Enzymes and inactive precursors are shown in *red*, cofactors in *blue*.

N-terminal Gla domain, two kringle domains, and a latent serine protease domain (FIGURE 14.2A).[49,58,59] *In vitro*, thrombin cleavage of prothrombin at Arg155–Ser156 generates prothrombin fragment-1 (PF1) and prethrombin-1 (PT1) (FIGURE 14.3B).[60,61] PF1 consists of Gla domain (residues 1 to 40) and kringle-1 domain (residues 65 to 155), whereas PT1 consists of prothrombin fragment-2 (PF2, residues 156 to 271), and prethrombin-2 (PT2), which contains the A chain (residues 272 to 320) and B chain (residues 321 to 579) of the *C*-terminus latent protease domain (FIGURE 14.3C). Cleavage of PT1 by FXa at Arg271–Thr272 releases PF2 from PT2. Proteolysis at Arg320–Ile321 by FXa then results in the two-chain active thrombin, which cleaves itself at R284-T285 to generate stable α-thrombin.[32,62,63] Physiologic activation of prothrombin by the prothrombinase complex (FXa, Ca^{2+}/Mg^{2+}, PL, FVa) occurs by sequential proteolysis at Arg271–Thr272 and Arg320–Ile321.[32,63,64] Initial cleavage at R320-I321 between the A and B chains is the preferred pathway under physiologic conditions and generates the active intermediate meizothrombin that retains all four domains of prothrombin. The alternative initial cleavage at Arg271–Thr272 generates inactive precursor PT2 (residues 272 to 579) and a combined PF1 and PF2 (residues 1 to 271). Cleavage of PT2 by FXa at Arg320–Ile321 generates a two-chain active thrombin composed of a 49 residue A chain and 259 residue B chain. This two-chain molecule, further processed by thrombin which cleaves chain A at Arg284, generates a stable α–thrombin with 36 residues A chain (FIGURE 14.3B).

APC circulates as a disulfide-linked two-chain zymogen PC.[65,66,67] The *N*-terminal light chain contains the Gla domain and two EGF-like domains (EGF1 and EGF2), and the heavy chain contains the latent serine protease domain (FIGURE 14.2B).[22,68,69] Although α–thrombin can activate PC to APC, the rate is extremely slow for a physiologically significant reaction. The physiologic activator of PC is the thrombin/thrombomodulin complex at the endothelial surface.[23,70,71] During conversion of PC to APC, a short 12-peptide fragment is removed from the heavy chain *N*-terminus to generate the active protease (FIGURE 14.3A).[60]

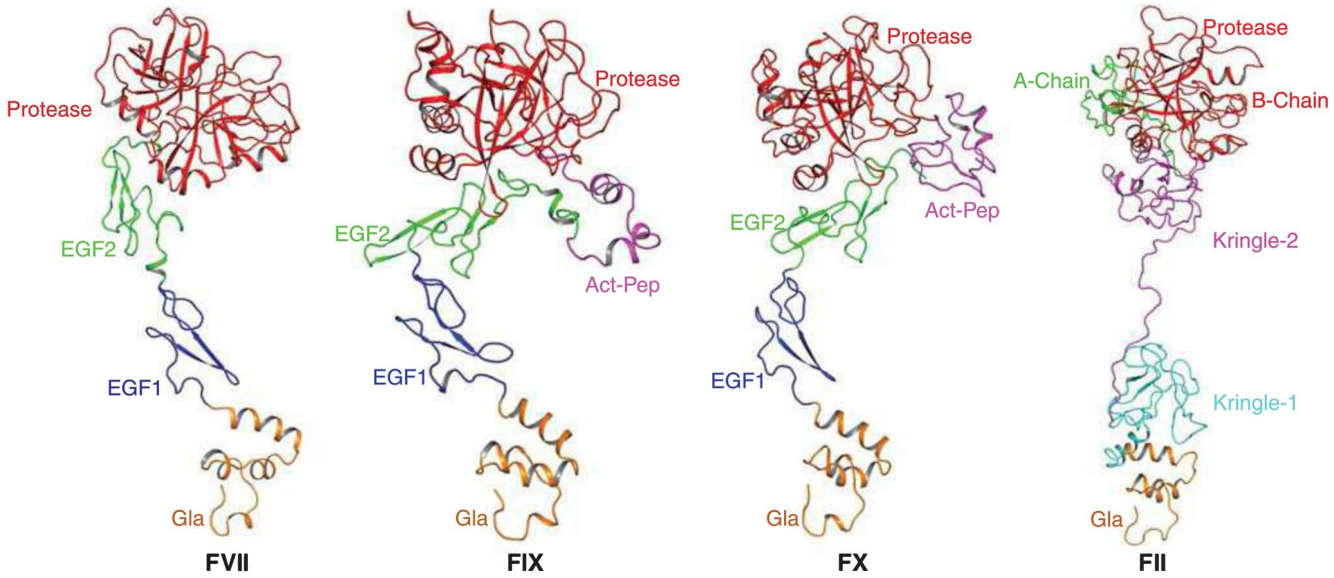
Cofactor Participation

The catalytic activity of each VKD proteolytic protein is augmented by binding to their respective cofactors (Table 14.2). TF functions as a cofactor for FVIIa in the activation of FX and FIX. TF is an integral membrane protein and consists of an extracellular region, a transmembrane region, and a cytoplasmic region, which is structurally homologous to the class 2 cytokine receptor family.[72] The extracellular region is made up of two fibronectin type-III domains that interact with all FVIIa domains.

FIXa requires FVIIIa as a cofactor for effective activation of FX. FVIII circulates in plasma in an inactive form consisting of a heavy chain (Mr varies between 90,000 and 200,000) that contains A1, A2, and B domains and a light chain (Mr ~ 80,000) that contains A3, C1, and C2 domains.[73,74] The activated form of FVIII is generated by the removal of B domain, either by FXa or by thrombin.[75] Similarly, FVa acts as a cofactor for FXa to augment prothrombin activation. FV (Mr ~ 330,000) circulates in plasma as a single-chain molecule having a similar domain organization as FVIII.[76,77] The release of domain B by the action of thrombin generates FVa,[78] a two-chain molecule consisting of a heavy chain (A1-A2 domains) and a light chain (A3-C1-C2 domains) (see Chapter 12).

PZ circulates in complex with PZI, as a single-chain molecule,[79] consisting of an *N*-terminus Gla domain (residues 1 to 41), two EGF-like domains (EGF1, residues 42 to 82; EGF2, residues 83 to 139), and a pseudocatalytic domain (residues 149 to 360) (FIGURE 14.2B). The typical active site residues of the serine proteases, His57 and Ser195 (chymotrypsin numbering), are replaced with Lys and Asp, respectively, in the *C*-terminal domain.[37]

PS circulates as a single-chain molecule[80] consisting of an *N*-terminus Gla domain (residues 1 to 41), a unique TSR (residues 42 to 75), four EGF-like domains (EGF1, residues 76 to 114; EGF2, residues 115 to 159; EGF3, residues 160 to 201; EGF4, residues 202 to 242), and a *C*-terminus sex hormone binding globulin (SHBG) domain (residues 243 to 635), which is completely different from other VKD proteins.[80] The SHBG



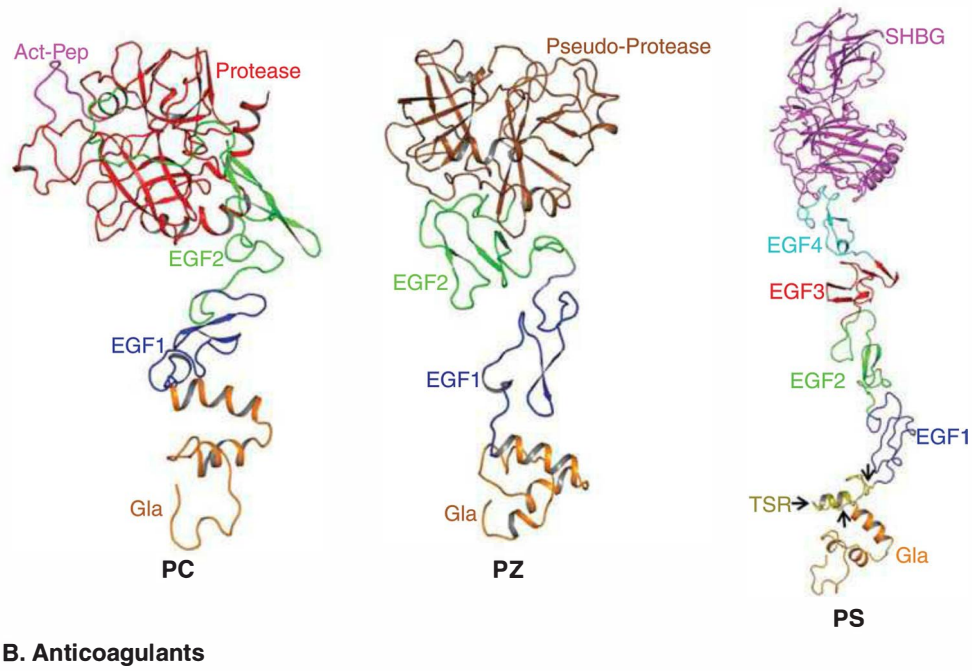


FIGURE 14.2 Modeled structures of the zymogen forms of coagulant **(A)** and anticoagulant **(B)** VKD proteins. The Gla domains are shown in *orange*, EGF1 domains in *blue*, EGF2 domains in *green*, and protease domains in FVII, FIX, FX, II, and PC in *red*. Kringle domains 1 and 2 of FII are colored *deep teal* and *magenta*, respectively, and the segments that become A and B chains in α-IIa are colored *green* and *red*, respectively. Activation peptide regions in FIX, FX, and PC are colored *magenta*. The pseudoprotease domain of PZ is colored *brown*. The thrombin-sensitive region (TSR), the EGF3, EGF4, and SHBG domains in PS are colored *yellow*, *red*, *deep teal*, and *magenta*, respectively; the SHBG domain in PS contains two laminin G-type binding subdomains.

region consists of two laminin G–like domains. PS functions as a cofactor for the anticoagulant APC and enhances the inactivation FVa and FVIIIa.[27,81,82]

POSTTRANSLATIONAL PROTEIN PROCESSING

γ-Carboxylation and Propeptide Cleavage

The propeptide region contains the carboxylase recognition site. In FIX, site-specific mutagenesis of Phe(−16) to Ala and Ala(−10) to Glu inhibits γ-carboxylation.[83,84] Naturally occurring Ala(−10) to Thr or Val and Asn(−9) to Lys mutations lead to warfarin hypersensitivity where severe depression of FIX occurs despite mild reductions in other VKD proteins.[85–87] Synthetic FIX propeptides with Thr(−10) or Gly(−10) have reduced carboxylase affinity compared to Ala(−10),[87] and mutation of Leu(−6) to Asp in FIX leads to impaired γ-carboxylation in tissue culture.[88] Similar studies on FII show that the propeptide residues at −18, −17, −15, and −10 are important for γ-carboxylation.[89] A DNA construct in which the propeptide region was placed adjacent to a region of thrombin rich in Glu residues resulted in γ-carboxylation of the Glu residues to Gla.[90] Moreover, deletion mutants of proprotein C lacking residues −17 to −12 were also defective in γ-carboxylation.[91] The NMR structure of synthetic FIX propeptide shows that the γ-carboxylase recognition site is likely within

Table 14.1
Properties of VKD zymogens

Zymogen	Number of Amino Acids	Molecular Mass (kDa)	Plasma Concentration (μg/mL)	Plasma Concentration nM
FVII	406	50,000	0.5	10
FIX	415	57,000	5	90
FX	448	59,000	10	180
FII	579	72,000	100	1390
PC	419	62,000	4	65
PZ	360	62,000	2–3	60
PS	635	69,000	25	360

an α–helical region that includes a hydrophobic surface similar to prothrombin.[92,93] These data support a concept that the propeptide region itself is sufficient to support γ-carboxylation.

Synthetic peptides with a complete propeptide sequence of FII were able to have their respective Glu residues γ-carboxylated efficiently with a K_m of approximately 3 μM,[94,95] whereas peptides with a shortened propeptide region or without the γ-carboxylase recognition site were poorly γ-carboxylated.[94,95] Moreover, a synthetic peptide based upon the propeptide sequence of FX stimulates γ-carboxylation of a pentapeptide Phe–Leu–Glu–Glu–Leu approximately eightfold.[96] Thus, it is feasible that the catalytic activity of carboxylase is regulated by binding to its normal substrate.

Importantly, the Gla domains also play a role in γ-carboxylase binding. In FIX, linkage of the propeptide to the Gla domain increased its affinity approximately 20-fold for γ-carboxylase.[97] Moreover, the Gla domain was found to play an important role in the rate of release of FIX from γ-carboxylase as the k_{off} of fully

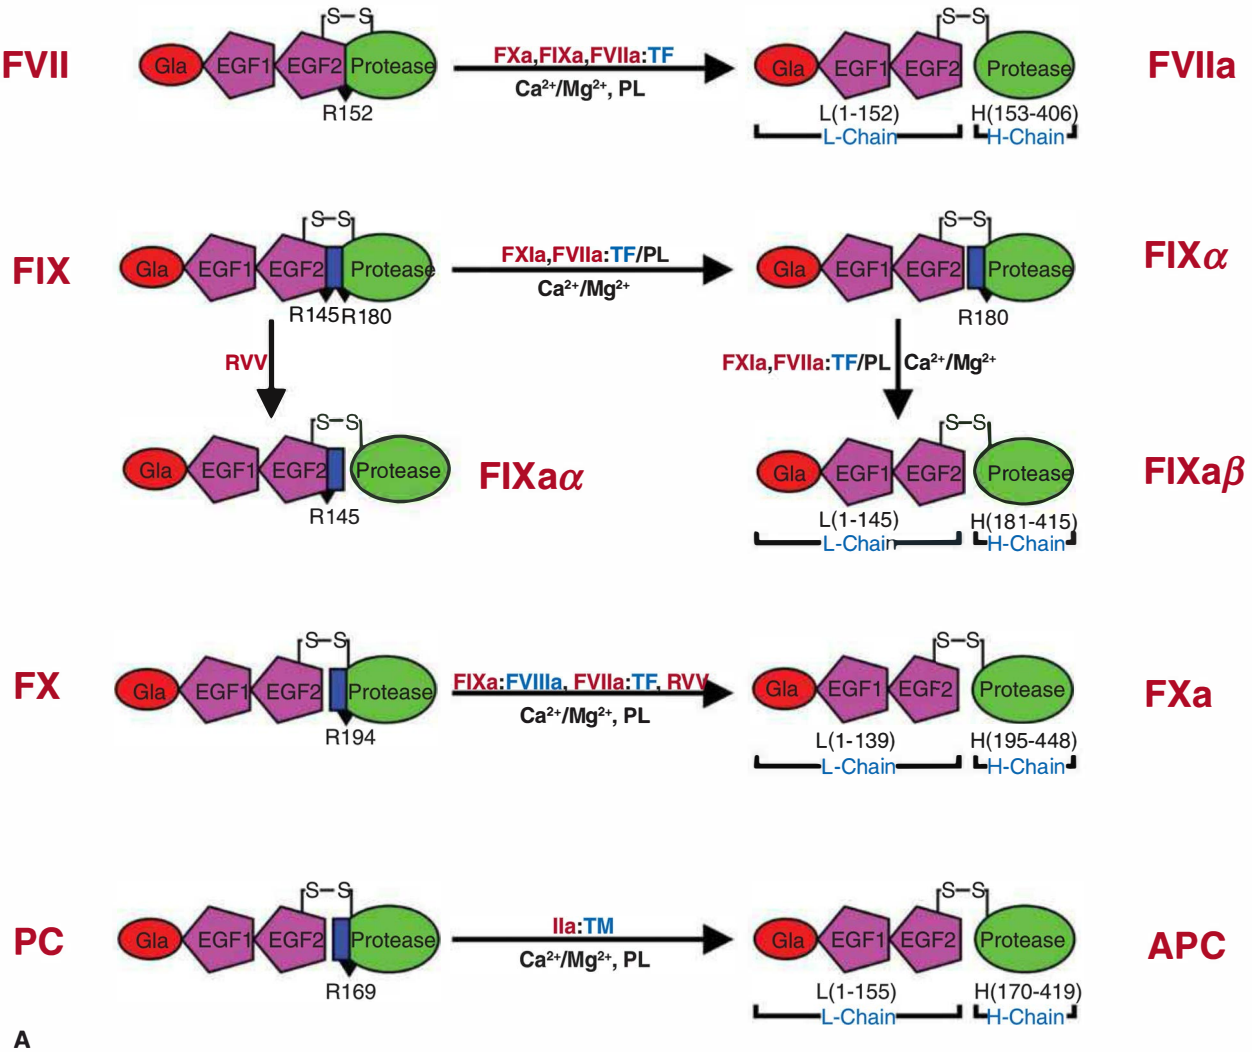

FIGURE 14.3 Schematic representation of zymogen activation. **A**: FVII, FX, and PC are converted to active forms by cleavage at a single residue at R152, R194, and R169, respectively. FIX is activated by FXIa and FVIIa/TF by sequential cleavages at R145 and R180 and by RVV by cleavage at R180. The activation peptide regions in FIX, FX, and PC are shown as *blue rectangles*, and the cleavage sites are marked with *black triangles*.

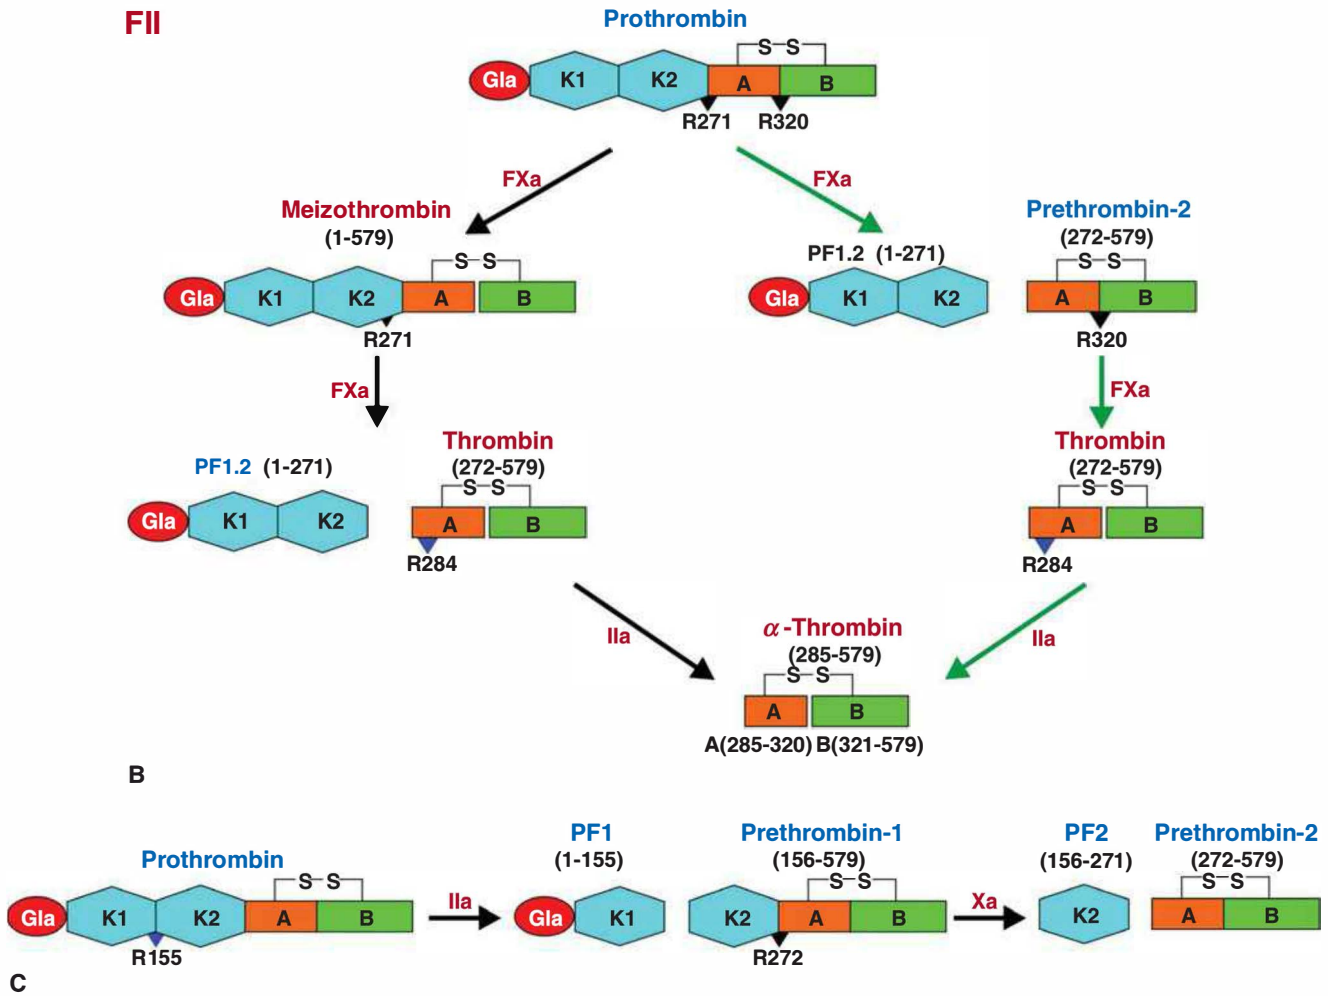

FIGURE 14.3 *(Continued)* **B**: Physiologic generation of thrombin from prothrombin. FXa converts prothrombin to thrombin, by proteolytic cleavages at R272 and R320, which occurs by two pathways. In one pathway (*black arrows*), cleavage at R320 yields meizothrombin, which is then cleaved at R271 to yield thrombin and PF1.2. In the second pathway (*green arrows*), cleavage at R271 yields PT2 and PF1.2. The generated PT2 is cleaved at R320 by FXa to yield thrombin. Thrombin generated by either pathway is further cleaved at R284 by thrombin itself to yield stable α-thrombin. FXa cleavage sites are indicated by *black triangles* and the thrombin cleavage site by the *blue triangle*. **C**: Thrombin-initiated conversion of prothrombin to thrombin starts with cleavage at R155, yielding PF1 and PT1. FXa cleavage at R272 in PT1 yields PF2 and PT2, which is converted to thrombin. Gla, γ-carboxyglutamic acid–rich domain; EGF1, epidermal growth factor–like domain 1; EGF2, epidermal growth factor–like domain 2; K, kringle domain; PF1, prothrombin fragment-1; PF2, prothrombin fragment-2; PF1.2, prothrombin fragment-1 and fragment-2.

Table 14.2
Cofactors for VKD enzymes

Cofactor	Enzyme	Substrate
TF	FVIIa	FX, FIX
FVIIIa	FIXa	FX
FVa	FXa	FII
PS	PC	FVa, FVIIIa
PZI	PZ	FXa

γ-carboxylated FIX Gla domain was approximately threefold faster than the k_{off} of noncarboxylated Gla domain.[97] Absence of γ-carboxylation at two or more sites results in a prothrombin molecule that is an ineffective substrate for the prothrombinase complex.[98] Thus, the prothrombin deficient in γ-carboxylation cannot bind Ca^{2+} and fails to undergo conformational changes that occur with Ca^{2+} binding. Moreover, the molecules are defective in binding to the PL surface on which the prothrombinase complex assembles.

The propeptide is cleaved from each VKD protein by PACE/furin,[99] which recognizes a consensus sequence Arg–X–Arg/Lys–Arg at positions −4 to −1 and cleaves after the −1 position Arg residue. In FIX, this sequence includes three basic residues,

Arg(−4)–Pro–Lys–Arg(−1)–Tyr(+1). Hemophilic mutations at the −4, −2, and −1 positions (P4, P2, P1) cause a severe bleeding tendency due to dysfunctional FIX.[100–102] FIX of hemophiliacs with Arg(−4) to Trp, Gln, or Leu react normally to antibodies that bind in the presence of Mg^{2+}, indicating that γ-carboxylation has occurred, but the FIX mutant proteins require more than 5 mM Ca^{2+} for binding to the PL surfaces.[103] Similarly, site-specific mutagenesis of Arg(−1) to Thr reduced propeptide cleavage by more than 99%, and nonconservative mutations at Pro(−3) and Leu(−6) also reduced propeptide cleavage in FIX.[104] Recombinant profactor IX with[105] full γ-carboxylation does not bind to PL membrane and is not activated by FXIa unless the propeptide is cleaved by PACE/furin. Thus, a free *N*-terminus is essential for proper conformational folding of the Gla domain, and acylation of Tyr(+1) is sufficient to prevent FIX binding to PL.[103]

β-Hydroxylation

The VKD proteins undergo posttranslational modification *via* hydroxylation of Asp and Asn residues by aspartyl β-hydroxylase.[106,107] FIX has β-hydroxylation at Asp64 in the EGF1 domain.[108] However, only one-third of the Asp64 residues are hydroxylated,[109] inhibition of hydroxylation in recombinant FIX does not decrease activity,[110] and the hydroxyl group is not necessary for Ca^{2+} binding.[111,112] Bovine FVII contains a β-hydroxyaspartic acid in the EGF1 domain at Asp63; however, Asp63 in human FVII is not β-hydroxylated.[113] PS contains a β-hydroxyaspartic acid at residue 95 in the first EGF domain, and the other three EGF domains contain β-hydroxylated Asn residues, which are incompletely hydroxylated.[114,115] Asp63 is hydroxylated in FX,[116] and Asp71 in PC,[117] whereas Asp64 is β-hydroxylated in PZ.[118]

Signal Peptide and Its Cleavage

In FIX, the hydrophobic signal peptide residue Ile30 is important as the hemophilic mutation to Asn results in no detectable FIX antigen.[100] FIX signal peptide cleavage occurs between Thr18 and Cys19 and mutation of Cys19 to Gly, Arg, Trp, or Tyr is associated with hemophilia B.[100] When the signal and propeptide sequences of FIX are substituted for those of PC, full γ-carboxylation occurs,[119] indicating that the signal and propeptide sequences are not specific among homologous VKD proteins (see Chapter 9).

Glycosylation, Sulfation, and Phosphorylation

Glycosylation occurs either *via* Asn or Ser/Thr residues, forming amide linked (*N*-linked) or *O*-glycosidically linked (*O*-linked) carbohydrate chains. Human FVII contains two *N*-linked carbohydrate chains attached to the residues Asn145 and Asn322[113] and two *O*-linked carbohydrate chains attached to the residues Ser52 and Ser60 in the EGF1 domain. Ser52 is linked to disaccharide (Xyl–Glc) or trisaccharide (Xyl_2–Glc),[120] whereas Ser60 is linked to a fucose.[121] Alanine mutations at Ser52/Ser60 revealed that these *O*-glycosylation sites do not affect TF binding or the proteolytic activity of FVIIa/TF complex toward FX or FIX, even though the mutant FVIIa had reduced activity.[122]

Bovine FIX contains 26% carbohydrate[123] and human FIX contains 17%,[124] oligosaccharides primarily *N*-linked to consensus Asn–Xxx–Thr/Ser sequences (four in bovine and two in human). The two sites of *N*-linked glycosylation in FIX are Asn157 and Asn167, both within the activation peptide region.[33] FIX from all species, all besides humans have an *N*-linked glycosylation at Asn260, all have Asn157, all but porcine have Asn167, and the sequences of ovine, bovine, and porcine predict an Asn172 site.[125] Notably, FIX activity is preserved following sialic acid removal with neuraminidase.[126] In the first EGF domain of FIX, Ser53 has *O*-linked di- and trisaccharides [Xyl_1- or Xyl_2-Glc-*O*-Ser][120] and Ser61 contains a tetrasaccharide [NeuAc-Gal-GlcNAc-Fuc-*O*-Ser].[127] Of note is the fact that FIX proteins from other species such as porcine do not have homologous Ser residues, so *O*-linked carbohydrate moieties in the EGF1 domain are unlikely to have functional importance. In the FIX activation peptide, the hydroxyl groups of Thr159 and Thr169 are glycosylated.[128] Plasma-derived FIX has an *O*-linked oligosaccharide at Thr172, sulfation of Tyr155, and phosphorylation of Ser158.[129] Importantly, of all the activation peptide modifications in FIX, only the equivalent of Ser158 phosphorylation and *N*-linked glycosylation at Asn157 are conserved in other species. Lastly, the catalytic serine protease domain has no posttranslational modifications.[129,130]

Human FX contains two *N*-linked carbohydrate chains attached to residues Asn181 and Asn191[35] and two *O*-linked carbohydrate chains attached to Thr159 and Thr171.[131] The *O*-glycosylation sites are found in the activation peptide region, which is removed during activation to FXa. Human FX contains neutral bi-, tri-, and tetra-antennary complex type oligosaccharides without a fucose residue at the *N*-glycosylation sites and disialylated Galβ1-3GlaNAc sequences at the *O*-linked sites.[132] The removal of the activation peptide or the Asn191 to Ala mutation affects the activation of FX by FVIIa/TF[133,134] and FIXa/FVIIIa[133] marginally. However, in another study, the carbohydrates contribute to the cofactor-dependent recognition of the zymogen by both the extrinsic and intrinsic Xase complexes.[135] Thus, the physiologic role of carbohydrate chains in FX remains unclear.[133–135] Human FII contains approximately 10% carbohydrates attached through the three *N*-linked glycosylation sites at Asn78 and Asn100 in the kringle-1 domain of PF1 and Asn102 of the thrombin B chain.[136] Partial deglycosylation at Asn102 using neuraminidase, β-galactosidase, and β-*N*-acetylglucosaminidase suggests that the carbohydrates at this site had no effect on thrombin functions.[137]

Similar to prothrombin, human PC contains only *N*-linked glycosylation sites. The *N*-linked glycosylation in PC is highly variable with several glycosylation variants present in human plasma that contain bi-, tri-, or tetra-*N*-linked carbohydrates attached to Asn97, Asn248, Asn313, and Asn329.[68,138] Mutational studies carried out at each glycosylation site of PC indicate that Asn97 glycosylation is essential for the efficient secretion of PC and affects the degree of core glycosylation at Asn329.[139] All glycosylation variants of PC can be activated; however, they have different rates of activation as well as different anticoagulant activities. Elimination of all the glycosylation sites in PC increases the anticoagulant activity two- to threefold.[140] Elimination of only the *N*-linked site at Asn313 yields a 2.5-fold increase in the rate of PC activation due to a decrease in K_m.[139] A polylactosamine on PC has been implicated in inhibiting cell adhesion through E selectin and may represent a potential anti-inflammatory function.[140]

Human PZ contains nine potential carbohydrate sites, of which five are *N*-linked sites and the other four are *O*-linked sites. The potential *N*-linked oligosaccharide are Asn59, Asn185, Asn193, Asn266, and Asn292, and the potential *O*-linked oligosaccharide sites are Ser53, Ser72, Ser196, and Ser275.[38] Ser53 is linked to either Xyl–Glc or the Xyl_2–Glc.[120] The functional role of

carbohydrate chains in PZ is unknown. PS contains three potential *N*-linked glycosylation sites at residues Asn458, Asn468, and Asn489 in the SHBG domain.[27,141] Asn to Gln mutagenesis revealed that Asn458 mutant affects cofactor activity while the Asn468 mutant affects γ-carboxylation.[142,143]

VKD CRYSTAL STRUCTURES

The coagulation process is regulated by VKD proteins that appeared to be evolved from the common ancestor. These proteins share high degree of sequence and structural homology; however, each VKD protein performs its function in a precise, controlled manner. Among the VKD proteins, FVIIa is the only one whose complete structure has been determined.[144,145] FVIIa adopts an extended conformation, where the Gla domain is on one end of the molecule and the catalytic domain is on the other. The binding of FVII/FVIIa to TF makes FVII/FVIIa somewhat more rigid and less flexible.[146] The sequence similarity and domain organization of FIXa, FXa, and APC indicate that these proteins may assume similar conformations.[147,148,149,150–154,155]

Crystal structures of IIa and its different forms as well as of FII fragments have been determined; these include PF1,[156,157] PT1,[158] meizothrombin des-F1,[159,160] PF2,[161] PT2,[162–164] and native and mutant thrombins.[165,166–175] The EGF2-protease segment of PZ in complex with ZPI has been reported,[176,177] but for PS, only the NMR structures of EGF3–EGF4 domains have been reported.[178]

Gla Domains

The common structural element among all VKD proteins is their *N*-terminal Gla domain, the glutamic acid residues within the first 40 residues being converted to Gla residues by carboxylase. The binding of Ca^{2+} and Mg^{2+} divalent metal ions to the Gla domain induces a structural transition from an unfolded, nonfunctional form to a folded functional form. In its functional form, the Gla domain binds to phosphatidylserine-exposed PL membranes with the aid of solvent-exposed hydrophobic residues in the ω-loop. Prothrombin, FVII, APC, and PS each contain seven divalent metal binding sites in their Gla domains, whereas FIX, FX, and PZ contain more than seven sites. In addition to membrane binding, Gla domains serve as cofactor and/or substrate binding recognition sites.

FVII/VIIa. Seven divalent metal binding sites[144] have been identified in the Gla domain of FVII/FVIIa and are necessary for stabilizing its functional fold. Among the 10 Gla residues present in FVII/FVIIa, 9 are associated with the metal ions. In the crystal structure of FVIIa/TF solved in the presence of Ca^{2+} only (PDB id 1DAN), all seven sites in the Gla domain are occupied by Ca^{2+} ions,[144] whereas in the presence of Ca^{2+}/Mg^{2+} (PDB id 2A2Q,[145]), three of the seven Ca^{2+} ions at positions 1, 4, and 7 are replaced by Mg^{2+} (compare FIGURE 14.4A,B). The fold of the Gla domain ω-loop in FVIIa is different between these two structures (FIGURE 14.4C). Folding of the ω-loop under near physiologic concentrations of Ca^{2+}/Mg^{2+} is similar to 2A2Q

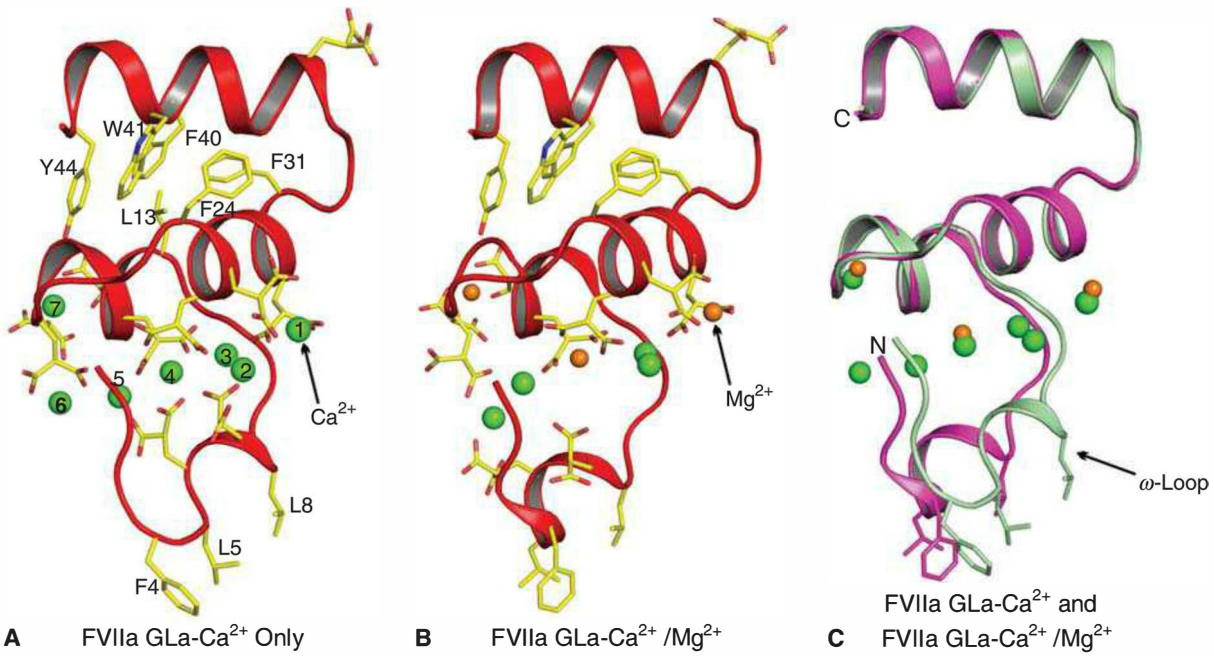

FIGURE 14.4 Structure of the FVIIa Gla domain in the presence of Ca^{2+} only, and with Ca^{2+} and Mg^{2+}. **Left**: Structure of the Gla domain in the presence of Ca^{2+} only.[144] The Gla domain of FVIIa contains seven metal binding sites, and all are occupied by Ca^{2+} in this structure. **Center**: Folding of the Gla domain in the presence of Ca^{2+}/Mg^{2+}.[145] In this structure, the external (numbers 1 and 7) and the central (number 4) metal sites are occupied by Mg^{2+} while the other sites are occupied by Ca^{2+}. **Right**: The superimposed structures shown in "A" and "B." Although the divalent metal ions occupy similar positions in the two structures, the fold of the ω-loop is different between the two structures. The membrane binding residues Phe4, Leu5, and Leu8 in the ω-loop as well as the Gla residues and the hydrophobic residues in the *C*-terminal helix of the Gla domain are shown in stick representation. The Ca^{2+} (*green*) and the Mg^{2+} (*orange*) are shown as *spheres*. The numbering system used is that of Tulinsky et al.[156]

structure, with identical positions for four Ca^{2+} and three Mg^{2+} (PDB id 3TH2,[179]). Further, the folding of the ω-loop under 45 mM Ca^{2+}/5 mM Mg^{2+} is similar to that reported in the presence of Ca^{2+} only (PDB id 3TH4,[179]); however, positions 1 and 7 are occupied by Mg^{2+} (PDB id 3TH4). Thus, it would appear that four Ca^{2+} and three Mg^{2+} ions are bound to the Gla domain in circulating FVII/FVIIa.

The portion of the Gla domain located at the bottom of FVIIa (FIGURE 14.5A) contains three solvent-exposed hydrophobic residues (Phe4, Leu5, and Leu8) present in the ω-loop that are hypothesized to be inserted into the PL membrane.[180,181] The carboxy terminus of sTF is also located near the bottom of the structure; in intact TF, this part of the molecule is linked to the membrane anchor by a short peptide sequence. Therefore, the membrane surface should be located at the bottom of the Gla domain, with TF linked to the membrane by its membrane-anchoring domain and the FVIIa interacting with PL head groups through the Gla domain. Fluorescence resonance energy transfer experiments indicate that the FVIIa/TF complex is oriented almost perpendicular to the membrane, with the active site of FVIIa located approximately 78 Å above the membrane surface.[182]

In addition to membrane binding, FVIIa Gla domain is involved in binding to the *C*-terminal region of TF, a mainly hydrophobic interaction involving the hydrophobic residues present in the Gla *C*-terminal helix. The FVIIa Gla domain also plays a role in FIX and FX substrate interaction where it serves the exosite recognition sites for macromolecular substrates. Biochemical and modeling data suggest that residues Asp33, Ala34, Gla35, Arg36, Leu39, Trp41, Ile42, and Lys48 in the FVIIa–Gla domain are involved in substrate interaction.[183–187]

FIX/IXa. The Gla domain of human FIX contains 12 Gla residues,[188] the first 10 of which are at homologous positions of other VKD proteins. The FIXa Gla domain undergoes a transition to an ordered structure on addition of Ca^{2+} or Ca^{2+}/Mg^{2}, as seen in x-ray diffracted crystals[189,190]; NMR studies indicate a very similar structure for FIX Gla domain in solution.[191,192] The coordination of the Ca^{2+} within the FIX Gla domain differs slightly from those in FVII, FX, and FII (FIGURE 14.5A).[193,194] The FIX Gla domain binds to eight Ca^{2+}, five of which are internal and three are on the surface and contribute to surface charge.[189,190] The three surface sites bind to Mg^{2+} as well.[189] Of the Gla residues, 8 of the first 10 that are homologous to the other VKD proteins are essential for activity. Of the 10, hemophilia B is associated with mutations in all but Gla15,[100] which coordinates to Ca^{2+}-7.[189,190] Gla21 mutations result in an inactive protein.[193] This is interesting because Gla21 coordinates to Ca^{2+}-6[189] and Ca^{2+}-6 coordinates to lysophosphatidylserine, displacing a water molecule from the coordination sphere in PF1.[190] In contrast, the nonhomologous Gla36 and Gla40 do not contribute to activity[194]; however, they provide all four ligands in coordinating to Ca^{2+}-8 or Ca^{2+}-9[193], indicating that Ca^{2+}-8 or Mg^{2+}-8 (FIGURE 14.5A) is not necessary for FIXa activity.

Antibodies that bind to the FIX Gla domain in the presence of divalent metal ions indicate the presence of both Ca^{2+} and Ca^{2+}/Mg^{2+}-dependent epitopes, and the latter are localized to the carboxy terminus of the domain.[195] Mg^{2+} binding to the Gla domain are important for FIX activity.[196,197] Comparison of immunoreactivity of FIX molecules substituted with portions of the FVII Gla domain indicates that Gla33, Thr39, and Gla40 are involved in a high affinity where Mg^{2+} can bind.[198] The ω-loop in FIXa is important in binding to negatively charged PL surface, involving Lys5 (FIGURE 14.5A) binding to the glycerol phosphate backbone and the carboxyl group of phosphatidylserine coordinating to Ca^{2+}-5 and Ca^{2+}-6 as has been shown for PF1.[157,199] Further, Mg^{2+} binding to the Gla domain enhances binding of FIX to PL at physiologic Ca^{2+}.[200]

Gla20 and Gla21 are in a conserved 4–amino acid disulfide loop that is buried with hydrophobic interactions to an aromatic stack composed of Phe41, Trp42, and Tyr45 near the carboxy terminus of the domain. Hemophilic or recombinant mutations of the Cys residues inactivate the protein.[201] Recombinant FIX without the aromatic stack can be activated by FXIa but has low specific activity; mutagenesis of Phe41 to Val or Asp similarly affects activity whereas Tyr41 retains 64% of FIX activity.[202] The Gla domain of FIX is important for activation by both FVIIa/TF[203] as well as by FXIa.[204,205] The Gla domain of FIXa has been implicated in binding to TF in the FVIIa/TF:FIXa ternary complex[187,206] and binds directly to FXIa.[205] The Gla domain of FIXa also binds to the FVIIIa C2 domain (A3-C1-C2),[207,208] most likely involving Phe25 and Val46. Mutation of Gly12 to Arg disrupts FVIIIa binding[209]; however, this is most likely due to a structural impairment rather than from a direct binding effect. More studies are needed to elucidate the exosites on FIXa important in binding to FVIIIa.

Cultured endothelial cells have specific receptors that bind FIX and FIXa,[210,211] allowing intrinsic FX activation without the need for platelets; this binding may also occur *in vivo*.[212] As is the case with the PL, binding of the Gla domain of FIXa involves residues 3 through 11[213] although collagen may account for some of the binding.[214] Using protein fragments to inhibit ^{125}I-labeled FIX binding to cultured endothelial cells, determinants in the first EGF-like domain of FIX were demonstrated, whereas binding to PL was only competed with the Gla domain peptides.[215] From domain exchange experiments with FIX and PC, optimal endothelial cell binding appears to involve the entire FIX Gla domain including its aromatic stack.[216] In kinetic studies, FVIIa activated FIX, but not FX, directly on the endothelial surface, and FIX activation was about one-sixth as rapid as compared to observed with stimulated platelets.[217]

In vivo, there is a basal low level of FIX activation by FVIIa,[218] presumably at the endothelial cell surface. Mutation of Lys5 to Ala or Val10 to Lys considerably reduces the affinity of FIX for endothelial cells, whereas Lys5 to Ala increases FIX affinity for bovine vascular endothelial cells threefold.[213] The endothelial cell–binding site for FIX involves two sites on collagen IV that are 50 and 98 nm from the *C*-terminus of collagen IV.[214,219] Further, FIX binds *in vivo* to the endothelial cell collagen IV surface,[220] and this binding may play an important role in regulating the concentration of FIX in the blood.

The distance from a rhodamine-labeled lipid surface to a fluorescein-labeled FIXa active site is at least 70 Å,[221] a value consistent with the molecular dimensions of the crystallographic structure if lipid binding involves the Gla domain and the balance of the protein extends vertically above the surface.[147] Electron crystallographic studies of two-dimensional (2-D) crystals of human FIX zymogen bound to a lipid layer support this orientation.[222]

FX/Xa. The human FX Gla domain contains 11 Gla residues and binds 8 Ca^{2+} ions (FIGURE 14.5A),[223] 7 of which have been observed in the crystal structure of the Gla domain of bovine FX. The Ca^{2+}-8 was not seen in the crystal structure and is

FIGURE 14.5 Structures of the Gla domains of coagulant **(A)** and anticoagulant **(B)** VKD proteins in the presence of Ca^{2+}. FVII, FII, PC, and PS contain seven metal binding sites, while FIX, FX, and PZ contain more than seven sites in their respective Gla domains. The Gla residues and the membrane binding hydrophobic residues at the *C*-terminal helix of the domain are shown in stick representation. The Ca^{2+} metal sites, which cannot be replaced by Mg^{2+} are shown as *green spheres* and those which could be replaced by Mg^{2+} are shown in *magenta*. In circulation, the depicted Mg^{2+} sites are most likely not occupied by Ca^{2+} and are likely specific for Mg^{2+}. The metal binding sites in the Gla domain of PZ and of PS are modeled based upon other VKD proteins.

modeled based upon the structure of the Sr^{2+} bound Gla domain of bovine PF1.[224] An additional Ca^{2+} site is in the Gla domain of bovine FX involving Gla residues 35 and 40; residue 35 is Asp in human FX Gla domain, which precludes binding of Ca^{2+} at this site. Ca^{2+} sites at positions 1, 4, and 7 were occupied by Mg^{2+} in the crystal structure of Gla domain of human FX in the presence of Mg^{2+} only.[152] Mutation of Gly11 to Val observed in FX deficient patients disrupts the activation of FX by either FVIIa/TF or FIXa/FVIIIa[225]; this mutation could partially impair folding of the ω-loop. Another mutation (Gla7 to Gly) may impair binding of Ca^{2+} at sites 2 and 3 and proper folding of the Gla domain.[226] The Gla domain of FXa is also important in the activation of FVII/TF to FVIIa/TF.[227]

Prothrombin (II). The first x-ray structure of the Gla domain was obtained for bovine PF1.[156] The Ca^{2+} ions are necessary to stabilize the Gla domain fold of FII.[156,228] Human FII contains 10 Gla residues and binds 7 Ca^{2+} in the absence of Mg^{2+} and 4 in the presence of Mg^{2+}.[145,229] Based upon the crystal structures of the FVIIa and FIXa Gla domains,[145,189] positions 1, 4, and 7 can be occupied by Mg^{2+} (FIGURE 14.5A). All Gla residues except Gla6 are important for proper function in FII.[230] Ca^{2+}/Mg^{2+} binding to the Gla domain are required for insertion of designated hydrophobic amino acids from the ω-loop into the PL surface.[112,156]

PC/APC. The Gla domain of PC/APC contains nine Gla residues and binds seven Ca^{2+} ions (FIGURE 14.5B)[68,187] in the absence of Mg^{2+}, and four in the presence of Mg^{2+}. Mutations of Gla residues 7, 20, 26, and 29 results in nearly complete loss of APC anticoagulant activity. Mutation of Gla25 decreases activity by 75%, but Gla6, 14, and 19 are not critical for APC functions.[231–234,235,236] Mutations at the hydrophobic residues near the *N*-terminus, particularly Leu5,[233] disrupt PL binding, and Arg15 is important in Ca^{2+} binding, as is the disulfide bond for function.[236] His10 is largely responsible for the 10-fold higher membrane binding affinity of human PC over bovine PC, which has a Pro at this position.[237] Endothelial protein C receptor (EPCR) can substitute for PL in promoting PC activation by binding to the Gla domain, but such binding requires near complete γ-carboxylation.[238–240] Binding of PC to EPCR increases PC activation *via* decreasing the K_m.[241,242] Soluble EPCR inhibits PC activation by blocking PC binding to cellular EPCR.[242] Human, but not bovine[243] FVa can potentiate PC activation on endothelium,[244,245] and human FVa can accelerate PC activation in solution.[245]

PZ. The human PZ Gla domain contains 13 Gla residues, which is the highest for any VKD protein.[37,38] Similar to FIX Gla domain, PZ has an additional residue at position 4 (FIGURE 14.5B).[37] The ω-loop of PZ contains four hydrophobic residues, unusual for the VKD proteins, while the others contain only three hydrophobic residues. Ca^{2+} binding studies performed with PZ and Des-Gla PZ revealed that only the Gla domain has Ca^{2+} binding sites, whereas the EGF-like domains and the pseudoprotease domain do not.[246] Direct Ca^{2+} binding studies performed from 0 to 0.8 mM Ca^{2+} indicate that the Gla domain of PZ contains only four sites[247]; however, from the positions of the Gla residues and the similarity with FIX and PF1, PZ might contain more than seven metal binding sites (FIGURE 14.5B). Two point mutations (Gln or Lys) have been reported in patients at residue Glu30, affecting PZ secretion from transfected cells.[247–249] PZ functions as a cofactor for PZI inhibition of FXa by binding to the PL through its Gla domain.[24] PZ has nearly 100-fold slower membrane binding and dissociation kinetics as compared to PS and PC because of the unique Gla residue at position 11.[250]

PS. Human PS contains 11 Gla residues and may contain seven metal binding sites (FIGURE 14.5B) and binds to PL membrane with higher affinity than PZ or PC.[251] Chemical modifications in the Gla residues of PS affect PL binding and also self association.[252] The Gla domain of PS binds to PL membrane in a Ca^{2+} dependent manner, but high Ca^{2+} (10 mM) disassociates the Gla domain from PL.[253] The TSR region in PS may affect Ca^{2+} binding and disrupt the structure of the Gla domain.[254] The Gly11Asp and Thr37Met missense mutations are reported in patients with PS deficiency, and mutagenesis studies reveal that Gly11 to Asp mutation affects its cofactor activity, while the Thr37 to Met mutation affects PS secretion.[255] Mutation at Gla36 affects its cofactor activity by 89% for FVa inactivation and completely for FVIIIa.[256] PS enhances the binding of APC to PL membrane,[257] and the Gla domain of PS is implicated in plasma clotting assays.[257]

EGF-Like Domains

EGF domains are mainly involved in protein–protein interactions and include human EGF receptor family ligands such as EGF and Transforming Growth Factor-α (TGF-α), low-density lipoprotein receptor, matrix proteins, the transmembrane receptor Notch, and proteins involved in blood coagulation and fibrinolysis.[107] The EGF domain contains approximately 45 amino acids and the fold is primarily stabilized by the three signature intradisulfide bond patterns as 1–3, 2–4, and 5–6. The EGF domain has two antiparallel β-sheets, which are referred to as major (*N*-terminal) and minor sheets (*C*-terminal). FVII, FIX, FX, PC, and PZ each contain two EGF-like domains, whereas PS contains four EGF-like domains in tandem. The first EGF domain in FVII, FIX, FX, and PC is a Ca^{2+} binding type domain, with functional significance, restricting Gla domain movement, which is necessary for the biologic activity. The first EGF domain in PZ or PS lacks the Ca^{2+} binding site and may be more flexible.

FVII/VIIa. The EGF domains present in FVIIa make strong interactions with TF. The main sites of contact on FVIIa are located in the first EGF domain and the protease domain, with additional points of contact within the second EGF domain and the aromatic stack region of the Gla domain. The sites of contact on TF are located on both fibronectin type III domains and the interfacial region between them,[144,145,258,259] Binding studies with proteolytic fragments and domain swapping experiments indicate that FVII EGF domains are important in binding to TF.[259,260] The *N*-terminus of the EGF1 domain contains a strong Ca^{2+} binding site, which is important for cofactor interaction and proteolytic function.[261,262] The Ca^{2+}-bound structure of EGF1 (FIGURE 14.6) shows Ca^{2+} coordinated to the main chain carbonyl oxygen of Gly47 and Gln64 as well as to the side chain carboxyl group oxygen of Asp46 and Asp63. Site-directed fluorescence experiments reveal that complex formation between sTF and FVIIa is initiated upon Ca^{2+} binding to EGF1.[263] The structural similarity between the Ca^{2+}-bound and Ca^{2+}-free structures suggest that Ca^{2+} binding is responsible for the increased affinity of FVII/FVIIa for TF.[264] Site-directed mutagenesis experiments in which Ca^{2+} binding residues Asp46 and Asp63 are replaced with Asn abolished Ca^{2+} binding and reduced FVIIa proteolytic activity.[265] The Asn57 to Asp

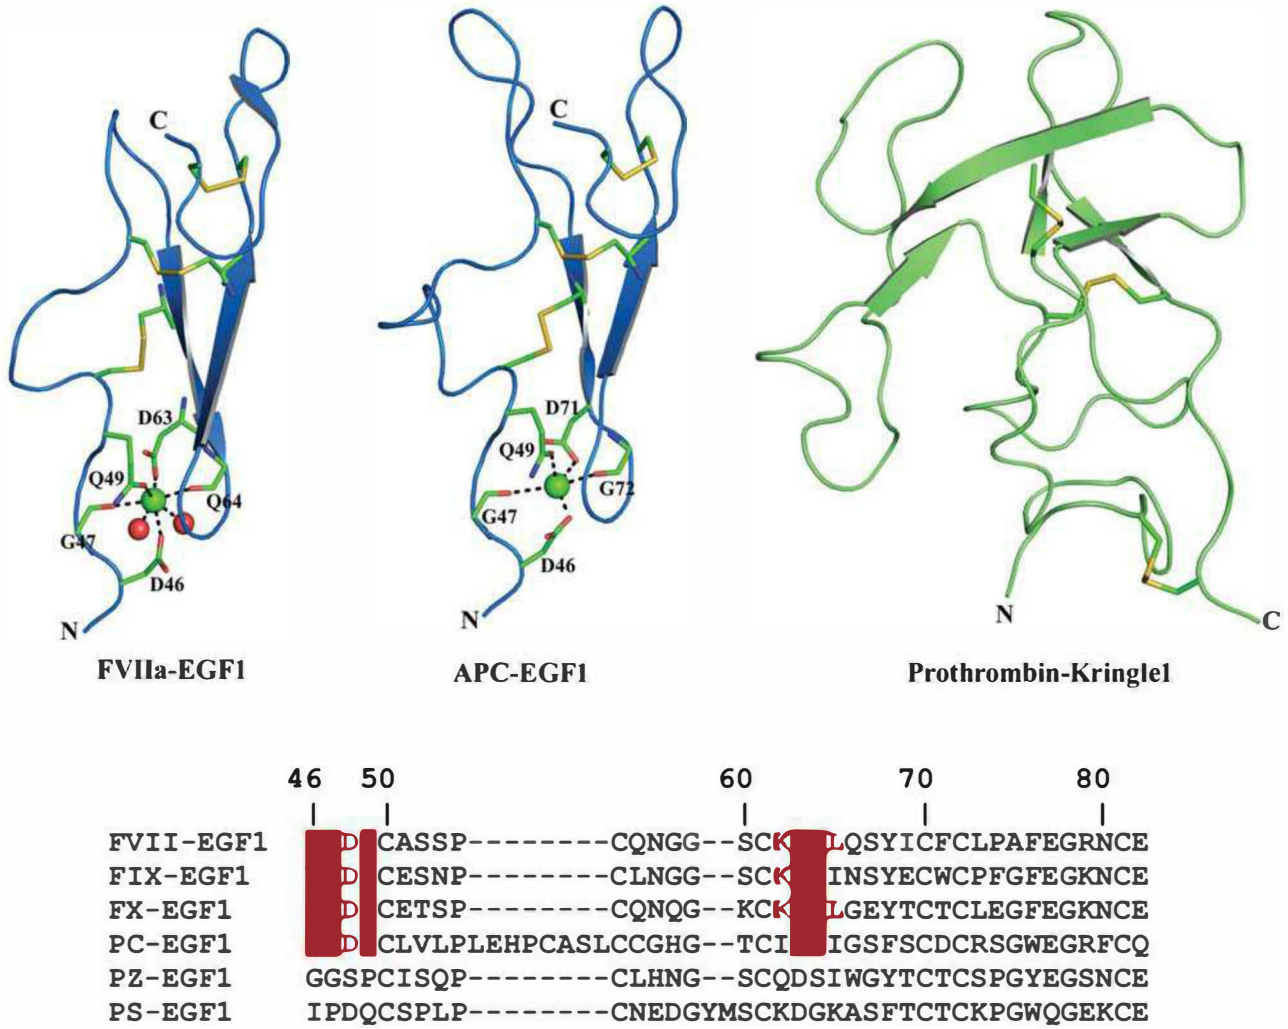

FIGURE 14.6 Cartoon representation of the EGF1 domains and the prothrombin kringle domain-1 (K1). The FVIIa EGF1 domain is on the **left**, APC EGF1 domain at the **center**, and K1 domain of prothrombin fragment-1 (PF1) is on the **right**. The Cys residues which form disulfide bridges are shown in stick representation. Ca^{2+} ions are shown as *green spheres*. The Ca^{2+} binding loops are similar in FVII, FIX, and FX, whereas APC has an eight-residue insertion in its Ca^{2+} binding loop. The multiple sequence alignment of EGF domains of FVII, FIX, FX, PC, PZ, and PS are shown at the **bottom**. The residues that serve as ligands for Ca^{2+} binding are highlighted in *red*; Mg^{2+} cannot replace Ca^{2+} in these domains. PZ or PS does not contain a Ca^{2+} binding site in the EGF1 domain.

mutation in EGF1 affects the FVIIa secretion as well as its activity.[265] Two other EGF2 mutations (Arg110 to Cys and Asp123 to Tyr) reduce FVII secretion.[266] FVII EGF domains also play a role in FX activation.[267] A peptide sequence from the EGF2 domain of FVII inhibits TF-dependent FX activation, most pronounced for a constrained sequence corresponding to residues 91 to 102.[267] These results suggest a direct role for the EGF2 domain of FVII, and in particular its loop I, in the formation and function of the FVII/TF/FX complex.[267]

FIX/IXa. The FIX EGF1 domain extends from the aromatic stack to EGF2, which lies under the catalytic domain.[147,148] The two FIX EGF domains interact through a salt bridge between Glu78 and Arg94 and by a hydrophobic patch.[268,269] There is more restriction of rotation between the two hydrophobic patches in FIXa than in FXa.[270] The interface between the EGF2 domain and the serine protease domain has extensive contacts involving aromatic residues.[270] The structure of the EGF fragment by 2-D–NMR[271] indicates that antiparallel β-pleated sheets observed in crystals also exist in solution. The first EGF domain of FIX was crystallized with Ca^{2+} bound to the Ca^{2+} site.[272] Similar to FVII, the first EGF domain in FIX binds a single Ca^{2+} with high affinity,[111,273–276] whereas the second EGF domain does not bind Ca^{2+}. Ca^{2+} in the EGF1 domain of FIX coordinates to the side chains of residues Asp47, Gln50, and Asp64 and to the backbone carbonyls of residues Gly48 and Asp65[273]; Val46Glu or Gln50Glu mutations do not affect binding of Ca^{2+} to the EGF1 domain.[276] Tyr69 to Cys produces severe hemophilia B[100] and site-specific mutagenesis indicates that this residue is important for activity but not for Ca^{2+} binding or β-hydroxylation.[277] Gly60 to Ser is a mild hemophilic mutation,[100] and modeling predicts misfolding

due to steric clash with the EGF1 Cys73–Cys82 disulfide bond.[278] Pro55 to Ser or Leu also causes mild hemophilia, caused by impaired FX activation.[279]

Domain exchange among homologous VKD factors has provided further evidence for key structural elements of the EGF-like domains. Lin et al.[280] found that replacing the first EGF-like domain of FX into FIX had little effect on activity and that substitution of both EGF-like domains with those of FX retained only 4% FIX activity. Conversely, replacing both the Gla and first EGF-like domain of FIX into FX led to a requirement of higher concentrations of FVa for FX activity[281]; therefore, cofactor binding was suboptimal but did not require specific FX sequences within the replaced segment. When the EGF-like domains of FIX were substituted with those of PC, the resulting APC had only 10% activity.[282] The first EGF-like domain of FVII has also been substituted for that of FIX in a recombinant protein[283]; this species is of particular interest because FVIIa/TF activates FIX, and this portion of FVII participates in TF binding. Curiously, the chimeric protein had twice the specific activity of wild-type FIX, enhanced binding to FVIIIa, and even enhanced activity in canine hemophilia B. Monoclonal antibody that recognizes the *C*-terminal part of the EGF1 domain, particularly Trp72 and Lys80, blocks FIX activation by FXIa, marginally decreases activation by the FVIIa/tTF complex, and slightly decreases the k_{cat} for FX activation.[284] Further, the Fab fragment of this EGF1 monoclonal antibody has 10-fold higher affinity for FIXa as compared to FIX,[285] indicating that the conformational changes that occur in the protease domain during activation and removal of the activation peptide are linked to the EGF1 domain and that the FIXa EGF1 domain is not involved in binding to FVIIIa.

The FIX EGF1 domain is required for activation by the FVIIa/TF complex but not by FXIa.[286,287] Further studies by Zhong et al.[288] revealed that the EGF1 domain of FIX interacts with TF in the FVIIa/TF. Recently, Ndonwi et al.[227] reported that EGF1 domain of FIXa is important for the feedback activation of FVII/TF to FVIIa/TF. Several studies have emphasized the importance of Ca^{2+} binding to the FIXa EGF1 domain for FVIIIa binding on PL.[111,268] However, Gln50 to Pro mutation only reduced affinity for FVIIIa in the presence of PL,[289] and replacement of the FIX EGF1 domain with that of PC resulted in approximately 80-fold decreased affinity for FVIIIa in the presence of PL and a minor difference without PL.[289] Monoclonal antibody to the EGF1 domain showed that the antibody does not affect FVIIIa binding to FIXa.[285] This study and others question whether the hydrogen bond between Glu78 in the EGF1 domain and Arg94 in the EGF2 domain is crucial for the interaction of FIXa with the light chain of FVIIIa, as hypothesized by Christophe et al.[268] Therefore, it appears that the EGF1 domain does not directly bind to FVIIIa but rather correctly positions the EGF2 and protease domains for proper interactions.

Within the second EGF-like domain of FIX, dysfunctional hemophilic mutations[100] cluster in the loop before the second disulfide bond and the main β-pleated sheet; mutations in the third disulfide loop are predominantly associated with near-normal specific activities. The EGF2 domain has been implicated in binding to FVIIIa, as well as in binding to platelets. Individual and complete replacement of the FIXa EGF2 loops with comparable FVIIa loops did not alter FVIIIa binding, but the K_d for assembly of the FX activating complex on platelets was increased for the replacement mutants.[288] Therefore, residues 88 to 109 in the FIXa EGF2 domain are important in assembly of the FX activating complex on platelets.[290] In studies of FIXa EGF2 mutants, the Leu84–Thr87 linker region had a substantial effect on FX activation in the presence of FVIIIa, but binding of the A2 subunit was marginally affected.[291] A decrease in FX activation was found with the purified protein from a patient with hemophilia with an Asn92His mutation.[292] Chang et al.[293] used scanning Ala mutagenesis of the EGF2 domain and proposed that residues 89 to 93 are involved in binding to FVIIIa and residues 102 to 108 are involved in binding to FX. Therefore, the EGF2 domain most likely plays a role in FVIIIa binding, tenase complex assembly, and mediating binding to the platelet surface. Replacement of the Asn89–Lys91 loop region decreased the activation of FX in the presence of FVIIIa by only a small amount. Other studies suggest that the EGF2 domain may bind to either the A2 subunit, the A3 subunit, or to both the A2 and A3 subunits of FVIIIa. Earlier studies have shown that the 1811–1818 region of the A3 subunit of factor VIIIa may bind to FIXa[294]; however, it is unclear as to which region of FIXa it binds to. For FIXa, cleavage of the Arg145–Ala146 bond appears to enhance binding of the FVIIIa light chain.[295]

FX/FXa. The two FX EGF-like domains keep the protease domain about 61 Å away from PL surface in the absence of cofactor FVa and 69 Å away in the presence of cofactor.[296] The first EGF domain binds a single Ca^{2+} ion, and residues Asp46, Gly47, Gln49, Hya63 (β-hydroxy aspartate), and Gly64 serve as ligands.[297] Ca^{2+} affinity is approximately 10- to 20-fold higher for the Gla–EGF1 pair than for the isolated EGF1 domain.[298] The *N*-terminal FX EGF1 domain is required for activation of both prothrombin and FVIIa/TF.[299] The EGF2 domain protects the surface-exposed hydrophobic residues in the FX protease domain and thereby stabilizes its structure.

PC/APC. Similar to FVII, FIX, and FX, APC contains two EGF-like domains, the first of which (EGF1) binds a single Ca^{2+} ion[300] (FIGURE 14.6). Residues Asp46, Gly47, Gln49, Asp71, and Gly72 serve as ligands for Ca^{2+}. PC EGF1 is different from the other VKD proteins in that there is an eight-residue insertion at the *N*-terminal end that contains extra cysteine residues (FIGURE 14.6), the functional significance of which is unknown. Mutation of the β-hydroxylated Asp71 to Glu in EGF1 resulted in loss of Ca^{2+} binding and a 90% reduction in anticoagulant activity.[300,301] Mutation of E149 to Ala in the linker peptide region after EGF2 increased anticoagulant activity and enhanced binding to PS.[302]

PZ. Multiple sequence alignment of EGF1 domains of VKD proteins indicates that neither PZ nor PS has the Ca^{2+}-site (FIGURE 14.6).[303] Similar to other VKD proteins, PZ EGF2 domain strongly interacts with the pseudoprotease domain, stabilizes its fold,[176] and keeps it at an appropriate height from PL surface to allow the ZPI associated with PZ to effectively inhibit FXa. In the modeled complexes of PZ/ZPI:FXa, the EGF2 domain is in close proximity to the FXa protease domain.[176]

PS. PS contains four EGF domains in tandem, the last three of which bind Ca^{2+} (FIGURE 14.6). The *C*-terminus EGF domain has 5,000-fold higher affinity for Ca^{2+} than the second EGF domain.[304] In the NMR structure of the EGF3–EGF4 fragment of PS, the EGF3 domain adopts a bent conformation, in contrast to the extended conformation of the other EGF domains in the presence of Ca^{2+}. Conformational switching could have functional importance and involvement in protein–protein interactions of PS.[178] Mutations in the PS EGF domain confirm that this section of the molecule has multiple functions.[305] EGF1 is involved in APC interaction.[306,307] The naturally occurring

mutation at residue Thr103 to Asn in EGF1 causes type II deficiency.[308] Deletion of PS EGF2 results in a comparable loss of its cofactor activity, indicating that EGF2 has a functional role rather than serving as just a spacer.[309] The Lys155 to Glu mutation in the PS EGF2 domain has low APC cofactor activity and also lacks the PS-mediated inhibitory effect on the prothrombinase complex and is associated with thrombotic disease.[310,311] The PS EGF domains also mediate interaction with FXa.[304]

Kringle Domains

Prothrombin contains two adjacent kringle domains between the Gla and the protease domains. PF1 contains the K1 domain, which was the first blood coagulation protein fragment structure determined by x-ray crystallography (FIGURE 14.6).[228] The Gla and the kringle-1 domains are linked by a 34 residue α–helical segment. The folding of the kringle is largely determined by close van der Waals contacts between the interloop cysteine disulfide bonds, which are buried in the interior and are inaccessible to solvent. K1 has potent antiangiogenic activity, which inhibits Lewis lung carcinoma tumor growth and metastasis[312] and is involved in FVa binding, during the assembly of the prothrombinase complex.[313] PF2 contains the K2 domain and has several interesting functional assignments.[312,314,315] K2 binds Ca^{2+} and is the primary region that mediates the interaction with FVa.[316–318] The interaction between K2 domain and FVa may be responsible for altering the conformation of FII, making it more accessible to FXa.[319]

Catalytic Domains

FVII, FIX, FX, FII, and PC contain a serine protease domain (S1 family of the SA clan)[320] at the *C*-terminus. These proteases mainly contain β-strands with the catalytic triad residues His, Asp, and Ser (FIGURE 14.7). The catalytic domain is folded into two six-stranded antiparallel β-barrel structure subdomains. The active and substrate recognition sites are formed at the interface between the two β-barrel domains. The inactive zymogen is converted to the active enzyme by the proteolytic cleavage of a single peptide bond at the *N*-terminus, releasing an activation peptide, as inferred from studies with trypsin.[321] The newly formed *N*-terminus residue is then inserted near the active site

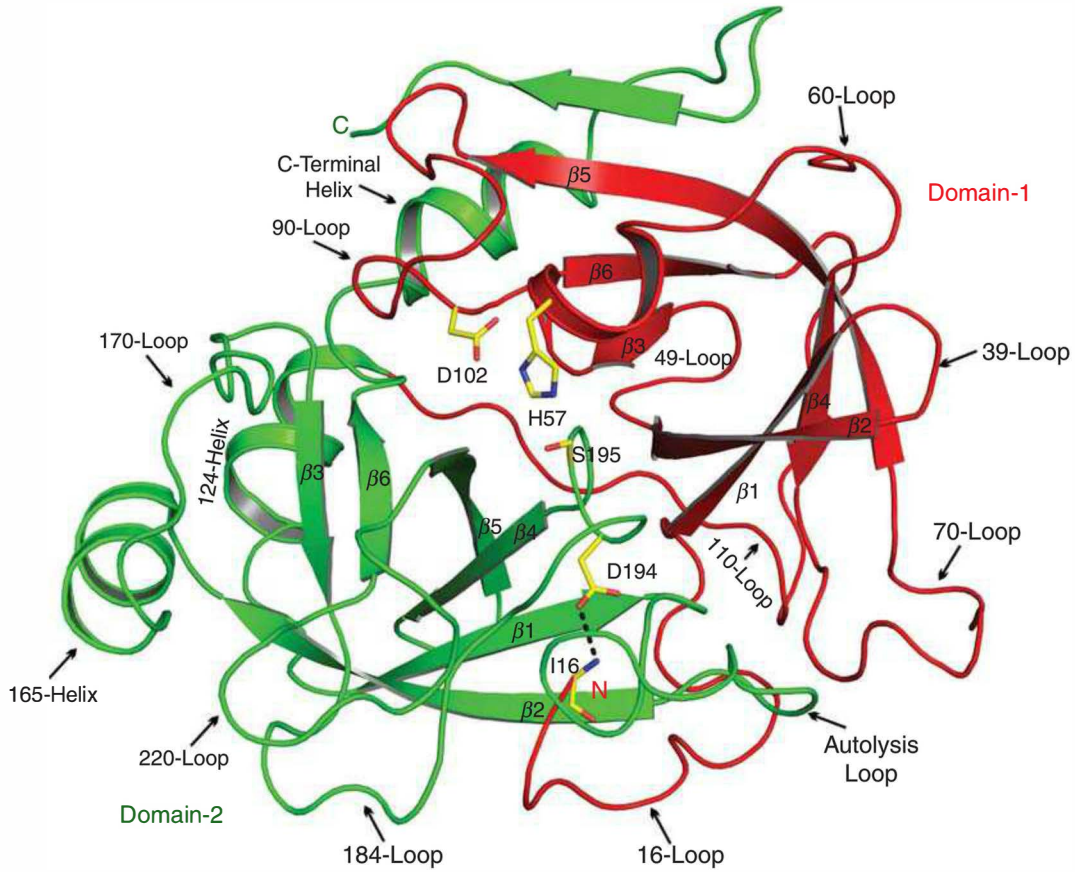

FIGURE 14.7 Cartoon representation of the FVIIa serine protease domain. The protease domain is primarily made up of β-strands with a few α-helical segments, folded into two subdomains, each of which consists of a six-stranded antiparallel β-barrel. Domain-1 is shown in *red* and domain-2 in *green*. The catalytic triad and the substrate binding cleft are formed between the two β-barrel domains. The active site residues H57, D102, and S195 (chymotrypsin numbering) as well as D194 and I16 are shown in stick representation. Upon conversion from the inactive zymogen form to the active form, the 16-loop, autolysis loop, 184-loop, and the 220-loop undergo a large conformational change. Upon activation, a salt bridge is formed between residue 16 and residue 194, shown by a *black dashed line*.

tahir99-VRG & vip.persianss.ir

pocket and makes a salt bridge with the side chain of Asp [c194], where [c] indicates chymotrypsin numbering. During the activation process, the residues in the c16-loop (residues 16 to 19, activation loop), c142-loop (residues 142 to 152, autolysis loop), c184-loop (residues 184 to 193), and the c220-loop (residues 216 to 223) undergo large conformational changes and restructure the protease domain to its functional form. In the functional form, the nucleophilic attack on the substrate peptide carbonyl moiety by Ser [c195], utilizing the charge relay system between the triad residues His [c57], Asp [c102], and Ser [c195], leads to the cleavage of the peptide bond.[321] The VKD proteins differ from trypsin in that activation alone is not sufficient enough to convert into physiologic active forms, requiring additional cofactors to perform biologic functions. The structure-based multiple sequence alignment of the VKD proteins is shown in FIGURE 14.8,[322] with differences primarily due to variations in loop regions, the greatest dissimilarity occurring in the autolysis loop. The secondary structural regions and few loop regions share similarity among the VKD proteins. The 70-loop, 90-loop, the autolysis loop, and their nearby regions provide the substrate recognition site. The different substitutions of amino acids together with the structural variations generate different substrate specificity and selectivity among the VKD proteins.

FVIIa. FVII is converted to FVIIa *via* proteolysis of a peptide bond between Arg^{152} [c15] and Ile^{153} [c16] without release of an activation peptide. The catalytic domain of FVIIa adopts a typical conformation of other serine proteases in which the active site catalytic triad residues His^{193} [c57], Asp^{242} [c102], and Ser^{344} [c195] are located at the interface between the two β-barrels. The FVIIa protease domain contains several hydrophobic residues on the surface that make contact with EGF2. FVIIa contains one Ca^{2+}, one Na^{+}, and two Zn^{2+} binding sites in the protease domain that play functional roles[145,323–325] (FIGURE 14.9A). The Ca^{2+} is coordinated to the carbonyl groups of residues Glu^{212} [c72] and Glu^{215} [c75], and side chains of Glu residues 210 [c70] and 220 [c80] present in the c70-loop (residues 210 to 220).[144,145] The Ca^{2+} binding to the c70-loop induces the conformational change and increases catalytic activity.[324,326] The Na^{+} binding site is located between the c184-loop and c220-loop. The back bone carbonyl oxygens of Tyr^{332} [c184], Ser^{333} [c185], His^{373} [c224], and Thr^{370} [c221] serve as ligands for Na^{+}.[145] The binding of Zn^{2+} to FVIIa has a negative effect on proteolytic activity, and affinity for sTF.[327] Residues His^{216} [c76], Glu^{220} [c80], and Ser^{222} [c82] provide ligands for the first Zn^{2+} site, and residues His^{257} [c117], Asp^{219} [c79], Gly^{209} [c69], and Lys^{161} [c24] provide ligands for the second Zn^{2+} site.[145] Overlapping Ca^{2+} and Zn^{2+} sites could explain Ca^{2+} reversal of the inhibitory effect of Zn^{2+}.[325]

The main natural substrates of FVIIa/TF are FIX and FX.[327–330] When FIX is activated, two peptide bonds must be cleaved; FVIIa/TF complex catalyzes the cleavage of Arg145 more efficiently than Arg180.[205,331] Residue Lys^{341}[c192] also plays an important role in substrate recognition.[332] The primary physiologic inhibitor of FVIIa is tissue factor pathway inhibitor (TFPI) complexed to FXa; however, FVIIa can also be inhibited by AT in the presence of heparin.[333,334] Truncated forms of FVII have been produced in which the Gla domain has been removed by limited proteolysis[335,336] or by expression of the truncated recombinant protein.[337] A form of FVII lacking both the Gla domain and the first EGF domain fails to bind to TF effectively.[338–340] A FVII mutant has been produced in which the activation cleavage site has been mutated so that it cannot be activated by its usual activators.[341] This mutant had no detectable enzymatic activity indicating that zymogen FVII is inactive.

The FVIIa residues at the *C*-terminus of the c126 helix (Arg^{266}–Val^{277} [c126–c129F]) and the following loop as well as the residues at the *N*-terminus of c165 (Thr^{307}–Gln^{312} [c165–c170]) helix and those of the preceding loop interact with TF[144,145] (FIGURE 14.10). The side chain of residue Met^{306} [c164] is implicated in allosteric activation of FVIIa. Substitution of Met^{306} [c164] by Asp essentially abolishes the TF-induced allosteric activation of FVIIa.[342] The FVIIa regions that play an important role in preventing the transition from the zymogen-like to the active enzyme-like molecule and how TF binding promotes this transition is under intense investigation.[343–348] The binding of TF induces an allosteric effect on FVIIa, which is then lead to a fully functional form of FVIIa. According to one proposed pathway, the binding of TF to FVIIa stabilizes the intramolecular interactions of TF binding helix (residues 307 to 312 [c165–c170]),[344] triggering the initiation of the allosteric effect at *C*-terminal of the helix, which is then transferred to the activation loop 3, leading to proper formation of the S1–S3 substrate sites.[349–351] In the second pathway, TF binding induces allosteric changes through the *N*-terminal side of the TF binding helix, where it stabilizes the hydrophobic interactions between Leu^{305} [c163] and Phe^{374} [c225], inducing conformational change in the activation loop 3, and the oxyanion hole containing loop and activation pocket at the S1 site. These transitions lead to the insertion of *N*-terminus Ile^{153} [c16] into the activation pocket.[351] These conformational changes in the protease domain result in the proper formation of the substrate recognition subsites.

When FVIIa binds to TF, its ability to catalyze the hydrolysis of small peptidyl-amide or peptidyl-ester substrates is enhanced approximately 20- to 100-fold,[324,352–355] primarily by enhancing substrate affinity of FVIIa rather than by altering the rates of any of the subsequent catalytic steps.[356] Higashi et al.[357] have proposed that free FVIIa is structurally more zymogen-like, and when bound to TF, it is more active enzyme-like. Alanine scanning mutational studies of surface residues in the protease domain of FVIIa support this concept.[358]

A defining feature of each serine protease is the presence of an oxyanion-binding site, generally known as the oxyanion hole[359]; however, it is absent in *p*AB-FVIIa/sTF (PDB id 2A2Q) or the benzamidine-FVIIa/sTF (PDB id 2AER) structures.[145] Earlier observations of an absent oxyanion hole were attributed to the unusual nature of the amidinophenylurea-based inhibitor, in which the amidino NH groups of the inhibitor induced approximately 180 degrees rotation of the Lys^{341}–Gly^{342} [c192–c193] peptide bond.[360] A similar peptide bond flip at c192–c193 has also been observed with sulfonamide[361] and phenylglycine amide inhibitors.[362] Thus, the abnormal conformation of the c192–c193 peptide bond in FVIIa/sTF is not related to the presence of the unusual inhibitors in the active site, but rather, it is likely an inherent property of the FVIIa active site.[145]

Binding of the substrate/inhibitor at the active site of FVIIa/TF provides energy for the flipping of the Lys^{341}–Gly^{342} [c192–c193] peptide bond and formation of the competent oxyanion hole.[145] The substrate/inhibitor induced formation of the oxyanion hole is also supported by the structures of the FVIIa EGF2/protease domain (PDB id 1KLI and 1KLJ) obtained in the absence of TF.[363] In this structure, the bottom of the S1 region of active site is occupied by benzamidine and top of the S1 site is occupied by a sulfate ion.[363] Here, occupancy of the sulfate oxyanion in the S1 site most likely induced 180 degrees flip of the c192–c193 peptide bond during crystallization. These

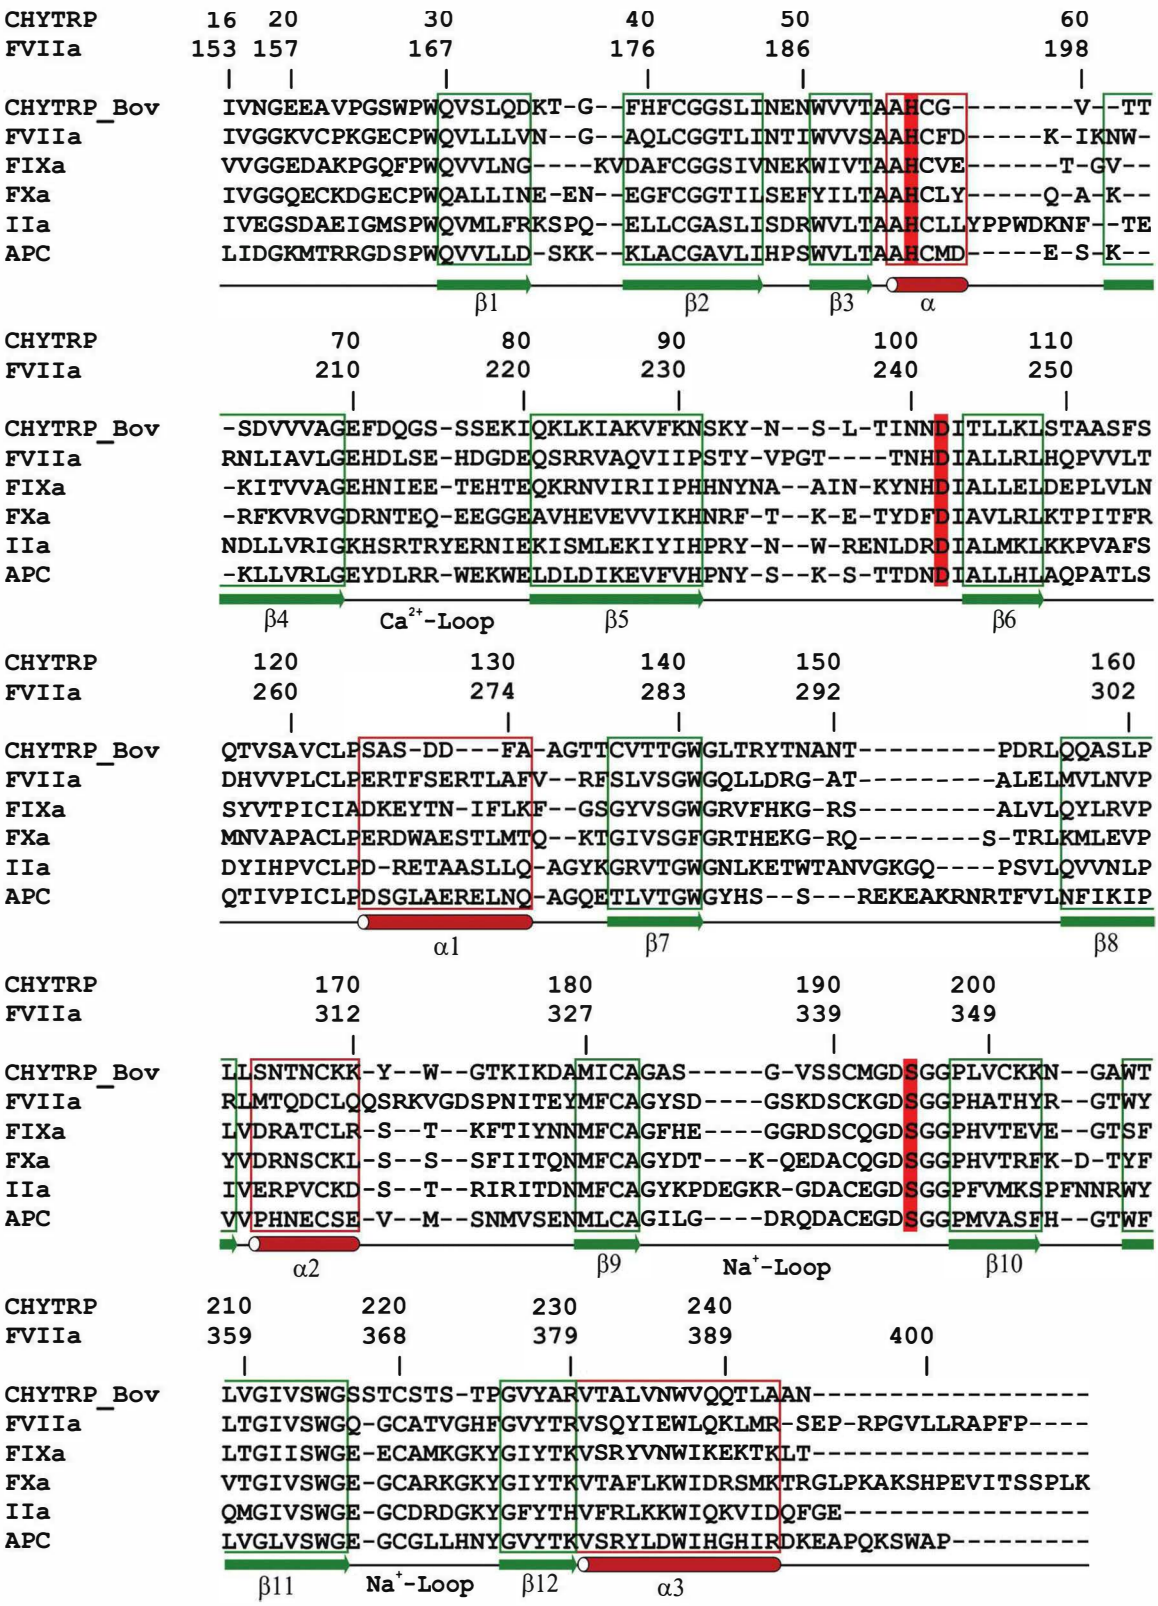

FIGURE 14.8 Structure-based multiple sequence alignment of the protease domains of coagulant and anticoagulant VKD proteins. The multiple sequence alignment of the protease domain of bovine α-chymotrypsin, FVIIa, FIXa, FXa, IIa, and APC was performed by structure-based alignment using the program Chimera. The secondary structural regions, strands, and helices are indicated below the sequences with *arrows* and *cylinders*, respectively. The chymotrypsin numbering and the FVII numbering are given. Ca^{2+} and Na^{+} binding loops are indicated, and the active site residues are highlighted in *red*; IIa does not have a Ca^{2+} binding site in its protease domain.

tahir99-VRG & vip.persianss.ir

observations lend support to a concept that the oxyanion hole in FVIIa is induced by the substrate/inhibitor and not by TF.

FIXa. The heavy chain of FIXa is comprised of the serine protease domain, which contains the catalytic triad, His^{221} [c57], Asp^{269} [c102], and Ser^{365} [c195]. Following activation peptide cleavage, a new amino-terminus Val^{181} [c16] is generated. As in other serine proteases, the amino group of Val^{181} [c16] must insert near the active site to form a salt bridge with the side chain carboxylate of Asp^{364} [c194] for conversion of zymogen FIX to enzyme FIXa. This converts the hydroxyl side chain of Ser^{365} to a reactive species, capable of hydrolyzing the activation cleavage site of FX. Lack of appropriate FIX cleavage as in Arg^{180} or Val^{181} mutation leads to severe hemophilia B.

As with other serine proteases, catalysis of FX proceeds by an acyl intermediate from the peptide bond being cleaved to the active hydroxyl group of Ser^{365} [c195] in FIXa with charge contributions from the other catalytic triad residues, His^{221} [c57] and Asp^{269} [c102] (FIGURE 14.9B). Substrate specificity is greatly restricted in FIXa,[364] perhaps related to variances in the c99-loop.[365,366] This loop restricts catalytic activity toward FX in the absence but not in the presence of FVIIIa.[366] In FIXa crystal structures 1PFX and 1RFN, Tyr^{266} [c99] has two different conformations.[147,148] In the 1RFN structure with *p*AB in the S1 site, access to the S2 site is hindered by Tyr^{266} [c99], whereas in the 1PFX structure Tyr^{266} side chain is rotated such that it is positioned to interact with Phe of PPAck inhibitor in the S4 site. Sichler et al.[367] have shown that mutation of Tyr^{259} [c94], Lys^{265} [c98], and Tyr^{345} [c177] produced a FIXa molecule with approximately 7,000-fold increased activity and altered specificity. It has been proposed that surface loop 199-204 [c30-c40] of FIXa is involved in macromolecular substrate interaction in the absence but not in the presence of FVIIIa.[368] The c99-loop, c60-loop, and

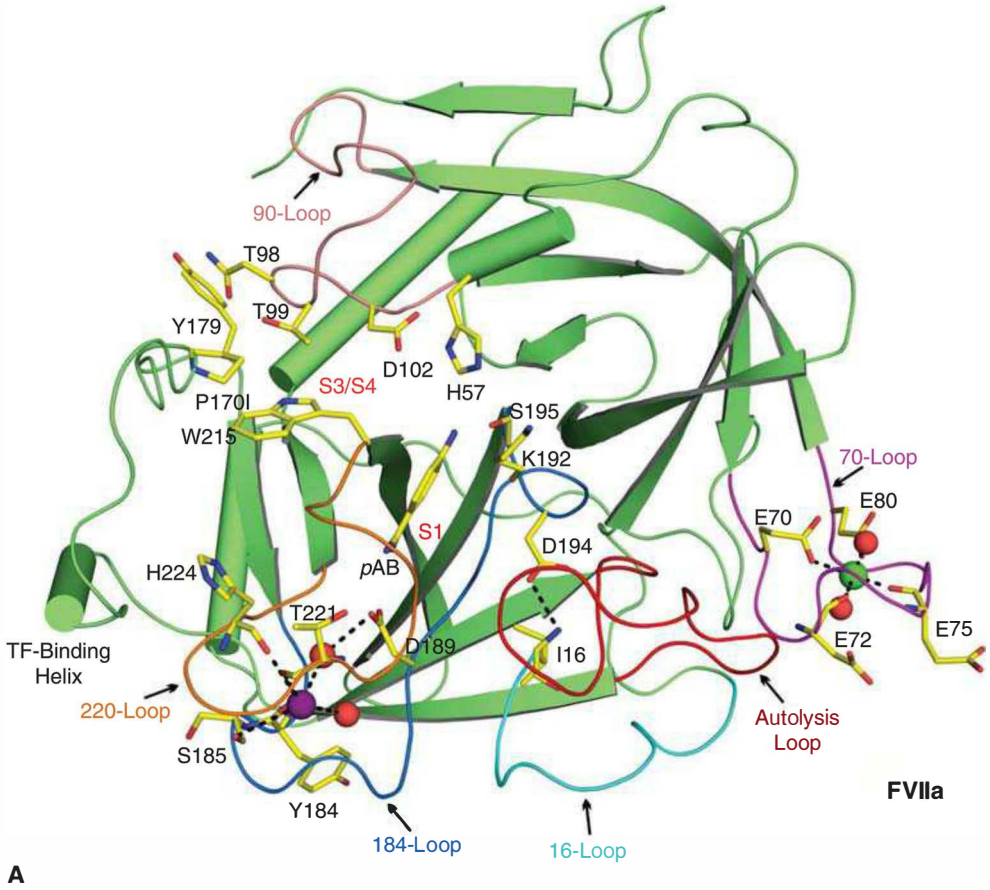

FIGURE 14.9 Ca^{2+} and Na^{+} binding sites in the protease domains of VKD coagulant and anticoagulant proteins. In each protease, the residues coordinated to Ca^{2+} and Na^{+} are shown in stick representation. Loops that are affected by Na^{+} and Ca^{2+} binding are marked; secondary structural elements, β-strands and helices are depicted as *arrows* and *cylinders*, respectively; Ca^{2+}, Na^{+}, and the water molecules are shown as *green*, *purple*, and *red spheres*, respectively; coordination bonds and the hydrogen bonds are represented by *black dashed lines*. The chymotrypsin numbering scheme is used to label the residues. The PDB ids used to draw the figures are: 2A2Q for FVIIa, 2D1J for FXa, 1SG8 for thrombin and 3F6U for APC. ***A*, FVIIa**: The side chains of E70 and E80, and main chain carbonyl oxygens of E72 and E75 serve as ligands for Ca^{2+}. Ca^{2+} binding stabilizes the 70-loop, 16-loop, and the autolysis loop. The main chain carbonyl oxygens of Y184 and S185 from the 184-loop, and T221 and H224 from the 220-loop serve as Na^{+} ligands. The Na^{+} binding stabilizes the 184-loop and 220-loop and the substrate S1 binding pocket. In the structure shown, the S1 site is occupied by *p*AB and its amino groups are hydrogen bonded to D189 and S195. The locations of the TF binding helix and of the substrate sites S3/S4 are marked.

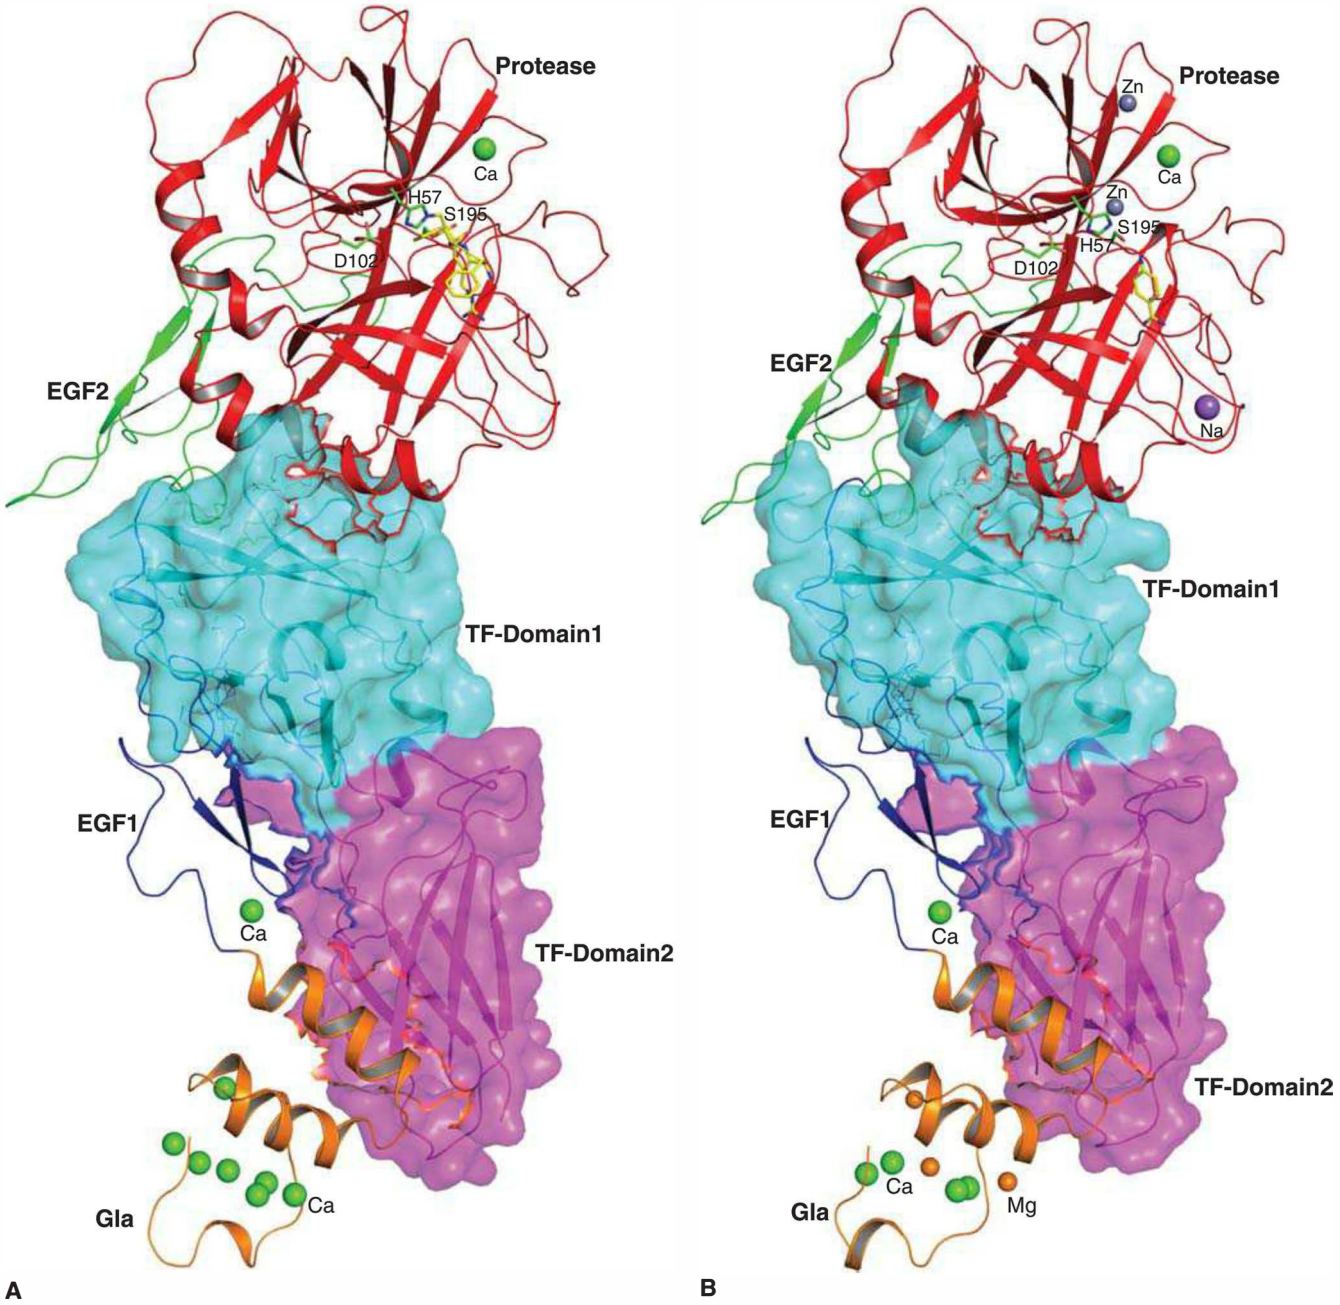

FIGURE 14.10 Interactive regions between FVIIa and the extracellular domain of TF (sTF). The FVIIa/sTF complex in the presence of Ca^{2+} only (pdb id 1DAN) is shown in (**A**) and in the presence Ca^{2+},Mg^{2+}, Na^{+}, and Zn^{2+} (pdb id 2A2Q) is shown in (**B**). All domains in FVIIa are involved in sTF interaction. The Gla domain of FVIIa binding sites are localized in *C*-terminal domain of TF. The EGF1 domain of FVIIa binding sites are localized at the interface between TF domain-1 and domain-2. The EGF2 and the protease domain of FVIIa binding sites are localized in TF domain-2. The active site triad residues H57, D102, and S195 as well as the bound inhibitors are shown in stick representation. FVIIa is shown in cartoon representation and the sTF is shown in surface representation. FVIIa Gla, EGF1, EGF2, and the protease domain are colored *orange*, *blue*, *green*, and *red*, respectively. The sTF domain-1 is colored *cyan* and the domain-2 is colored *magenta*. The Ca^{2+}, Mg^{2+}, Zn^{2+}, and Na^{+} are shown as *green*, *orange*, *black*, and *purple spheres*, respectively.

the residue Tyr [c177] of FIXa is implicated in modulating the catalytic activity.[367–369] A sequential activation mechanism has been proposed for FIXa that depends on its cofactor FVIIIa and its substrate FX. Binding of FVIIIa to the c162-helix of FIXa[289] might release the steric hindrance caused by Tyr [c177] but not by the Lys [c98].[149,369] Further, apart from the cleavage site, an unidentified site on FX binds to the Lys [c98] and completes the opening of the entrance to the S1 site in FIXa.[369,370] Thus,

tahir99-VRG & vip.persianss.ir

cofactor and macromolecular physiologic substrate act in concert to potentiate the catalytic activity of FIXa. Mutations of the catalytic triad residues produce hemophilia with normal circulating levels of dysfunctional protein.[100–102] Gly^{207} to Glu mutation within the His^{221} disulfide loop eliminates a hydrogen bond that stabilizes the active site.[370]

Trypsin-like serine proteases bind their substrates' Arg side chain to the S1 binding pocket with Asp^{359} [c189] at the bottom. Mutation of Asp^{359} to Gly in factor IXa causes hemophilia B^{100} most likely due to defective activation of FX. Mutations of Val^{307} are predicted to disrupt this binding pocket as well.[371] Ser^{360} [c190] is important in substrate binding to the S1 site as it allows an additional H-bond to be formed with the P1 Arg or Lys residue, thus stabilizing the substrate residues.[339] Mutation of Gly^{363} [c193] also causes hemophilia B.[372] Gly^{363} [c193] is involved in formation of the oxyanion hole in FIXa and other serine proteases. Mutation to any other residue most likely repositions the backbone amide of residue 363 [c193] such that it is pointing away from the oxyanion hole and unable to stabilize the developing oxyanion of the tetrahedral intermediate.[372] FX binding includes secondary binding sites such as one that is partially disrupted with an $Ile^{397}Thr$.[373,374] This is a common recurrent mutation and represents a founder effect.[103] A recombinant $Arg^{338}Ala^{375}$ was created to examine a potential thrombin inactivation cleavage site.[376] The recombinant Ala^{338} protein had threefold enhanced activity, but this was due to enhanced k_{cat} for FX cleavage, indicating involvement of this mutation in substrate interaction as opposed to stabilization from cleavage. Arg^{338} is in a Cys^{336}–Cys^{350} disulfide loop, and these data suggest this region can affect catalysis, possibly through interaction with factor VIIIa. Of note, thrombin cleavage of FIX is inhibited by physiologic calcium binding.[377] The catalytic domain's high affinity calcium binding site is in a loop involving Glu^{235} [c70] and Glu^{245} [c80] carboxyl groups (FIGURE 14.9B), adjacent to the autolysis loop containing a potential proteolysis site at Arg^{318}–Ser^{319}.[378] Cleavage of FIXa in the autolysis loop generates a molecule, FIXaγ, impaired in catalytic activity toward small synthetic substrates as well as in FX activation.[378,379] Thus, Ca^{2+} most likely protects the autolysis loop from cleavage by thrombin or FXIa. When Glu^{235} [c70] was replaced by Lys, 75% of activity remained as predicted from the structure of thrombin, <10% FIX reactivity remained in a recombinant species in which both Glu's were mutated to Lys.[374]

Molecular modeling studies suggest that the FIXa protease domain possesses a sodium binding site that is similar to that in factor Xa and APC but not to IIa.[155,380] However, Na^+ site was not observed in the crystal structures of mutant FIXa molecules[149,369] and in FIXa bound to antithrombin.[150] Notably, Na^+ site was also not observed in FXa bound to antithrombin.[381] Thus, the FIXa loops involved in Na^+ binding could be modulated by mutations, and Vadivel et al.[382] observed the Na^+ site involving the predicted loops in the crystal structure of wild-type FIXa at 1.64 Å resolution.

Although the specificity of the FIXa active site is restricted, it is rapidly inactivated by AT-III with heparin.[383,384] Heparin binding increases the reactivity of FIXa toward both peptidyl substrates and bovine pancreatic trypsin inhibitor (BPTI) inhibition through induced conformational changes from the exosite to the active site.[385] Residues Lys^{293} [c126], Arg^{333} [c165], Arg^{338} [c170], Lys^{390} [c230], and Arg^{393} [c233] in FIXa are part of an exosite that binds to heparin.[386] Further, the affinity of full-length FIXa for heparin is increased approximately 10-fold by Ca^{2+} indicating that Ca^{2+} promotes FIXa inhibition by the template mechanism.[387]

FIXa activation of FX is enhanced several orders of magnitude by PL and FVIIIa.[388] FVIIIa binding increases the catalytic activity of FX activation approximately 10^6-fold with no effect on synthetic substrate hydrolysis.[389,390] Strong evidence exists for the involvement of the 293-helix [c126-helix], 330-helix [c162-helix], and Asn^{346} [c178] in binding to FVIIIa.[289,368,391] Thus, it appears that heparin may bind to the same exosite on FIXa that FVIIIa binds. Further, residues Phe^{342}–Asn^{346} [c174–c178] of FIXa contribute to interaction with the endocytic receptor low-density lipoprotein receptor–related protein.[392] Ethylene glycol increases the catalytic activity of FIXa toward synthetic substrates in a bell-shaped pattern with maximum activity at approximately 35% to 45% ethylene glycol concentration,[367,393] and it binds between the Glu^{224} [c60] and Pro^{255} [c90] in FIXa, which mimics the effects of FX binding on the 266-loop [c99-loop].[367] Under some conditions, FIXa can activate $FVII^{10}$ or FVIII.[394,395]

FX/FXa. The FXa protease domain contains a Ca^{2+} binding site in the c70-loop and Na^+ binding site between the c184-loop and c220-loop (FIGURE 14.9C). The side chain of Asp [c70] and Glu [c80] and the main chain carbonyl oxygen atoms of Asn [c72] and Gln [c75] are coordinated to Ca^{2+}.[153,380] The Asp [c70] mutation to Lys abolished the Ca^{2+} binding without affecting the catalytic activity of FXa.[396] The residues Tyr [c185], Asp [c185A], Arg [c222], and Lys [c224] backbone atoms serve as Na^+ ligands.[170,380] The alanine mutational studies performed in c184-loop residues Asp [c185A] and Lys [c186] result in the impairment of Na^+ binding and reduction in catalytic activity toward the macromolecular substrate prothrombin; however, saturating concentration of FVa restores the catalytic activity.[397] FXa activates FVII,[398] FVIII,[399] and FV[400] in addition to its main role in activation of prothrombin. FXa has two physiologic inhibitors, AT and TFPI.

Prothrombin/Thrombin. Human α–thrombin can be autodegraded by cleavage at Arg382 and Asn394 in the B chain to form β-thrombin and by cleavage at Arg443 and Lys474 in the B chain to form γ-thrombin.[401,402] These degraded forms of α–thrombin retain some ability to hydrolyze small synthetic substrates[403,404] and to cleave FXIII,[405] AT,[406] and FII.[407] However, β-thrombin and γ-thrombin do not cleave fibrinogen, thrombospondin, or PC.[406,408,409]

In addition to the α–, β-, and γ-thrombin forms, there are two additional forms that also have physiologic activity: meizothrombin and meizothrombin des-fragment 1.[60] Once cleaved at Arg320, meizothrombin can then cleave itself at Arg156, thus releasing PF1 and generating meizothrombin des-fragment 1.[60] The meizothrombin des-fragment 1 can then be autolytically cleaved at Arg283 to form α–thrombin. Meizothrombin is currently viewed as the first product produced by the prothrombinase complex during prothrombin activation.[62,63] Meizothrombin is a potent vasoactive agent and acts on the adrenergic receptor[410] and is five- to sevenfold more potent than α–thrombin in inducing vascular constriction.[408,411] Meizothrombin has substantially reduced activity toward fibrinogen and platelets as compared to α–thrombin,[60,412] but it does cleave other thrombin substrates. Meizothrombin and α–thrombin have similar abilities to cleave PC, FV, FXI, and small synthetic substrates.[60,412–417]

The PF2 (K2 region of FII) noncovalently associates with thrombin with a dissociation constant of approximately 10 nM.[418,419] PF2 interacts with exosite II (heparin-binding region) of thrombin,[161,420–423] involving salt bridges between the inner loop of K2 and FII exosite II.[424] Consequently, it inhibits AT inhibition of IIa,[425] alters the IIa active site and exosite I,[426] enhances IIa activity toward small peptide substrates,[418] inhibits IIa cleavage of fibrinogen,[427] and influences PC activation.[428]

There is considerable sequence homology as well as conservation of the disulfide bonds between α–thrombin and α–chymotrypsin. However, there are key differences between human α–thrombin and α–chymotrypsin,[429] including deletion of the residue c218, addition of NH_2-terminal residues 285 to 292 (II numbering), minor insertions of 1 or 2 amino acids, a 13-residue insertion (residues 307 to 319) called the *A* loop, and the insertion of residues 367 to 375 ("c60 B loop," FIGURE 14.8) near the active site of α–thrombin.[165,429,430,431,432] The "E loop" represents an insertion composed of residues 513 to 516 and is located near the bottom of the active site pocket.[429] The position of the "C loop" or "γ loop," residues 470 to 474 (c148 loop), varies considerably between the FPR-ck-α–thrombin and the hirudin–α–thrombin structures, indicating that this segment of α–thrombin is mobile in solution.[429]

The Na^+ binding site of IIa is contained within a cylindrical cavity formed by three antiparallel β-sheets of the α–thrombin B chain (FIGURE 14.9D). The site is more than 15 Å away from the catalytic site. The cavity containing the Na^+ binding site bisects the α–thrombin molecule from the active site to the opposite surface and contains Asp [c189].[173] In the presence of Na^+, α–thrombin recognizes and cleaves fibrinogen acting as a procoagulant; when no sodium is bound, α–thrombin has increased specificity for PC. This change in specificity allows α–thrombin to act as both a procoagulant and an anticoagulant.[433,434] IIa variants cTrp215Ala/cGlu217Ala or cGlu217Lys act as anticoagulants and activate PC in a thrombomodulin dependent manner. Structural studies reveal that these mutants are in the inactive E* form and their Na^+ binding loops c186 and c220 as well as the active site are highly disordered.[435,436]

The fibrinogen binding site (exosite I) is an anion-binding electropositive site, distinct from, but acting in concert with, the active site.[433] Exosite I also binds the COOH-terminal domain of hirudin, the hirudin-like region of the thrombin receptor protease-activated receptor (PAR)-1 and PAR-4, and the fifth and sixth EGF-like domains of thrombomodulin.[433] Exosite I is comprised of insertion loops c30–c40 and c70–c80.[165,421] Hirudin demonstrates a high affinity interaction with α–thrombin to form a stable, noncovalent complex with a dissociation constant in the range of 2×10^{-14} M.[437,438] Hirudin binds to both exosite I and the active site of thrombin.[438–440] In solution, the COOH-terminal domain of hirudin is disordered.[441,442] However, in the α–thrombin–hirudin complex, the COOH-terminal of hirudin interacts with the large groove in the α–thrombin molecule and extends across the face of the molecule to interact with exosite I which is distant from the active site of α–thrombin. The interaction of α–thrombin and hirudin is stabilized by electrostatic, polar, and hydrophobic interactions that account for the very high affinity interaction between the two proteins.

Exosite II is positively charged and serves as an anion-binding site on the opposite side of α–thrombin compared to exosite I, which binds hirudin and fibrinogen. Exosite II is responsible for binding highly sulfated polysaccharides like heparin,[443] the COOH-terminal domain of the B chain of thrombin,[422] and the chondroitin sulfate moiety of thrombomodulin.[434] The fourth binding site, the active site region, interacts with substrate molecules.[444] Kunitz inhibitor BPTI reacts very poorly with thrombin, restricted by Trpc60D, which sits over the active site pocket.[445] When Glu192 is mutated to Gln, the thrombin–BPTI complex is tightened[446] sufficiently to allow structural studies of the complex.[445] In the complex, Trp60D is shifted approximately 8 Å from its normal position, consistent with previous modeling studies.[165] Kinetic analysis showed that thrombomodulin binding to thrombin does increase the on rate approximately 10-fold,[447] suggesting that it induces conformational changes that contribute to the altered substrate and inhibitor specificity. Thermodynamic linkage between exosite II, Na^+ site, and the active site arises from the interconversions of zymogen- and enzyme-like forms of IIa.[448]

APC. The active site of APC (triad residues, His^{211}[c57], Asp^{257}[c102], and Ser^{360}[c195]) is relatively open compared to that of thrombin or FXa (FIGURE 14.9E), contributing to the resistance of APC to inhibition by plasma proteinase inhibitors. APC contains substrate recognition sites on the prime side, as well as on the non-prime side that are common to other serine proteases.[154] The APC contains a Ca^{2+} binding site and a Na^+ binding site in the protease domain (FIGURE 14.9E). The c70-loop contains two Arg residues at positions c74 and c75; Ca^{2+} bind to APC and the residues Glu [c70], and Glu [c80], and the main chain carbonyls of Asp [c72] and Arg [c75] coordinated to Ca^{2+}.[154,155] Na^+ binds between the c184-loop and c220-loop similar to that of FVIIa, FIXa, and FXa and is coordinated to the backbone carbonyl oxygen atoms of Ile [c184A] and Leu [c185] from c184-loop, and Leu [c221A] and Asn [c224]. Ca^{2+} binding enhances catalytic activity of PC and Na^+ binding to APC increases catalytic efficiency approximately 100-fold for small synthetic substrates. Na^+ binding is thermodynamically linked to both Ca^{2+} and the S1 site, while the Ca^{2+} site is linked only to the Na^+ site.[155,449]

The autolysis loop is involved in binding to the PC inhibitor (PCI),[450] and the basic residues on the surface at c30, c60, and c70-loops of the protease domain are involved in protein–protein interactions for activation and binding to heparin, heparin sulfate, and α–1 antitrypsin.[451] The Lys residues at position c37, c38, and c39 in the c37-loop of PC bind to the thrombomodulin–thrombin complex[452] and provide the substrate recognition exosite for FVa that is important for cleavage of Arg506 in FVa.[453] Lys^{217} [c62] and Lys^{218} [c63] are part of a heparin-binding site that is important for heparin-mediated inhibition of APC by PCI.[454] The Lys residues at position c37, c38, and c39 form a secondary binding site for FVa, which is important for the cleavage of FVa at Arg-506 while having no effect on Arg306 cleavage. The Thr [c99] to Tyr mutant inactivated FVa twofold better than the wild-type APC.[455] The mutations observed in the catalytic domain of PC at Arg^{169} to Trp, and the Trp^{402} to Cys cause structural instability and are related to hereditary thrombophilia.[456–458]

Glu residues at positions 309 [c192] and 310 [c39] in thrombin make unfavorable interactions with Asp residues in the P3 and P3′ 311–313 positions of PC, which are largely overcome by thrombomodulin binding to thrombin. Increasing the P3-binding energetics by mutation of Glu [c217] to Lys in thrombin resulted in considerably enhanced PC activation rates[459,460] and converted thrombin into an anticoagulant

tahir99-VRG & vip.persianss.ir

protein. Mutation of both the P3 and P3′ residues of PC augment PC activation[461,462] and increase the rate of thrombin activation sufficiently to allow PC to serve as an anticoagulant *in vitro*.[463] Meizothrombin is a better activator of PC than α–thrombin,[413,417] an important point, given that early on during coagulation, its concentration is higher than α–thrombin.[414,417]

To be activated to APC, PC must be bound to the endothelial cell surface where thrombin/thrombomodulin can cleave it between Arg169 and Leu170 and release a 12–amino acid activation peptide. With its cofactor PS, APC cleaves FVa and FVIIIa to inactivate them.[25,82,464] APC binding to its cofactor, PS, is necessary for FVa inactivation; however, APC inactivation of FVIIIa in the tenase complex requires both PS and FVa as cofactors.[465] PS circulates both as a free form (~40%) and in a complex with C4b-binding protein.[466] FV serves as a cofactor for APC inactivation of FVa and FVIIIa.[467] Flexibility in the APC molecule may contribute to the observed topographical changes in APC, which are observed following interaction with PS.[468] Thrombomodulin binding to thrombin potentiates the activation of PC >1,000-fold, and EPCR binding of PC potentiates PC activation another approximately 20-fold.[469] Different models have been put forth to explain this enhancement. Sadler et al.[470,471] were the first to show that point mutations within anion-binding exosite 1 on thrombin, which binds both fibrinogen and thrombomodulin, disrupt fibrinogen clotting or PC activation by the thrombin/thrombomodulin complex differentially.

Sodium bound to IIa enhances fibrinogen clotting activity approximately eightfold[472,473] and decreases PC activation rates by the thrombin/thrombomodulin complex by 30%.[474] Mutation of this site has been utilized to generate thrombin mutants with increased anticoagulant activity.[475] On the basis of detailed kinetic analysis, residues Glu [c39], Glu [c192], and Trp [c60D] are linked to the Na^+ transition.[476] Mutation of Lys [c37] to [c39] to acidic or neutral residues had no influence on the activation rates of PC by thrombin or the Ca^{2+}-dependent inhibition of this process; however, the mutants were activated approximately 10-fold slower by the thrombin/thrombomodulin complex at all Ca^{2+} concentrations tested.[452] Thus, it is clear that thrombomodulin binding to PC influences PC activation. Thrombomodulin binding to IIa mediates conformational changes, making it a better activator of PC. The EGF3 domain of thrombomodulin is important in thrombin-activatible fibrinolysis inhibitor activation, whereas the EGF4 domain of thrombomodulin has been implicated in PC activation.[477] Data supporting the thrombomodulin-induced conformational changes in thrombin includes changes in fluorescence of covalently attached dyes,[478,479] selective changes in the electron spin resonance of covalently attached probes,[480] and changes in synthetic substrate hydrolysis.[428,478,481] PC may be able to function as an antithrombotic agent, and several studies have structurally altered PC to enhance thrombin activation. Mutations of both the P3 and P3′ residues of PC augment PC activation[461,462] and increase the rate of IIa activation sufficiently to allow PC to serve as a plasma anticoagulant *in vitro*.[463]

PS circulates in free form and bound to C4b-binding protein,[466] an interaction of high affinity in the presence of Ca^{2+}.[482,483] The steroid hormone binding globulin-like region (2 LamG domains) of PS is important for binding to the β-subunit of C4b-binding protein. Specifically, the β-chain complement control protein (CCP) 1 domain binds to PS *via* a hydrophobic patch on CCP1 comprised of Ile16, Val18, Val31, and Ile33.[483,484]

APC cleaves FVa at Arg306, Arg506, and Arg679,[485,486] but an FV mutation (Arg506 to Gln), known as factor V Leiden, is resistant to APC inactivation[465]; individuals carrying this mutation are at increased risk for venous thrombosis. Notably, APC cleavage at of FVa at Arg506 is kinetically favored over cleavage at Arg306, and cleavage at Arg506 is less dependent on the presence of PS than cleavage at Arg306.[26,27,465,486,487] Modeling of APC with FVa shows that basic residues in the c60-loop, c37-loop, c70-loop, and c148-loop of the protease domain of APC likely interact with negatively charged regions surrounding the Arg506 cleavage site in FVa.[477]

FVIIIa inactivation by APC requires both FV and PS as cofactors,[465,467,488] the laminin G2 domain being important in this synergistic cofactor activity.[482,489] APC cleaves FVIIIa at Arg336 and Arg562.[490,491] APC cleavage of FV at Arg506 is important for it to serve as a cofactor.[465,488,492,493] FV's anticoagulant cofactor activity is lost when thrombin cleaves after Arg1545 between the B domain and A3 domain.[492] PS can inhibit thrombin generation in plasma in the absence of APC,[494] most prominently at picomolar concentrations of TF.[495] PS serves as a cofactor for TFPI in its inhibition of FXa,[496] decreasing the Ki for TFPI/Xa complex formation from 4.5 to 0.5 nM.[496] It is likely that PS binds *via* its Gla domain to the Kunitz domain 3 and *C*-terminal tail of TFPI.[497–499]

ENZYME AND COFACTOR INTERACTIONS

The cofactor for FVIIa is TF, that for FIXa is FVIIIIa, that for FXa is FVa, that for APC is PS, and that for PZ is PZI[24] (Table 14.2). Thrombin does not require a cofactor in performing coagulant function but requires thrombomodulin to perform its anticoagulant function. The only enzyme–cofactor complex that has been crystallized to date is FVIIa/TF.

Interaction of FVIIa/TF with FXa or FIXa

The FVIIa/TF complex activates both FIX[500] and FX,[501] which depends on Ca^{2+}/Mg^{2+} and the PL membrane. In a reciprocal fashion, FXa and FIXa both activate FVII/TF.[12,13,51,52] FX chimeras show that the affinity of FX–Gla and FX–EGF1 domains toward FVIIa/TF is stronger than the FIX–Gla and FIX–EGF1 domains and that activation is slower for FX chimeras.[227] The FIX and FX chimeras with PC EGF domains also confirm the role of EGF1 in activation.[502] The experimental evidence confirms that Gla and EGF1 domains of FIX and FX bind to FVIIa/TF and the differences in the activation process arise from the variations in their affinity toward the FVIIa/TF complex.[184,205,227,337]

Computational models have been proposed for the ternary complexes of FVIIa/sTF–FXa, FVIIa/sTF:FIXa, and FVIIa/sTF:$FIX_α$.[185,186,206,227] In the absence of experimentally determined structures, these models serve as reasonable basis for understanding how Gla and EGF1 domains of FIX/IXa and FX/Xa interact with FVIIa/TF. In these models, the Gla domains of FXa[184–186,502] and FIXa/FIXα[205,206] interact with the TF domain as well as with the Gla domain of FVIIa. Although the structures of FXa and FIXa are similar, the variations in their sequences at the interface regions with sTF and with the Gla domain of FVIIa make associations different from each other. The residues between 9 and 12 in the Gla domain of FX and FX interact with FVIIa/TF. This region is basic in FXa, whereas hydrophobic and neutral in FIXa. The sequence variations in this region

tahir99-VRG & vip.persianss.ir

make interactions weak for FIXa and provide an explanation for why FIX binding is weaker as compared to FX. The *C*-terminal helix of the Gla domain in FX/Xa and of FIX/IXa interacts with *C*-terminal region of sTF.[203,205,206,223,227,337,503,504] Mutagenesis studies support the role of TF residues Arg200, Lys201, Thr167, and Lys165 in its interaction with the Gla domain of FXa/FIXa.[337,503] Comparable interactions exist between the *C*-terminal helix of the Gla domains of FXa or FIXa with TF.

Arg36 in the Gla domain of FVIIa is one of the key residues in substrate recognition for FX.[183] However, the recent FVIIa/sTF crystal structure at 1.72 Å reveals that Arg36 in FVIIa is involved in network of hydrogen bonds with TF.[179] The TF region containing residues Lys165 and Lys166 are well defined, and it appears that only one of these residues can interact with FXa. The *N*-terminal regions of EGF1 in FXa/FIXa domains interact with sTF in a similar manner; however, this region does not interact with FVIIa. Very little information is available about the EGF2 domain as well as the regions other than the activation peptide that are involved in ternary complex formation. The residue Arg^{290} [c147] in FVIIa protease domain is implicated to be important in FX activation.[505] The residues involved in the ternary complexes of FVIIa/TF with FXa or FIX/FIXα are described elsewhere.[186] Experimentally determined structures of the ternary complexes are needed to precisely define the interactive regions and to precisely understand the activation process for conversion of FX and of FIX to their respective enzymes.

Interaction of FIXa with FVIIIa

The recent crystal structure of FVIII reveals its domain organization and the regions which could possibly interact with FIXa.[506,507] FIXa:FVIIIa models[508,509] show that the protease domain of FIXa interacts with the A2 subunit of FVIIIa, part(s) of the EGF2/EGF1 domains interact with the A3 subunit of FVIIIa, and the Gla domain interacts with the C2 subunit of FVIIIa (FIGURE 14.11A,B).

Binding of FVIIIa to the FIXa protease domain was suggested by anti-FIX monoclonal antibody inhibition activity.[510] This antibody binds to a conformational epitope in the amino-terminal half of the catalytic domain.[511] Mutation of charged surface residues to the homologous residue in FX, however, failed to identify a species that had reduced FVIIIa binding.[512] Strong evidence supports the involvement of residues from the 293-helix [c126-helix], the 330-helix [c162-helix], and Asn^{346} [c178] in FIXa in binding to FVIIIa.[368,389,391,513] The 330-helix [c162-helix] binds to the 558-565 region of the A2 subunit of FVIIIa.[513] Isolated A2 domain enhances FIXa activation of FX approximately 200-fold,[514] although this is very much less than the effect observed with intact FVIIIa. Plasma-derived, recombinant wild type, and two protease domain Ca^{2+}-site mutants Glu^{235} [c70] to Lys and Glu^{245} [c80] to Val were compared in terms of the effect of PL and apparent FVIIIa binding.[378] Results allow one to infer that the Ca^{2+} binding loop is not directly involved in binding to FVIIIa but instead imparts a structural change in conformation that favors binding to FVIIIa.[512] Proteolysis in the autolysis loop, residues 310 to 323 [c141–c155] of FIXa, decreases binding to FVIIIa[378,379]; further, mutation of Lys^{316} [c148] to Ala or Glu,[366] mutation of Arg^{312} [c143] to Ala,[515] and proteolysis at the Lys^{316}–Gly^{317} [c148–c149] peptide bond[379] substantially reduce the rate of FX activation. Thus, the autolysis loop of FIXa is most likely involved in FX binding. Proteolysis of the autolysis loop is hypothesized to affect FVIIIa binding because the two helices important in binding to FVIIIa, 293-helix [c126-helix] and the 330-helix [c162-helix] are each linked to the autolysis loop *via* a single β-strand.[516]

The FIXa protease domain contains a Na^+ site[516] that coordinates to the carbonyl groups of residues 353 [c184A], 354 [c185], 391 [c221A], and 394 [c224]. The two Na^+ binding loops are held together by H-bond between Tyr^{395} [c225] and His^{354} [c185], and Tyr^{395} [c225] makes van der Walls contacts with the 330-helix [c162-helix] that binds FVIIIa.[516] A hemophilia B mutation in which Tyr^{395} [c225] is changed to His has been reported,[100] which could be due to impaired Na^+ and FVIIIa binding.

There is also evidence for a specific interaction between the FIXa EGF2 domain and FVIIIa. The EGF2 domain (residues 88 to 109) is important in assembly of the tenase complex.[290] Replacement of the Asn^{89}–Lys^{91} loop region only marginally

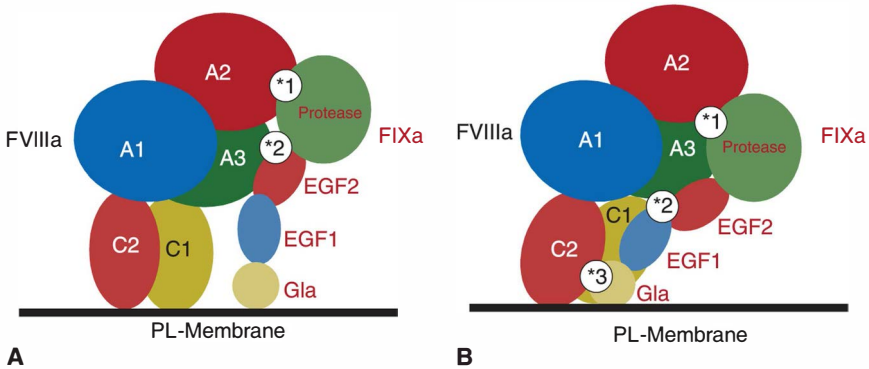

FIGURE 14.11 Schematics of the proposed models of the FVIIIa/FIXa complex. **A**: The protease domain of FIXa binding sites are localized in the A2 and A3 domains of FVIIIa and are indicated by 1* and 2*. The EGF2 domain binding sites in FIXa are localized in the A3 domain of FVIIIa and are indicated by 2*. **B**: The protease domain of FIXa binding sites are localized in the A2 and A3 domains of FVIIIa, but the EGF1 and EGF2 domains of FIXa interact with the A3 domain of FVIIIa. Further, the Gla domain of FIXa interacts with C2 domain of FVIIIa. These binding regions are indicated by 1*, 2*, and 3*.

tahir99-VRG & vip.persianss.ir

decreased the activation of FX in the presence of FVIIIa; however, replacement of the EGF1/EGF2 linker region Leu[84]–Thr[87] greatly decreased the activation of FX in the presence of FVIIIa (less effect with the A2 subunit).[291] Chang et al.[293] mutated every residue in the EGF2 domain to Ala and concluded that residues 89 to 94 are important in binding to FVIIIa, and residues 102 to 108 are involved in binding to FX. Thus, there is some discrepancy between these studies and results that remain to be resolved. It is possible that the EGF2 domain binds to either the A2 subunit, the A3 subunit, or to both the A2 and A3 subunits of FVIIIa.

The EGF1 domain may also influence FVIIIa binding, although this may not be due to a direct interaction. Several studies have emphasized the importance of Ca^{2+} binding to the EGF1 domain of FIXa in FVIIIa binding on PL surface,[111,294] and Gln[50] to Pro mutation only reduces affinity for FVIIIa in the presence of PL and not in its absence.[289] Studies with monoclonal antibody to the EGF1 domain indicate that conformational changes in the protease domain of factor IXa that occur during activation are allosterically transmitted to the EGF2 and EGF1 domains.[284] Thus, it appears that the EGF1 domain does not directly bind to FVIIIa but rather correctly positions the EGF2 and protease domains for proper interactions.

The Gla domain may also be involved in FVIIIa binding. Using synthesized Gla domains with Phe[9], Phe[25], or Val[46] replaced with benzoylphenylalanine, Gla25BPA and Gla47BPA constructs were cross-linked to FVIIIa, and immunoprecipitation experiments suggest that the Gla domain of FIXa interacts with the C2 domain of FVIIIa.[207,208,517] Mutation of Gly[12] to Arg has also been reported to disrupt FVIIIa binding[209]; however, this is most likely due to a structural impairment rather than from a direct binding effect. Thus, more studies are needed to elucidate the exosites on FIXa important in binding to FVIIIa, particularly with respect to the EGF2, EGF1, and Gla domains.

Interaction of FXa with FVa

The association of FXa with its cofactor FVa increases the conversion rate of prothrombin to thrombin by 10^6-fold (FIGURE 14.12). Structural models[518] have been proposed for the prothrombinase complex based on the crystal structure of inactivated bovine FVa.[519] In the FXa/FVa complex, the protease domain of FXa interacts with A2 and A3 domains of FVa, whereas EGF2 domain interacts with A2 domain of FVa. The experiments performed with FX chimera containing FIX Gla and EGF1 domains suggest that the EGF2 and protease domains in FXa are sufficient for FVa binding, whereas the Gla and EGF1 domains are not directly involved in FVa binding.[281,299,502] Alanine mutagenesis at the conserved basic residues in FXa show that the heparin-binding sites and the FVa sites overlap with each other and the residues in 344-loop [c162-loop] are involved in FVa binding.[520] Mutational experiments involving autolysis loop indicate that the activation loop is not part of the FVa binding site.[521] The *C*-terminal helical region is also shown to be involved in FVa binding.[522] The alanine mutations in c184-loop and c220-loop of FXa impair the Na^+ binding and show reduction in its activity toward both synthetic and macromolecular substrates; however, binding of the cofactor FVa restores the FXa catalytic activity.[299,523] These results support the hypothesis that the Na^+ and FVa-binding sites in FXa are energetically linked to each other and the binding of FVa to FXa induces conformational change in the Na^+ binding loops and keep them in a Na^+ bound active conformation.[381,520,523]

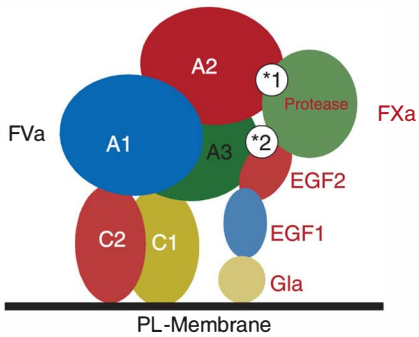

FIGURE 14.12 Schematics of the proposed model of FVa/FXa complex. The protease domain binding sites in FXa are localized in the A2 and A3 domains of FVa and are indicated by 1* and 2*, while the EGF2 domain binding sites in FXa are localized in the A3 domain of FVa and are indicated by 2*.

CHAPTER

15A Factor XI

PETER N. WALSH AND DAVID GAILANI

Coagulation factor XI (FXI), previously known as plasma thromboplastin antecedent, was first identified by Rosenthal et al.[1] as a deficiency in the plasma of patients with abnormal bleeding and, subsequently, was found to be particularly common in patients of Ashkenazi Jewish descent.[2,3] FXI was first purified from bovine[4] and human[5] plasma as a 160-kDa homodimeric protein that participates in interactions with coagulation proteins of the contact phase of blood coagulation.[6–9] Factor XI is the zymogen of a trypsin-like serine protease that is activated by FXIIa and by both thrombin and FXIa,[10,11] and it can then recognize FIX as its normal macromolecular substrate in plasma.[12–14]

GENE STRUCTURE AND REGULATION

The approximately 23 kb human FXI gene contains 15 exons and is located on the distal end of the long arm of chromosome 4 (4q35).[15,16] The FXI cDNA derived from human liver mRNA is 2,097 nucleotides long.[17] The first exon is untranslated, while the second encodes the signal peptide. The factor XI polypeptide in plasma contains 607 amino acids encoded by exons 3 to 15 (see FIGURE 15A.1).[15,17,18] Exons 3 to 10 encode four repeats called *apple domains* (A1 to A4 from the *N*-terminus).[18] The intron–exon boundaries are located at similar positions within each apple domain, indicating duplication from a common ancestral sequence.[15] Apple domains are members of the PAN (*P*lasminogen, *A*pple, *N*ematode) module family, with homology to the *N*-terminal domains of hepatocyte growth factor and plasminogen[19] and similar core topology to PAN domains from leech antiplatelet protein,[20] the protozoan microneme antigen EtMIC5,[21] and apical membrane antigen 1 from *Plasmodium falciparum*.[22]

Exons 11 to 15 of the FXI gene encode the trypsin-like catalytic domain and are organized similarly to genes for tissue plasminogen activator and urokinase.[15] The proteases thrombin and factors VIIa, IXa, and Xa have tyrosine or phenylalanine in their catalytic domains at the position corresponding to residue 225 in chymotrypsin. This confers Na^+-induced allosteric regulation on the catalytic domain and is associated with an AGY codon for the active site serine residue (Ser195, chymotrypsin numbering), consistent with these proteases having evolved from a common thrombin-like protease.[23,24] In contrast, FXIa and the contact proteases α-kallikrein and FXIIa have proline at position 225, indicating they are not regulated by sodium. Pro225 is associated with a TCN codon for Ser195, suggesting these proteases evolved from a trypsin-like protease distinct from the ancestor of the vitamin K–dependent proteases.[23]

The amino acid sequence of human FXI is 58% identical to plasma prekallikrein (PK, the zymogen of α-kallikrein),[17] which also consists of four apple domains and a trypsin-like catalytic domain.[18,25] The PK gene contains 15 exons, with intron–exon boundaries in identical positions to those of the FXI gene,[26] indicating the genes are products of a duplication event. Consistent with this, exon 15 of the PK gene is only approximately 8 kb from exon 1 of the FXI gene in humans.[27] Analyses of vertebrate genomes reveal that fish do not have homologs for FXI or PK.[28,29] A gene encoding a serine protease with four apple domains that is clearly ancestral to both proteins is found in amphibians, birds, reptiles, and the primitive egg-laying mammal (monotreme) the duck-billed platypus.[29,30] The proteins encoded by the ancestral genes have features that are more similar to PK than FXI.[30] Distinct genes for FXI and PK are present in the opossum, a marsupial, and in placental mammals, indicating duplication of the ancestral gene occurred after the common lineage leading to these two groups diverged from monotremes.[30]

The normal site of synthesis of plasma FXI is the liver. FXI levels decrease in liver disease, and patients have acquired,[31,32] or been cured of,[33,34] FXI deficiency by liver transplantation. Northern blot analysis confirms that the liver is the major, if not exclusive, site of FXI mRNA synthesis in mice.[35] In humans, FXI mRNA has been found by northern blot[35] and reverse-transcriptase polymerase chain reaction (RT-PCR)[36] in liver, pancreas, and kidney; and by RT-PCR in platelets.[37–39] Immunohistochemistry studies confirmed that FXI protein is present in human hepatocytes, pancreatic islet cells, and the proximal and distal tubules in the kidney.[40] The sequence between base pairs −385 and −350 of the human FXI gene promoter contains a binding site for hepatocyte nuclear factor-4α (HNF-4α), a transcription factor that appears to be required for hepatocyte-specific FXI expression.[27] Mice with a liver-specific deletion of HNF-4α have reduced plasma FXI levels.[41] HNF-4α is expressed at high levels in human pancreatic islets and kidney,[42,43] explaining the presence of FXI in these tissues. There is a small amount of FXI activity associated with platelets (~0.5% of the activity in plasma),[44–48] but it is not clear that FXI mRNA found in platelets is responsible for this. Platelet FXI is discussed in detail below.

Large epidemiologic studies have demonstrated an association between plasma FXI level and venous[49] and arterial thrombotic disease[50]; however, genetic factors controlling FXI gene expression are not well understood. Common single nucleotide polymorphisms (SNPs) are present in the human FXI gene promoter at base pair −403 (G/T) and −273 (C/G), the latter of which clearly alters transcription factor binding in gel mobility shift assays.[51] However, it is not clear that there is a relationship between these SNPs and plasma FXI level. Two common SNPs within the FXI gene have recently been associated with deep

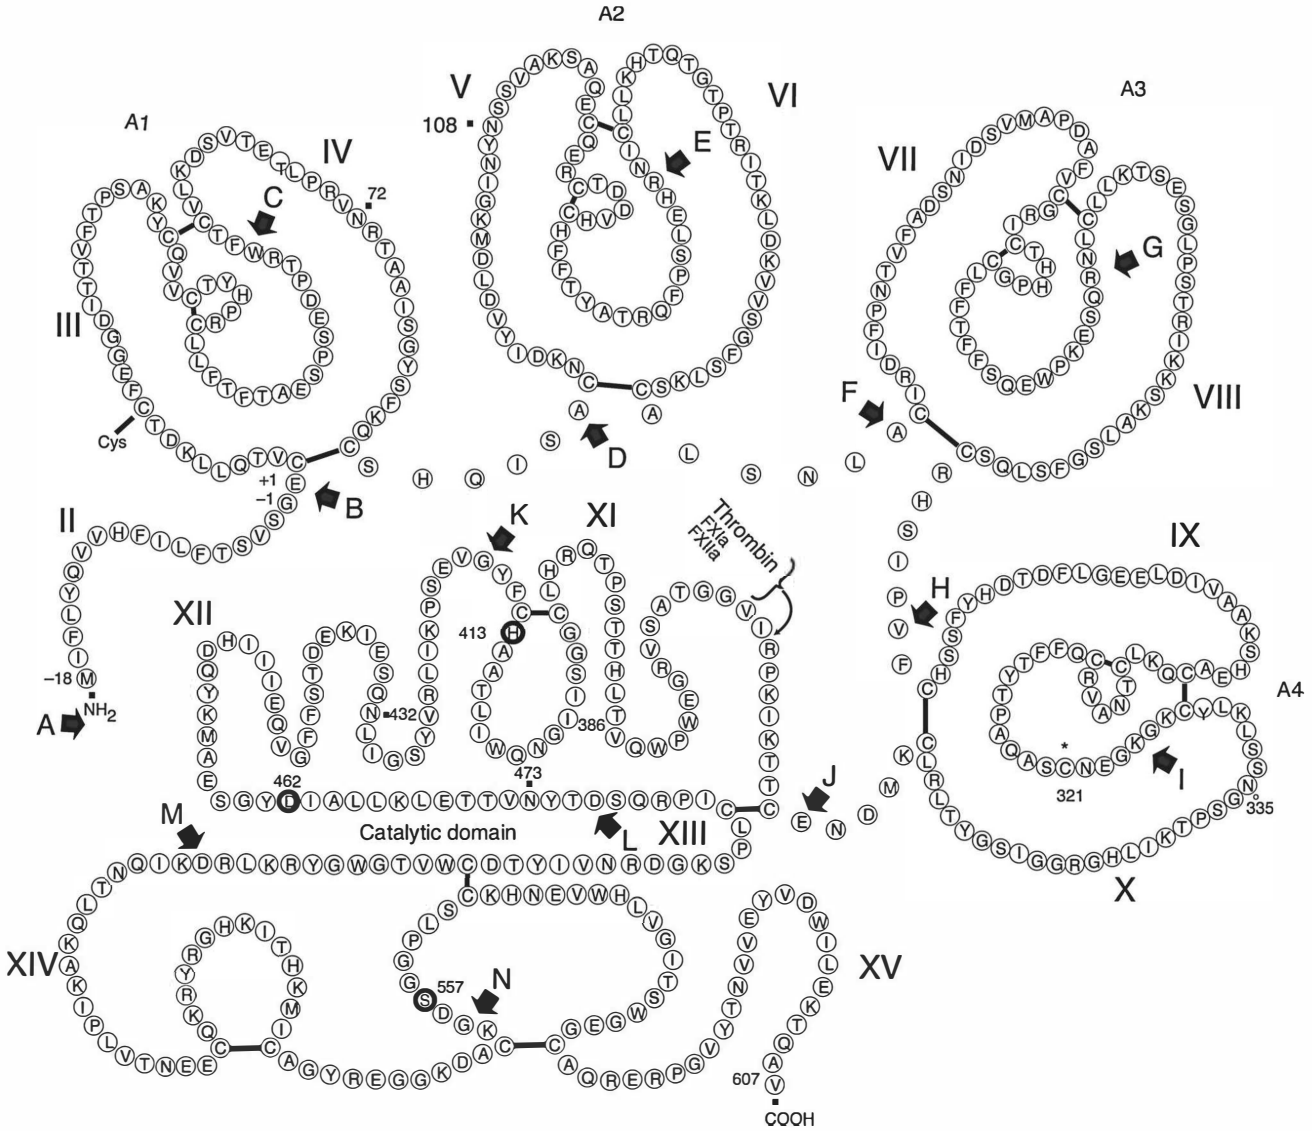

FIGURE 15A.1 Amino acid sequence and primary structure of human FXI. The signal sequence (numbered −18 to −1) is removed during biosynthesis by signal peptidase by the cleavage of the G–E bond between −1 and −2. Factor XI circulates in plasma as a homodimer connected by a single disulfide bond linking C321 in both of the fourth apple domains. The 14 introns (A to N) are shown by *solid arrows*. The exons are denoted by II to XV amino- to carboxy-terminus, with exon II representing the propeptide and exon I (not shown) representing the 5′ untranslated region. The four apple domains (consisting of 90 to 91 amino acids) are labeled as A1, A2, A3, and A4. The site of cleavage catalyzed by thrombin, factor XIa, or factor XIIa during the conversion of factor XI to factor XIa is shown with a *small, curved arrow*. The three members of the catalytic triad (H413, D462, and S557) are *circled* in *bold*. The four *N*-linked carbohydrate chains (i.e., N72, N108, N432, and N473) are shown by solid squares. (Figure redrawn and modified from McMullen BA, Fujikawa K, Davie EW. Location of the disulfide bonds in human coagulation factor XI: the presence of tandem apple domains. *Biochemistry* 1991;30:2056–2060.)

venous thrombosis (DVT) and high plasma levels of FXI.[52,53] Interestingly, the SNPs remained associated with risk of DVT even after adjustment for FXI level,[53] but the mechanisms by which these polymorphisms contribute to thrombosis risk is not known.

Full-length and partial FXI cDNA sequences are now available for more than a dozen mammalian species. The best characterized of these are the murine[35] and rabbit[54] cDNAs, which encode proteins of 624 amino acids (18 amino signal peptides and 606 amino acid mature polypeptides) with 78% and 87% amino acid sequence homology to human FXI. In most species, the two polypeptides of the FXI homodimer are covalently linked by a disulfide bond involving Cys321 in the A4 domain.[55,56] The single known exception is rabbit FXI, which migrates as a monomer during denaturing gel electrophoresis due to histidine replacing Cys321.[54] Western blot analysis using a monoclonal antibody that recognizes a conserved epitope on the apple 2 (A2) domain confirms that FXI from species

other than the rabbit can form disulfide bond-linked dimers.[57] Despite lacking the Cys321-Cys321 bond, rabbit FXI exists in plasma as a noncovalently associated homodimer that is functionally identical to human FXI.[54]

There is little detailed information regarding intracellular processing and posttranslational modification of FXI. The protein undergoes N-linked glycosylation at Asn72, Asn108, Asn432, and Asn473, but not at the potential glycosylation site at Asn335.[17] Dimer formation is an intracellular event that was initially thought to be required for normal secretion of the protein, based on observations that naturally occurring mutations in the fourth apple domain that interfere with dimerization are associated with poor secretion.[58,59] However, it is now apparent that some forms of monomeric FXI with mutations that disrupt the dimer interface are synthesized and secreted similarly to wild-type protein in culture.[56] Failure to secrete some FXI variants that have defects in dimer formation, therefore, are likely related to structural perturbations distinct from the defect in dimerization.

PROTEIN STRUCTURE

Human FXI (M_r ~ 143,000) is a disulfide-linked homodimer containing approximately 5% carbohydrate (i.e., 0.6% hexose, 2.7% *N*-acetylhexosamine, and 1.7% *N*-acetylneuraminic acid), and is present in human plasma at a concentration of 4 to 6 μg/mL (~30 nM) in the form of a zymogen that requires proteolytic activation to develop serine protease activity.[5,8,60–62] The zymogen form of the protein is unique among coagulation factors because it is a disulfide-linked homodimer consisting of two identical polypeptide chains. Each FXI polypeptide contains 607 amino acids, and each can be proteolytically activated by FXIIa, thrombin, or FXIa[5,8,9,10,11] at an internal R369–I370 bond to yield a heavy chain (i.e., 369 amino acids) and a light chain (i.e., 238 amino acids) that contain a typical trypsin-like catalytic triad, consisting of H413, D464, and S557, with a typical trypsin-like substrate-binding pocket.[17,18] After cleavage at R369–I360 bond, the catalytic domain contains an amino-terminal sequence of I-V-G-G characteristic of most serine proteases. The M_r of the homodimer is 135,979 without carbohydrate, and 143,000 with four carbohydrate chains at N72 and N108 within the heavy chain and at N432 and N473 within the catalytic domain, whereas no carbohydrate is present on N335, another potential *N*-glycosylation site.[17]

The primary sequence and domain structure of FXI, including its disulfide linkages, are shown in FIGURE 15A.1. The amino-terminal 369 residues of each FXI monomer after propeptide cleavage comprises the heavy-chain region of FXIa, which consists of four tandem repeat sequences (Apple domains) of 90 to 91 amino acids, each containing six or seven cysteine residues that form three internal disulfide bonds. The amino acid sequences of each apple domain are 23% to 34% identical to the other apple domains of FXI and 58% identical to the corresponding apple domains of plasma PK. In both plasma FXI[17,18] and plasma PK, a characteristic disulfide-bonding pattern links the first and sixth, second and fifth, and third and fourth cysteines in each of the four apple domains.[18] An additional cysteine is present at position 11 in the A1 domain of FXI and forms a disulfide bond with another cysteine residue, whereas C321 in the A4 domain is disulfide-linked to the corresponding C321 to form the homodimer.[18]

Crystal structures have recently been reported for full-length FXI[63] (see FIGURE 15A.2), and for the catalytic domain of FXIa in complex with both synthetic and natural inhibitors including

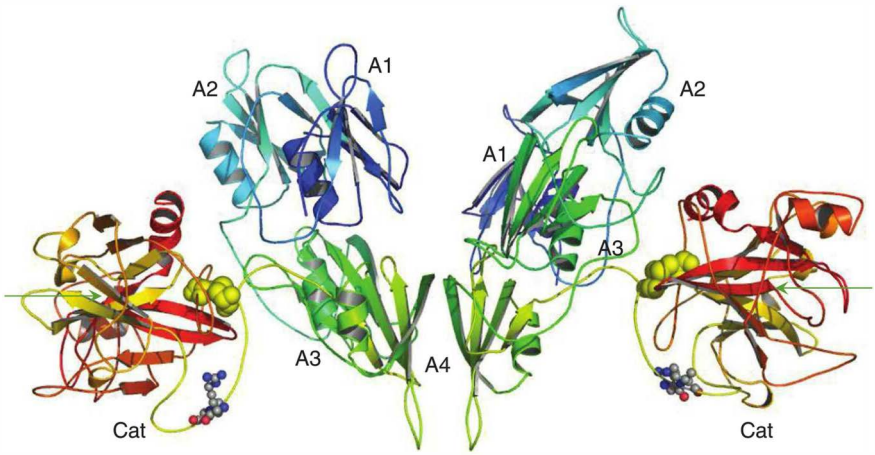

FIGURE 15A.2 X-ray crystal structure of human factor XI zymogen. The FXI dimer is shown with the two monomeric subunits interacting with noncovalent interactions mediated by residues within the two Apple 4 (A4) domains and stabilized by a disulfide bond (not shown) between the two Cys321 residues in each of the two A4 domains. The four apple domains constituting the heavy chain region of each monomer are designated A1, A2, A3, and A4 and the catalytic domains (light chains of FXIa) are designated Cat. The disulfide bonds between Cys362 in the A4 domain and Cys482 in the catalytic domain are designated by the *yellow space-filling ball structures*. The site (Arg369-Ile370) cleaved by FXIIa, thrombin, or FXIa is designated by the small space-filling balls in the connecting loops between the A4 domains and the catalytic domains. The *fine arrows* point at the active site Ser557 residues within each of the catalytic domains. (Figure modified from Papagrigoriou E, McEwan P, Walsh PN, et al. Crystal structure of the factor XI zymogen reveals a pathway for transactivation. *Nat Struct Mol Biol* 2006;13:557–558.)

the Kunitz protease inhibitor (KPI) domain of protease nexin-2 (PN2)[64,65,66]. The structural features of FXI and their implications for molecular function have recently been discussed in detail[67]. In addition, the solution structure of the FXI A4 domain has been reported[68] that predicts a major conformational change in the structure of FXI when it is activated to FXIa.

PLATELET FACTOR XI

There are differing opinions regarding the possibility that human platelets contain FXI activity and that the activity is associated with a form of FXI encoded by an alternatively spliced mRNA from the FXI gene. FXI coagulant activity and antigen have been described in washed platelet suspensions, and it has been estimated that the activity constitutes up to 0.5% of the FXI activity in normal plasma.[44–47,69] Polyclonal, but not monoclonal, antibodies to human plasma FXI cross-react with a platelet protein with an apparent M_r of 220,000 on nonreducing SDS-PAGE which decreases to 55,000 after reduction. For comparison, plasma FXI has an M_r of 160,000, and each subunit has an M_r of 80,000.[44–46] Thus, it has been suggested that platelet FXI could represent a disulfide-linked tetramer of identical 55,000-M_r subunits. Alternatively, the 55,000-M_r protein could be disulfide linked to a platelet membrane protein.[37,45,70] A candidate for this putative platelet FXI-binding protein is glycoprotein Ib (GP Ib) (M_r ~ 170,000). This possibility is supported by studies demonstrating that platelets from patients with Bernard-Soulier syndrome who lack GP Ib contained no detectable FXI activity in washed platelet suspensions.[71] It is important to point out, however, that the 55,000-M_r species has not been shown to have FXI activity (i.e. the capacity to activate factor IX) in functional assays.

If the 55,000-M_r platelet protein is encoded by an mRNA transcribed from the FXI gene, the mRNA would need to be spliced differently than FXI mRNA in hepatocytes. FXI mRNA is present in platelet RNA; however, there are conflicting reports on its nucleotide sequence.[37–39,72] The FXI mRNA in hepatocytes is 2.1 kb in size. A 1.9 kb mRNA transcript was isolated from a megakaryocytic leukemia cell line (MEG-01) that had an identical open reading frame to the hepatocyte species, with the exception that it lacked nucleotides corresponding to exon V.[37] This would result in deletion of amino acids A91 through R144 within the A2 domain. By contrast, two other groups have reported that the FXI mRNA in platelets and megakaryocyte cell lines (including MEG-01) is identical in sequence to FXI mRNA in liver.[38,39] Furthermore, attempts to express a FXI cDNA lacking exon V in a fibroblast line resulted in a poorly expressed protein of 73,000-M_r that was not secreted.[73] Thus, the data linking the platelet protein detected with the polyclonal anti-FXI antibody or the FXI mRNA species detected in platelet mRNA to FXI activity are not compelling, and it is not currently possible to conclude that the FXI activity associated with platelets is distinct from plasma FXI of hepatocyte origin.

STRUCTURE–FUNCTION RELATIONSHIPS

Factor XI Activation

Plasma FXI circulates as a zymogen in human plasma as a complex with high molecular weight kininogen (HK),[7] which is required for binding of FXI to negatively charged surfaces[74] (see Chapter 15B). FXI can be activated by four biologically relevant proteases: FXIIa, FXIa, thrombin, and meizothrombin.[5,10,11,75,76] It can participate in the contact phase of blood coagulation in a reaction that requires the presence of anionic surfaces for optimal surface-mediated *in vitro* activation by FXIIa.[6,7,74,77,78] However, because deficiencies of FXII, PK, and HK are not associated with hemostatic abnormalities but deficiency of FXI produces abnormal bleeding complications in at least 50% of affected individuals,[2,3,79–81] it has been suggested that the more relevant *in vivo* pathway for activation of plasma FXI might be by the feedback activation by thrombin or, possibly, by autoactivation by FXIa.[10,11,82] It has been shown that β_2-glycoprotein I (β_2-GPI) binds FXI and inhibits its activation by thrombin and FXIIa, whereas cleaved β_2-GPI binds FXI but fails to inhibit FXI activation.[83] All four proteases (i.e., thrombin, FXIIa, FXIa, and meizothrombin) cleave each monomer of FXI at the R369–I370 bond, generating the new amino-terminal sequence of the catalytic domain, I-V-G-G, which then activates the catalytic triad of the serine protease. It has been postulated that on anionic surfaces, such as in extracorporeal circulation, a ternary complex is formed when FXI, in stoichiometric complex with HK in plasma, is adsorbed to the negatively charged surface, where FXIIa recognizes it as a substrate.[6,7,74,77,78,84–87] The FXI homodimer is thereby cleaved to generate two disulfide-linked heavy chains (M_r ~ 50,000) and two active-site–containing light chains (M_r ~ 30,000).[5,8] Recent observations demonstrate that FXI activation by thrombin or FXIIa proceeds through the generation of an intermediate consisting of one cleaved and one uncleaved subunit, referred to as ½-FXIa, which can be detected in plasma undergoing contact activation.[88]

An important role for the dimeric structure of FXI in zymogen activation has been demonstrated. Thus, the A4 domain of FXI mediates dimer formation between the two identical polypeptide chains comprising FXI through disulfide bond formation at C321,[17,18,55,56,58,89–91] and the two identical subunits of FXI utilize a substantial interface (886 Å^2) between two adjacent A4 domains to form the dimeric structure of the mature protein.[63,68] Utilizing FXI with substitutions for Cys321, which still form stable dimers, it has been demonstrated that hydrophobic interactions involving Leu284, Ile290, and Tyr329, and salt bridges between Lys331 of one subunit and Glu287 of the other[56] are required for dimer formation, and that FXI dimer formation is required for efficient FXI activation by thrombin, FXIIa, and FXIa.[55,56,63,68,89–92]

Functional Domains of Factor XI

Prior to the availability of FXI structures from x-ray crystallography and NMR and based on the use of molecular models of the four FXI apple domains,[93–97] monoclonal antibodies, conformationally constrained synthetic peptides, and recombinant proteins[98] with site-directed mutations, the binding sites within FXI for a number of physiologically relevant plasma or cellular ligands have been identified and characterized.

Thrombin,[99,100] HK,[73,93,95,101] and the kringle 2 domain of prothrombin[103] have all been shown to bind to contiguous subdomains within the carboxy-terminal half of the A1 domain (E1–S90). Thus, HK binds to a subdomain within the A1 domain comprising residues F56–S86, whereas thrombin binds to a partially overlapping and contiguous site comprising subdomain A45–R70. Different amino acid side chains appear to be essential for these interactions because E51 and E66 are important for thrombin interactions with FXI but not for HK binding, whereas V64 and I77 are important for HK binding but not

for thrombin binding[101]. The kringle 2 domain of prothrombin can bind to a subdomain comprising residues A45–S86, but fine mapping of this site has not yet been accomplished.[102] Occupancy of these sites by their respective ligands is likely to be important in promoting the binding of FXI the GP Ibα subunit of the GP Ib/IX/V complex on the platelet surface[100] either in the presence of HK and Zn^{2+} ions or prothrombin and Ca^{2+} ions.

The A3 domain of FXI has been identified as the locus of binding sites for both platelets[97,103–108] and heparin.[109,110] Thus, activated platelets expose specific reversible, high-affinity binding sites for FXI that require the presence of HK and $ZnCl_2$,[111] or prothrombin and $CaCl_2$.[102] Binding of FXI to activated platelets through the A3 domain[97,111] is required for optimal rates of FXI activation by FXIIa.[112] The sequence of residues within the A3 domain of FXI (i.e., N235–R266) that comprises a contact surface for interaction with a platelet receptor consisting of the GP Ibα subunit of the GP Ib/IX/V complex[107,108] contains amino acids that mediate this binding, including N248, R250, K255, F260, and Q263.[104,106] The A3 domain of FXI also contains all the binding energy required for interaction of FXI with heparin in a heparin-binding consensus sequence (i.e., T249–F260) that contains amino acids K252 and K253, and possibly K255, which at least in part mediate the binding of FXI to heparin.[109,110]

A major role of the A4 domain of FXI is to mediate dimer formation, the functional significance of which is discussed in detail above in the section on FXI activation. Furthermore, a natural mutation in FXI (F283L), resulting in diminished intracellular dimerization and secretion of the protein,[58] also markedly affects dimer dissociation and the unfolding mechanism of FXI, indicating that F283 is important for noncovalent dimer formation.[91] In addition, a sequence of residues (i.e., A317–G350) within the A4 domain of FXI appears to contain three peptide structures, possibly consisting of three antiparallel β-strands that together comprise a contact surface for interaction with FXIIa. This site may participate in the activation of FXI by FXIIa.[96,103]

CELLULAR INTERACTIONS

Early observations suggesting that platelets participate in the contact phase of blood coagulation[113–117] were subsequently confirmed by the evidence that isolated human platelets activated with either adenosine diphosphate or collagen could promote the proteolytic activation of FXII by kallikrein and, subsequently, the activation of FXI by FXIIa in the presence of HK.[47,112,118,119] The mechanism underlying the role of activated platelets in the activation of FXI involves the generation of high-affinity (dissociation constant, K_Φ ~10 nM), specific, saturable binding sites (~1,500 sites per platelet) on the surface of activated platelets that require the presence of HK and Zn^{2+} ions.[111] The observation that HK also binds to platelets under similar conditions originally suggested that the two proteins bind to the platelet surface as a complex.[120,121] However, it has subsequently been shown that HK interacts with FXI through a surface-exposed site encompassing residues F56–S86 within the A1 domain[93,95,122], resulting in the exposure of a platelet binding site encompassing residues N235–R266 within the A3 domain of FXI.[97] It has also been demonstrated that prothrombin can substitute for HK as a cofactor for the binding of FXI to the surface of activated platelets.[102] In this way, prothrombin appears to bind to a site in the A1 domain of factor XI contiguous to the site used by HK for binding to the A1 domain.[102] The platelet receptor that binds factor XI and colocalizes it with thrombin for efficient activation has recently been shown to consist of the GP Ibα subunit of the GP Ib/IX/V complex that is localized within platelet membrane microdomains referred to as *lipid rafts*.[107,108] This interaction of FXI with surface membranes of activated platelets has been shown to be mediated by binding of residues (i.e., R250, K252, K253, K255, F260, and Q263) within the A3 domain of FXI[104] to the leucine-rich repeat motifs of GP Ibα.[123] The binding of FXI to activated platelets and activation by thrombin are mediated by the interaction of FXI and platelet GP Ibα with thrombin anion-binding exosites I and II, respectively.[100,124,125]

Endothelial cells can expose specific, saturable, high-affinity binding sites for both FXI and HK, as well as other coagulation proteins, which raises the possibility that endothelium as well as platelets can participate in the activation of FXI by FXIIa.[126–132] However, it has recently been shown that what was interpreted as a specific interaction of FXI with the endothelial cell surface is an artifact of binding to microtiter plates, suggesting that endothelial cells do not participate in the initiation of the consolidation phase of blood coagulation.[133,134] Moreover, the interaction of FXIa with activated platelets, but not with endothelial cells, promotes the activation of FIX.[133,134] Therefore, the endothelial cell surface is generally regarded as anticoagulant and nonthrombogenic (see Chapter 42), and it has been suggested that the binding of HK to endothelial cells may be more important for the regulation of bradykinin production[135–137] and for the activation of prourokinase[138] and plasminogen[135,138] than for the procoagulant functions promoted by FXI.[133,134,136,137]

FXIa Enzymatic Activity

After activation on artificial surfaces, FXIa remains surface bound and recognizes FIX as its normal macromolecular substrate.[12–14,139] In the presence of calcium ions, FXIa cleaves FIX, a single-chain 57,000-M_r glycoprotein with 17% carbohydrate, at an internal R145–A146 bond, forming an intermediate that is subsequently hydrolyzed at an R180–V181 bond to generate active FIXa and to form a 10,000-M_r activation peptide, 50% of which is composed of carbohydrate.[12–14,139–144] The light chain of FXIa or catalytic domain (i.e., C362–V607) contains a typical trypsin-like catalytic triad comprising residues H413, D462, and S557 (H57, D102, and S195, chymotrypsin numbering) that are activated when FXI is cleaved at R369–I370 bond to expose a new amino-terminal tetrapeptide, I-V-G-G, typical of trypsin-like serine proteases. The active site of FXIa can cleave and activate two major macromolecular substrates, including FIX[12–14] and FXI.[10,11] In addition, both FXIa and plasma kallikrein have been shown to activate prohepatocyte growth factor, raising the possibility that they may regulate processes that involve the HGF/c-Met pathway, such as tissue repair and angiogenesis.[145]

The interaction of FXIa with its preferred macromolecular substrate, FIX, involves Ca^{2+}-dependent binding of FIX to a substrate-binding site within the heavy chain of factor XIa.[14,146,147] The location and characterization of this substrate-binding site have been studied in two laboratories with conflicting results.[94,148,149] One of these studies used molecular modeling and conformationally constrained synthetic peptides to identify a sequence of residues (i.e., A134–L172) within the A2 domain of FXIa that contains three antiparallel β-strands connected by

β-turns that have the characteristics of a substrate-binding site for FIX because they act as competitive inhibitors of FIX activation by FXIa.[94] In contrast, recombinant FXI proteins, in which each of the four apple domains is individually replaced with the corresponding domain from the homologous but functionally distinct protein PK, revealed that when the A3 domain of PK was inserted into FXIa, the Michaelis constant (K_m) for activation of FIX was 35-fold higher than the K_m for activation by wild-type FXIa or by the other FXI/PK chimeras.[148,149] Mapping of the A3 domain of FXIa by alanine-scanning mutagenesis has identified residues in the *N*-terminus (i.e., I183–V191, and possibly S195–I197) and the *C*-terminus (i.e., F260–S265) of the A3 domain that are required for FIX activation.[149,150] The interaction of FXIa with FIX is also dependent on the γ-carboxyglutamic acid (Gla) domain of FIX.[151] Therefore, the putative substrate-binding site for FIX resides either within the A2 or A3 domain (or both) of FXIa. A possible resolution of these two apparently conflicting studies is that intimate interdomain interactions between A2 and A3 may be required for maintaining an intact substrate-binding site that interacts with the Gla domain of FIX. Evidence has also been published to indicate that the Gla domain of FIXa binds to the A3 domain of FXIa,[152] and that loss of the A3 domain has a more deleterious effect on cleavage of FIX at Arg180-Val181 than at Arg145-Ala146, suggesting that the A3 domain exosite facilitates cleavage of FIXα to FIXaβ.[88,153] In addition to the FIX substrate-binding exosite within the heavy chain of FXIa, recent studies demonstrate the presence of an additional exosite for FIX binding, remote from the active site, within the catalytic domain, that is required to mediate the formation of the Michaelis complex and efficient cleavages of the two spatially separated scissile bonds of FIX.[153]

Cellular Interactions and Regulation of Factor XIa

The regulation of FXIa depends on its localization (i.e., whether it appears on the platelet surface, in the proximity of endothelium, or in the plasmatic compartment of the blood). Within the plasma, four separate serine protease inhibitors (serpins) have been demonstrated to inactivate FXIa: antithrombin III, α_1-protease inhibitor, C1 inhibitor, and α_2-antiplasmin.[8,60,154–163] It has also been shown that another serpin, protease nexin-1, which is not present at physiologically significant concentrations in plasma but which is secreted in low concentrations from platelet α-granules, inhibits FXIa in the presence of heparin with potency greater than that of C1 inhibitor.[164] FXIa also has been reported to be inhibited by plasminogen activator inhibitor 1[165] and protein C inhibitor.[166] The inhibition of FXIa within the plasma compartment has been postulated to occur predominantly through the action of α_1-protease inhibitor,[156] although studies on the modulation of contact system proteases by glycosaminoglycans indicate a selective enhancement of the inhibition of FXIa by C1 inhibitor[167] and by protease nexin-1.[164]

Because FXIa can be formed on the platelet surface[47,111,112,119] and it can bind to high-affinity (K_d ~ 800 pM), specific, saturable receptors (130 to 500 sites per platelet) on activated platelets in the presence of HK, the binding being mediated by a catalytic domain exosite within the enzyme and distinct from those for FXI,[133,168,169] it has been suggested that FIX activation by FXIa might also occur on the platelet surface.[170] Although the binding of FXIa to platelets does not appear to enhance rates of FIX activation,[133,170,171] both FXIa[133,168] and FIX[172] can bind to high-affinity, saturable receptors on activated platelets. Within the environment of activated platelets, FXIa is regulated by different mechanisms from those operative in plasma because platelet-bound FXIa is protected from inactivation by α_1-protease inhibitor.[159]

In addition, platelets are known to secrete inhibitors of FXIa[173–177] including PN2, a truncated form of the transmembrane Alzheimer β-amyloid protein precursor that contains a Kunitz-type serine protease inhibitor (KPI) domain. PN2 is a potent inhibitor of FXIa (inhibition constant, K_i 2.9 to 4.5×10^{-10} M) that has considerably enhanced inhibitory activity in the presence of heparin (K_i 2.5 to 4.5×10^{-11} M),[65,175–181] which provides a template for the assembly of FXIa/PN2 complexes.[178] Although the release of PN2 from activated platelets inhibits plasma FXIa activity in the environment of the hemostatic thrombus, platelet-bound dimeric (but not monomeric) FXIa is protected from inactivation by PN2.[133,171,180] In contrast, endothelial cells have no such protective effect, suggesting that whereas FXIa is protected from inactivation by PN2 when bound to the platelet surface, inactivation of FXIa by PN2 might be enhanced on the surface of endothelial cells that contain heparan sulfate glycosaminoglycans. Therefore, it has been suggested that the colocalization of dimeric FXIa and FIX to the activated platelet surface may serve to localize FIX activation and subsequent coagulation reactions to the activated platelet surface that contains specific, high-affinity, saturable binding sites for the enzyme FIXa. In the presence of FVIII, the occupancy of these sites can increase the catalytic efficiency (k_{cat}/K_m) of FX activation by more than 20 millionfold.[172,182–184]

MOLECULAR GENETICS OF FACTOR XI DEFICIENCY

Hereditary FXI deficiency is an autosomal disorder characterized by trauma-related hemorrhage, and only rarely by the "spontaneous" bleeding typical of FVIII or FIX deficiency.[185–187] Clinical manifestations and treatment are discussed elsewhere (see Chapter 53). Bleeding is highly variable, although it tends to be more prevalent with severe reductions in plasma FXI (<0.2 U/mL).[80,185,186,188] However, patients with mild deficiency (0.2 to 0.5 U/mL) can experience posttraumatic bleeding, while those with very severe deficiency may not bleed excessively.[2,3,80,185,187–189] This situation has contributed to difficulties in establishing inheritance patterns. First described by Rosenthal et al.[1] in 1953, FXI deficiency was initially considered a dominant disorder with variable penetrance,[79,190,191] in contrast to deficiencies of other coagulation proteases, which are usually symptomatic only in the homozygous or compound heterozygous states. Rapaport et al.[2] suggested that FXI deficiency exists in major (<1% to 20% of normal plasma activity) and minor (20% to 65% normal activity) forms, more consistent with a recessive mode of inheritance. Recessive inheritance is generally accepted for the more common forms of the disorder caused by the Glu117Stop and Leu283Phe mutations (discussed below).[185,186] Brenner et al.[192] used a logistic regression model to assess bleeding in 45 families with FXI deficiency caused primarily by these mutations, and determined the odds ratios for bleeding were 13.0 and 2.6 for homozygotes and heterozygotes, respectively.

The incidence of severe FXI deficiency is estimated at one per million in the general population[193,194]; however, the disorder is common in Ashkenazi Jews in whom the carrier (heterozygous)

frequency for a FXI gene mutation is approximately 5%, with severe deficiency (<15% of normal level in this population) in 0.1% to 0.3%.[185–187,194,195,196] The Glu117Stop (type II) and Leu283Phe (type III) mutations account for >90% of abnormal FXI alleles in Jews.[185,195,196,197] The type II mutation codes for a premature termination codon in the A2 domain; however, the mRNA for this allele is unstable[198] and homozygotes lack plasma FXI antigen. The type III mutation causes an amino acid substitution in the A4 domain that partially interferes with dimer formation.[58,59] In Ashkenazi Jews, the allele frequencies for the type II and III mutations are 0.0217 and 0.0254, respectively.[196] The type II allele is also found in Iraqi, Sephardic/North African, and other Middle Eastern Jews, and in Arabs, consistent with an ancient origin (>2,500 years ago).[195,196] The type III mutation is found predominantly in Ashkenazi Jews and appears to be of more recent European origin.[195] Other relatively common FXI gene mutations include Cys38Arg, with an allele frequency of approximately 0.5% in French Basques[199]; Cys128Stop, which accounts for approximately 10% of mutant alleles in Great Britain[193,200]; and Gln88Stop, which has been observed in several families in Nantes, France.[201]

Since the description of the type II and III mutations,[197] nearly 200 FXI gene mutations have been identified in factor XI deficient patients (www.med.unc.edu/isth/mutations-databases/Factor_XI.htm; www.factorxi.org), including more than 100 missense mutations.[202,203] Congenital deficiency of a vitamin K–dependent coagulation protease (factors II, VII, IX, or X) is frequently associated with a circulating variant protein (cross-reactive material positive [CRM+] deficiency).[194] In contrast, CRM+ factor XI deficiency is rare,[80,202,204] with only seven missense mutations proven, or suspected, of causing CRM+ deficiency. Gly155Glu is in the A2 domain,[205] and recombinant protein carrying this substitution binds HK with approximately 10-fold lower affinity than wild type protein.[67] Arg184Gly replaces a residue in the A3 domain that is critical for the interaction of FXIa with FIX.[149,206] Ser248Asn, also in the A3 domain, is located within a binding site for the platelet glycoprotein 1b receptor, and interferes with FXI binding to platelets.[207,208] Val371Ile is located in proximity to the FXI activation cleavage site.[209] The substitution slows protease activation, and likely interferes with formation of a salt bridge required for catalytic domain activation.[67] Pro520Leu,[210] Gly555Glu,[211,212] and Thr575Met[213] involve substitutions in the catalytic domain that compromise substrate catalysis. A possible explanation for the rarity of CRM+ variants lies in the compact FXI structure.[63,67,205] The extensive interfaces between individual apple domains, between the disk formed by the apple domains and the protease domain, and between subunits in the dimer may make the protein sensitive to structural perturbations from amino acid substitutions.

While the preponderance of evidence indicates that the type II and type III mutations are associated with a syndrome that is inherited in a recessive manner, the dimeric structure of FXI could allow the product of a single mutant allele to exert a dominant negative effect on the product of a normal allele through formation of heterodimers. Gene mutations that result in CRM-FXI deficiency appear to fall into three mechanistic categories[214]: (a) mutations that interfere with or prevent synthesis of a polypeptide, including premature stop codons such as Glu117Stop,[185,201,215–221] frameshifts,[199,219,222] deletions,[223] intronic splicing defects,[199,222,224–226] and substitutions that cause protein instability or severe structural perturbations[67,205]; (b) mutations that interfere with protein dimer formation (i.e., Phe283Leu and Gly350Glu),[59] with associated retention of mutant FXI monomer in the cell; and (c) mutations that result in a poorly secreted polypeptide that can form homodimers or heterodimers with normal FXI polypeptide (Ser225Phe, Cys398Tyr, Gly400Val, and Trp569Ser).[59,214] When fibroblasts are cotransfected with expression constructs for one of these latter mutations and wild type FXI, secretion of wild type FXI is reduced, consistent with the mutant exerting a dominant negative effect on the wild type polypeptide.[59,214] This mechanism could account for families in which FXI deficiency is inherited as a dominant condition.[59,190,227] A dominant negative effect on wild type FXI release is not seen with cotransfection with constructs for the type II or type III mutations, consistent with the apparent recessive mode of inheritance for these mutations.[59]

PHYSIOLOGY AND PATHOPHYSIOLOGY OF FXI

A great deal of information has been acquired on the physiologic role of FXI through the study of patients with FXI deficiency and through the definition of the associated genetic defects. However, in many patients, the reported lack of correlation between the plasma level of FXI and the severity of clinical bleeding manifestations[2,3,70,80,185,188,189] emphasizes the incomplete nature of the understanding of how FXI participates in hemostasis. A study utilizing flow cytometry has shown that a small number of selected patients with severe plasma FXI deficiency and minimal or absent hemostatic defects have a platelet protein that is recognized by anti-FXI antibodies.[70] This raises the possibility that a platelet form of FXI can participate in hemostasis and may even substitute for plasma FXI.[44,45,70,71,80] However, additional work is required to determine the biochemical relation between plasma and platelet FXI, including the mechanisms and enzymes that activate these two proteins and the substrate specificity of each of the activated proteases.

An important tool to facilitate investigations of the physiologic roles of plasma FXI (and possibly of platelet FXI) is the development of a murine model of severe plasma FXI deficiency using the technique of homologous recombination in embryonic stem cells.[228] In this model, the murine FXI gene[35] was disrupted by the introduction of a neomycin phosphotransferase gene into exon V, resulting in the absence of FXI activity in plasma and of FXI mRNA from liver. No evidence of hemostatic deficiency was detected in homozygous null mice, and the genotypes of progeny from mating of mice heterozygous for the FXI null allele showed the expected Mendelian ratio of wild-type, heterozygous, and homozygous null animals, suggesting that increased intrauterine mortality did not result from severe FXI deficiency. It is not known whether normal murine platelets contain platelet FXI, but if they do, it is possible that disruption of exon V with a neomycin phosphotransferase gene would not prevent the expression of platelet FXI that lacks exon V. Future studies with murine FXI knockout models may provide important insights into the relative contributions of plasma FXI and platelet FXI to physiologic and pathologic processes.

The details of the clinical manifestations and management of FXI deficiency are presented in Chapter 53. However, insights into normal physiologic function can be gleaned from certain clinical facts. For example, responses to the infusion of plasma in patients with FXI deficiency provide evidence that the recovery of FXI is >90% after infusion and that the half-life of the plasma protein is 52 ± 22 (mean ± SD) hours.[229,230] Another clinical fact worthy of note is that patients with severe plasma FXI deficiency are especially at risk for bleeding from tissues with high local fibrinolytic activity, including the urinary tract, the nose, the oral cavity, and the tonsils.[185,231] Moreover, FXI can be activated by thrombin[10,11] and appears to play a role in the protection of fibrin clots against fibrinolysis.[82] These facts suggest that FXI, in addition to its procoagulant activity, promotes an antifibrinolytic activity. This FXI-dependent downregulation of the activation of fibrinolysis[82] has been postulated to occur as a consequence of a FXI-dependent burst in thrombin generation, resulting in the activation of thrombin-activatable fibrinolysis inhibitor (TAFI) or procarboxypeptidase B,[232–235] which inhibits the activation of plasminogen by removing carboxy-terminal lysines from fibrin that are essential for plasminogen binding and activation.[234–236]

In addition to its demonstrable role in hemostasis, published evidence has focused attention on the possible contributions of high levels of FXI as a risk factor for venous thrombosis[49] and cardiovascular disease in women,[237] although inherited FXI deficiency apparently confers no protection against acute myocardial infarction.[238] However, there appears to be a reduced incidence of ischemic stroke in patients with severe FXI deficiency.[239] One study followed 600 patients with a first episode of venous thromboembolism and found an increased risk of recurrence, especially among those with increased levels of TAFI and FXI,[240] whereas another study showed that increased levels of TAFI, but not FXI, increased the risk of venous thromboembolism in patients with factor V_{Leiden} carrier status.[241] These studies are consistent with the results of an investigation in rabbits demonstrating increased rabbit jugular vein thrombolysis by antibody neutralization of FXI because of diminished indirect activation of TAFI.[242] Two studies in mice with targeted FXI gene deletion, either alone[243] or in combination with targeted deficiency of protein C,[244] showed protection from $FeCl_3$-induced carotid thrombosis[243] or from early lethality caused by thrombosis in protein-C–deficient animals.[244] Another study reported the important role of FXI in the growth of arterial thrombi using a rabbit model of arterial thrombosis,[245] whereas another demonstrated the dependence of surface- and tissue factor–initiated thrombus propagation on FXI in primates.[244] Therefore, FXI levels may comprise a significant risk factor for thrombosis, and the FXI molecule may constitute a reasonable target for the development of antithrombotic drugs.[246]

The physiologic pathways by which FXI is activated and the mechanisms by which it participates in normal blood coagulation and hemostasis are important aspects of a revised theory of blood coagulation that focuses on the assembly of coagulation protein complexes on the platelet surface. The original theories of blood coagulation[247,248] envisioned a series of enzymatic reactions initiated by activation of intrinsic blood coagulation by the assembly of the contact proteins on a foreign surface. However, the absence of bleeding complications in patients with deficiencies of FXII, PK, and HK, and the presence of hemostatic defects in patients with FXI deficiency, has led to a search for alternative pathways of FXI activation. Although the demonstration[249,250] that the TF–FVIIa complex can directly activate not only FX but also FIX has been used to suggest an explanation for the absence of bleeding manifestations in patients with contact phase deficiencies[251]; this observation does not account for the presence of abnormal bleeding in some patients with FXI deficiency. Nonetheless, evidence exists that the initiation of blood coagulation *in vivo* is a consequence of the formation of the catalytic complex that occurs when FVII or FVIIa is assembled on the transmembrane protein TF found in many cell types.[252] Furthermore, the discovery of the tissue factor pathway inhibitor (TFPI) and the elucidation of its mechanism of action provides some of the information necessary to understand why both FXI and FVII appear to be necessary for normal hemostasis.[253–259] The complex of TF and FVIIa is almost immediately inhibited when a complex is formed between FXa and TFPI.[260,261] Therefore, the generation of FXa results in the immediate inactivation of the enzyme complex that initially forms it (i.e., TF–FVIIa). Furthermore, it has been observed that the formation of thrombin through the extrinsic pathway is transient and that the continuous generation of thrombin by the intrinsic pathway is required to assure normal hemostasis.[261] All of these observations suggest that FXI is required for normal functioning of the intrinsic pathway and that an alternative mechanism for the activation of FXI exists independent of the contact proteins.

The mechanism of FXI activation and the expression of FXIa enzymatic activity on the platelet surface are discussed in detail in Chapter 35 (The Role of Platelets in Blood Coagulation). Both Naito and Fujikawa[10] and Gailani and Broze[11] have independently demonstrated that human FXI can be activated either by thrombin, by FXIIa, or by FXIa (i.e., autoactivation of FXI). Although the kinetics of FXI activation by thrombin in solution are quite unfavorable, the presence of dextran sulfate as a negatively charged surface enhances the rate of FXI activation by thrombin by approximately 2,000-fold.[10,11,262] However, the presence of either HK[10,11,263] or fibrinogen[263] has major inhibitory effects on the autoactivation and the thrombin-mediated activation of FXI in the presence of dextran sulfate. The physiologic surface upon which FXI activation by thrombin occurs remains elusive.

CHAPTER

15B The Factor XII–Driven Plasma Contact System

THOMAS RENNÉ

SUMMARY

The contact system is a protease cascade that is initiated by coagulation factor XII activation and operates on cardiovascular cells. The plasma proteins trigger procoagulant and proinflammatory reactions, *via* the intrinsic pathway of coagulation and the kallikrein–kinin system, respectively. The biochemistry of the contact system is well understood; however, its *in vivo* functions are just beginning to emerge. Recent data in animal models have shown that deficiency in contact system proteins largely abolishes thrombus formation but does not interfere with hemostatic mechanisms. Here we present an overview about the biochemistry and cell biology of the plasma contact system and its contribution to thromboembolic and inflammatory diseases.

PROTEINS OF THE PLASMA CONTACT SYSTEM

In the original waterfall cascade model, fibrin formation may be initiated by two distinct pathways, triggered by exposure of blood to a damaged vessel wall (extrinsic) or to blood-borne (intrinsic) factors.[1,2] The intrinsic pathway of coagulation is initiated by factor XII (FXII, Hageman factor), in a reaction involving high molecular weight kininogen (HK) and plasma kallikrein (PK), collectively referred to as plasma contact system.[3,4–7,8,9] Contact with negatively charged surfaces induces a conformational change in zymogen FXII resulting in a small amount of active FXII (FXIIa).[10] FXIIa cleaves PK to generate active kallikrein, which in turn reciprocally activates FXII zymogen.[11] FXIIa initiates fibrin formation through its principal substrate of the intrinsic coagulation pathway, factor XI (FXI), and also triggers liberation of the inflammatory mediator bradykinin (BK) by PK-mediated HK cleavage.[5] Binding of BK to the kinin B2 receptor (B2R) activates various proinflammatory signaling pathways that dilate vessels, induce chemotaxis of neutrophils, and increase vascular permeability and fluid efflux[12] (FIGURE 15B.1). The serpin C1 esterase inhibitor (C1INH) is the major plasma inhibitor of FXII and PK and controls proteolytic activity of the system.[13]

Factor XII

Factor XII (FXII, Hageman factor, EC = 3.4.21.38) is the 596–amino acid single-chain zymogen[14] of the plasma serine protease α-factor XIIa.[15] The single-chain glycoprotein migrates with an apparent molecular weight of 80 kDa in SDS-polyacrylamide gel electrophoresis (PAGE). FXII has a plasma concentration of 375 nM (30 μg/mL; normal range 15 to 45 μg/mL) and circulates in plasma with halftime of 50 to 70 hours.[16] The human FXII gene spans approximately 12 kb on chromosome 5 (q33-qter) and has 14 exons.[17,18] The protein is primarily expressed by hepatocytes; however, low levels of extrahepatic FXII mRNA synthesis have been detected in other tissues such as the placenta.[19] Hepatocyte-specific expression of FXII in mice depends on the transcription factor HNF4α.[20] Whether HNFa accounts for liver-specific expression of the coagulation factor in humans is not entirely clear; however, HNF4α antagonizes estrogen-induced upregulation of FXII gene expression in humans.[21] Estrogens increase expression of FXII, and elevated FXII plasma levels are found in woman on hormonal contraception and during pregnancy. Indeed, the FXII gene promotor harbors a consensus motive (5′-G^{-43}GGCANNNTGACC^{-31}-3′) for an estrogen-responsive element.[22]

Protein Biochemistry of Factor XII

FXII is a multidomain plasma protein. The clotting factor is composed of a *N*-terminal fibronectin type II domain (encoded by exons 3 and 4), an epidermal growth factor (EGF) domain (exon 5), a fibronectin type 1 domain (exon 6), a second EGF domain (exon 7), a kringle domain (exons 8 and 9), a 55–amino acid long "proline-rich" hinge region (exon 9), and a trypsin-like protease domain (exons 10 to 14).[18] The signal peptide that mediated secretion of the protein is coded by exon 2, whereas the first exon is noncoding. FXII binds to negatively charged surfaces *via* its heavy chain (*N*-terminal 353 residues) with implications for contact-mediated autoactivation of the zymogen (see below).

The FXII surface-binding site is not precisely known, and several regions of the heavy chain appear to contribute to a discontinuous binding pocket. Studies using recombinant FXII deletion variants or antibodies that interfere with surface-mediated FXII activation identified nonoverlapping portions in the proximal *N*-terminus (residues 1 to 28), the fibronectin type II domain (residues 39 to 47), the fibronectin type 1 domain (residues 134 to 153), the second EGF domain, the kringle domain, and the proline-rich region as potential FXII surface-binding sites.[23–26] The monoclonal anti-FXII antibody (F1) binds to the kringle domain and enhances proteolytic activation.[27] Within the first fibronectin type II domain, two histidine-containing Zn^{2+} ion-binding sites have been identified (residues 40 to 44 and 78 to 82[28]). Binding to zinc ions stabilized intermediate structures of the activation process and largely accelerates contact-induced formation of the active serine protease.[29] FXII is activated by cleavage of a single peptide bond (Arg353-Val354). Limited proteolysis is either a result of autoactivation[30] or mediated by another protease such as α-kallikrein, factor XIa,

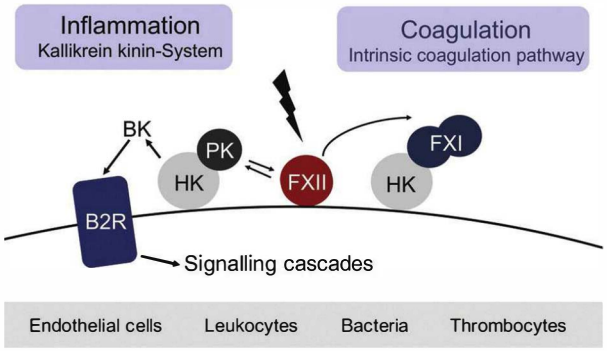

FIGURE 15B.1 The factor XII (FXII)-driven contact system. Contact with negatively charged surfaces activates coagulation factor XII (FXII) on leukocytes, bacteria, endothelial cells, and thrombocytes and initiates procoagulant and proinflammatory protease cascades. FXII triggers fibrin formation through the factor XI (FXI)-driven intrinsic pathway of blood coagulation. Activated FXII initiates the kallikrein–kinin system that generates the proinflammatory peptide hormone BK by PK-mediated cleavage of HK.

factor XIIa, plasmin, or trypsin.[13] Among these FXII processing enzymes, α-kallikrein is by far the most potent activator.[11] The product of activation, α-FXIIa, consists of a 52 kDa *N*-terminal heavy chain and 28 kDa *C*-terminal light chain (protease domain), connected by a disulfide bond between residues Cys340 and Cys367.[31] Both binding to negatively charged surfaces and binding to zinc ions largely accelerates FXII activation. Plasma prokallikrein (PPK) and factor XI are the principal substrates of α-FXIIa during contact activation.[32,33] FXIIa can activate plasminogen and factor VII; however, the *in vivo* relevance of these steps remains to be established. α-FXIIa gets further cleavages at Arg334 and Arg343 resulting in β-FXIIa. The latter form lacks most of the heavy chain, binds poorly to surfaces, and does not support surface-mediated activation of PPK or factor XI.[34,35] β-FXIIa can activate PPK in the fluid phase and also activates complement factor C1 in plasma.[36] FXII and FXIIa stimulate the proliferation of cultured human hepatoma cells (HepG2) through a mitogenic activity that may reside in the EGF-like domains.[37] Consistently, FXII stimulates ERK1/2 and Akt through uPAR, integrins, and the EGFR to initiate angiogenesis.[38] The major plasma inhibitor of both α- and β-FXIIa is C1INH, with antithrombin III (ATIII) and plasminogen activator inhibitor-1 (PAI-1) having FXIIa-blocking activity.[39]

Plasmakallikrein

PPK is the zymogen of the trypsin-like serine protease α-PK.[40,41] PPK circulates in plasma at a concentration of approximately 580 nM (50 μg/mL), 75% to 90% in a noncovalent 1:1 complex with HK.[42] PPK is primarily expressed by hepatocytes; however, PPK mRNA is found in numerous tissues, and small amounts of PPK are secreted from non-liver cells including pancreatic islets and kidney tubules.[43] PK is a paralog of factor XI and both genes have evolved from a common ancestor.[44] The human PK gene covers approximately 30 kb on chromosome 4q34–35,[45] and is approximately 8 kb distant from the factor XI gene locus, consistent with a gene duplication event as underlying mechanisms for the two distinct proteins.[46] Exon 1 of the PK gene is not translated, exon 2 encodes the signal peptide, exons 3 to 10 the four apple domains, and exons 11 to 15 the protease domain.

Plasma Kallikrein Functions

The principal mechanism of PK is to cleave the high molecular weight bradykinin precursor (HK) that liberates BK.[47,48] Despite similar names, PK is not related to the large group of kininogenases called tissue-type (urinary or glandular) kallikreins. Mature human PK is a 619–amino acid single-chain polypeptide. Similarly to factor XI, PK is composed of four 90– to 91–amino acid apple domains (Apple 1 to 4) that form the heavy chain of the molecule and a *C*-terminal protease domain.[49] The high degree of homology between PK and factor XI is supported by the findings that apple domains of PK and factor XI can be exchanged without compromising the capacity of the protein to be synthesized and secreted.[50] In contrast to factor XI, PK is a monomer. PK migrates as a doublet with 86 and 88 kDa on nonreducing SDS-polyacrylamide gels. The two bands represent differentially glycosylated proteins. The residue Cys321 that forms the interchain disulfide bond in factor XI (connecting the two polypeptides of the dimeric protein) forms an intrachain bond with Cys326 in Apple 4 domain. PPK is a substrate of α-FXIIa, β-FXIIa, and trypsin.[51] PPK is converted by these proteases to active α-kallikrein by proteolytic cleavage of the Arg371–Ile372 bond.[52] Limited proteolysis of the single peptide bond results in heavy and light chain fragments (50 and 35 kDa) that remain connected by a disulfide bond connecting Cys364 in the Apple 4 domain and Cys484 within the protease domain.[41] Similarly to FXII, a surface-dependent PPK autoactivation has been shown, but the physiologic importance of that mechanism is disputed. Following long-term incubation in buffer, α-kallikrein undergoes further conversion to β-kallikrein. Cleavage of the Lys140–Ala141 bond within Apple 2 domain abolished β-kallikrein binding to HK.[50,53] So far the β-kallikrein form has not been identified *in vivo*. PPK may also be activated independent of FXII activity involving the prolylcarboxypeptidase (PRCP).[54] PRCP has been originally recognized as a lysosomal exopeptidase exopeptidase. The physiologic relevance of PRCP as potential PPK activator *in vivo* and the molecular mechanisms by an exopeptidase that could function as an endopeptidase mediating limited proteolysis of PPK are subject to ongoing research. Gene targeting of PRCP accelerates thrombosis in mice.[55] In contrast, targeting PPK expression interferers with thrombosis,[56] arguing against PRCP-mediated PPK activation in thrombotic diseases. Additionally, extracellular carbonic anhydrase may activate PPK with implications for control of retinal permeability.[57] PK functions as a kininogenase and cleaves HK resulting in release of BK. In a positive feedback loop, α-kallikrein also activates surface-bound FXII to α- and β-XIIa.[58,59] Furthermore, PK has the capacity to convert prourokinase to urokinase[60] and plasminogen to plasmin[61] and for triggering the renin–angiotensin system by conversion of prorenin to renin.[62] Due to its BK forming capacity, α-kallikrein has potent *in vitro* effects on leukocyte migration, stimulates monocytes, and induces neutrophils aggregation,[63] chemotaxis, and elastase release.[64] α-Kallikrein bound to mast cell surfaces has been identified as an activator of plasminogen during epithelial cell apoptosis, adipocyte differentiation, and stromal remodeling during mammary gland involution. Recent studies have suggested a role of PK for control of intracerebral hemorrhage in hyperglycemia.[65] In contrast, hereditary deficiency in PK (Fletcher trait) and its substrate HK

(Fitzgerald trait) is not associated with increased bleeding risk or hemostatic abnormalities.[66] The enzymatic activity of PK is primarily regulated by C1INH and α_2-macroglobulin, with some contribution of protein C inhibitor, PAI-1, and ATIII.[67,68]

High Molecular Weight Kininogen

HK is a 120-kDa β-globulin glycoprotein that circulates in plasma at a concentration of 670 nM (80 μg/mL) and is a member of the cystatin family of cysteine protease inhibitors. The human kininogen gene that is 27 kb in size contains 11 exons, and is located on chromosome 3 (3q-26qter). It is part of a cluster of related genes including α_2-HS glycoprotein (α_2-HS; also termed fetuin-A) and histidine-rich glycoprotein (HRG).[8,69,70] Through alternative mRNA splicing, the kininogen gene produces transcripts for HK (3.5 kb) and its splice variant low molecular weight kininogen (LK, 1.7 kb), a 68 kDa glycoprotein with a plasma concentration of 1.3 μM (90 μg/mL).[71] Alternative splicing of the primary transcript is controlled by the direct interaction of U1 small nuclear ribonucleoprotein ("snurp") and the complementary sequences of the kininogen hnRNA. Exons 1 to 9 and a portion of exon 10 that codes for BK and its *C*-terminal 12 amino acids are common to the mRNAs for HK and LK, and the proteins share identical heavy chain regions (domains D1 to D3) and a BK-containing domain (D4) coded by these exons. The 5′-terminal portion of exon 10 encodes the unique 56-kDa *C*-terminal light chain of HK. This part of exon 10 and its flanking 90-nucleotide sequence are spliced out in the LK mRNA. The 4 kDa light chain of LK is coded by exon 11.[72]

In rats a pseudogene resembling the "canonical" kininogen gene as well as two other functional kininogen ("T-kininogen") genes have been identified that are each transcribed as a single mRNA species. The T-kininogen mRNAs produce two closely related isoforms of T-kininogen (TK-I and TK-II), the precursors of T-kinin (TK, ISRPPGFSPFR).[73] In contrast, mice have two functional highly homologous genes for kininogens (*Kng1, Kng2*) that result from a gene duplication event. Each *Kng* gene account for about half of the concentration of H-kininogen 1 and 2 and L-kininogen 1 and 2, respectively, in mouse plasma.[74]

In humans and rodents, HK and LK are predominantly expressed in the liver but can also be found in endothelial cells, granulocytes, renal tubular cells, and α-granules of platelets.[75–77] It is not clear whether these cells synthesize kininogens or whether the proteins are taken up from plasma or cell culture supernatant containing serum components. Kininogen secretion into the plasma is mediated by amino-terminal signal peptides of 18 residues. The mature forms of LK (409 amino acids) and HK (626 amino acids) contain multiple posttranslational modifications such as hydroxylation and glycosylation.[78] The detailed functions of the various carbohydrates are unknown, but they most likely affect solubility, half-life, and secretion of the kininogens. LK and HK contain 18 cysteine residues each, which form 9 disulfide bridges.[79] Eight loops are present in the *N*-terminal portions, while a single disulfide bridge spans the extreme amino- and carboxy-terminal portions of LK and HK. The kinin-free form of HK (HK_a) migrates with largely different apparent molecular weight than the 120 kDa single-chain form. The discrepancy indicates that HK undergoes major structural changes upon BK liberation. Under reducing conditions on SDS-PAGE, HK_a has a heavy chain of 63 kDa and a light chain of 58 kDa, the latter of which is rapidly degraded by α-kallikrein and FXIa to smaller-sized fragments. HK is a typical multidomain plasma protein. HK domains D1, D2, and D3 of the heavy chain are homologous to cystatins, with D2 and D3 retaining cysteine protease inhibitory activity.[80] The D4 domain harbors the kinin peptide that is releasable from both HK and LK through limited proteolysis mediated by kininogenases. HK is the preferred substrate for α-kallikrein, and its cleavage at residues Lys362 and Arg371 generates the nonapeptide BK (NH_4-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg).[81] In contrast, LK is cleaved predominantly by tissue kallikreins resulting in formation of Lys-BK (kallidin).[82,83] Kininogens are also cleaved by factor XIIa, factor XIa, and plasmin in reconstituted systems, but the physiologic relevance of these reactions is not clear. Release of BK and kallidin differs in kinetics and possible mechanism. BK is liberated locally and in response to stimuli on cell surfaces by the contact activation mechanism. There is a constant turnover of LK and basal static kallidin release.[84] The two-chain form of LK that is the result of kallidin release is composed of a heavy chain (residues 1 to 362) and a light chain (residues 372 to 409). A single disulfide bridge spanning Cys10 with Cys389 connects both fragments. BK-free HK contains the same heavy chain as LK (domains D1 to D3, residues 1 to 362), and a much larger light chain composed of domains D5H and D6H (residues 372 to 626) is connected to the heavy chain by a single disulfide bond (Cys10–Cys596).[8,85]

A total deficiency of kininogens is rarely found in humans. In the case of Williams trait, a single C to T base transition at position 587 changes a CGA codon (Arg) to a TGA codon (stop) in exon 5, affecting the synthesis of both LK and HK.[86] HK and LK deficiency in Brown-Norway Katholiek rats results from a single base pair substitution leading to a Tyr for Ala exchange at amino acid 163. This subtle change in kininogen sequence does not affect biosynthesis but leads to defective posttranslational modification and/or secretion of the kininogens such that their plasma levels are <1% of normal.[87] T-Kininogen genes and, therefore, T-kininogen biosynthesis are unaffected in these rats.

Bradykinin

BK and kallidin are ligands of kinin B2 receptors and bind to the G-protein–coupled receptor with binding affinities in the lower nanomolar range.[88,89] Kinins in plasma have short half-lives of <20 seconds and are rapidly degraded to inactive peptides by angiotensin converting enzyme, neutral endopeptidases, and aminopeptidases. BK and kallidin are also cleaved by carboxypeptidases, collectively referred to as kininase I (carboxypeptidase N, EC 3.4.17.3), to yield des-Arg9-BK and des-Arg10-Kallidin, which have longer half-lives and activate the kinin B1 receptor. Kininase II, identical to the angiotensin-converting enzyme (ACE), and neutral endopeptidase (NEP24.11, EC 3.4.24.11) inactivate BK or kallidin by removing a dipeptide, Phe–Arg, from the *C*-terminus.[90,91] Kinins are potent proinflammatory mediators. The peptide hormones initiate an increase in intracellular Ca^{2+} that activates endothelial nitric oxide synthase–mediated nitric oxide formation.[92] Endothelial denudation of large arteries abrogates the vasodilatory response to kinins. Kinins also stimulate the production and release of autacoids such as prostaglandin PGI2 and prostacyclin PGE_2.[93] Kinins induce vasodilatation, regulate local tissue perfusion, and importantly increased vascular permeability.[94] Excessive BK production is the cause for a life-threatening swelling disease, hereditary angioedema (HAE) (see below). The importance of

the blood pressure lowering effects of kinins is highlighted in the clinical use of ACE inhibitors such as captopril and ramiprilate for the treatment of hypertension and cardiac failure.[95,96]

Kinin-Independent HK Functions

In addition to the kinin sequence, other portions of HK have been associated with biologic function. The histidine/glycine-rich region in the HK D5H domain mediates binding of the protein to anionic surfaces such as heparin.[97] A peptide spanning the region in D5H between His479 and His498 of HK (HKH20) has been identified as the major cell-binding site of HK. Residues in the D3 domain contribute to HK binding to a broad variety of cells with 1,000 to 10^7 binding sites per cell.[98] Heparan and chondroitin sulfate type proteoglycans have been identified as major HK cell surface binding site.[99,100] The glycosaminoglycan chains of proteoglycans such as syndecans and glypicans bind the plasma protein to cardiovascular cells. Consistent with the interaction of the histidine-rich polypeptide in D5H with negatively charged glycosaminoglycans, zinc ions critically promote HK cell binding—presumably by an intercalating mechanism. Binding to glycosaminoglycans protects HK from cleavage, and detaching the hormone precursor seems to be a prerequisite for BK formation.[101] Alternatively, HK has been shown to interact with p33/gC1qr (a mitochondrial protein[102]), urokinase receptor, and the cytoskeleton compound cytokeratin-1.[103,104] The physiologic relevance of the proposed ternary complex for providing cell-surface HK-docking sites on intact cells is currently not precisely known.

Peptides from the D5H domain have antimicrobial activity and potently kill pathogens such as *Escherichia coli, Pseudomonas aeruginosa*, and *Enterococcus faecalis* by disrupting bacterial membranes. Similarly, an antibacterial fragment of the HK D3 domain has antibacterial activity versus *Streptococcus pyogenes, Staphylococcus aureus*, and *Salmonella.*[105] A synthetic 26–amino acid peptide had similar properties. A protease from *P. aeruginosa* generates antimicrobial peptides from the D5H domain, demonstrating that products of HK processing other than BK provide part of the first line of defense against microbial invasion *in vivo*. D5H fragments have also been shown to have antiangiogenetic[106] and leukocyte-recruiting[107] activities with potential therapeutic implication.[108] Cleaved HK or peptides from HK's domain D5H blocks FXII-induced ERK1/2 and Akt phosphorylation.[38] The D6H domain in the HK light chain region contains binding sites for factor XI and PK, and most of these proteins circulate in plasma bound in a complex with HK. Both PK and factor XI bind with high affinity (9 nM) to HK. The factor XI and PK binding sites on HK overlap, therefore, one molecule of HK can bind either a molecule of factor XI or a molecule of PK. Consistent with a high degree of homology PK and factor XI, apple domains A1, A2, and A4 form a discontinuous binding site for HK. Domain swapping experiments between PK and factor XI support a similarity in binding site among the zymogens and indicate that the Apple 2 domain contains the core region of the discontinuous HK-binding site.[50] The contact induced procoagulant activity of HK as measured in the activated partial thrombin time (PTT) assay requires both D5H-mediated association of HK with artificial anionic surfaces and D6H-mediated binding of factor XI and PK to HK. Since LK is not binding to PK or factor XI, the protein lacks procoagulant activity in the PTT assay (FIGURE 15B.2A,B).

CONTACT ACTIVATION

Mechanism of Contact Activation

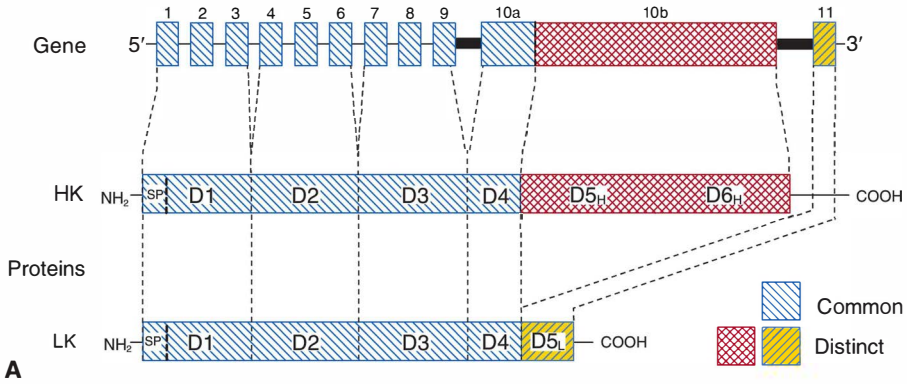
Contact activation is the mechanism of contact-induced FXII zymogen activation. Contact activation is initiated by activation of FXII on a surface, and activated FXII (α-FXIIa) catalyzes activation of additional FXII. Alternatively, α-FXIIa catalyzes conversion of PK to α-kallikrein, which in turn amplifies the process through reciprocal activation of FXII.[11] The relative importance of FXII autoactivation on surfaces versus reciprocal activation of FXII and PK remains to be analyzed and may depend on the nature of the contact system activating surface. Contact activation can propagate from the activating surface into the plasma fluid phase. α-Kallikrein cleaves HK and liberates BK, activates the renin–angiotensin system by converting prorenin to renin, and initiates the alternative complement pathway by activation of C3. Surface-bound α-FXIIa is concerted to β-FXIIa, which does not bind to surfaces but potently activates PK, and the classical pathway of complement *via* its substrate C1. The importance of contact system–driven activation of the complement system for host-defense reactions *in vivo* is not precisely known; however, some individuals with severe deficiency in contact system proteins appear to suffer from increased susceptibility for bacterial infections.[109]

Contact activation provides the mechanistic basis for one of the most commonly used diagnostic clotting test, the activated partial thromboplastin time (aPTT). The contact surface used in aPTT assays is typically a negatively charged nonphysiologic substance such as kaolin (aluminum silicate), celite (diatomaceous earth), or ellagic acid. The aPTT is widely used in clinical practice for preoperative screening and monitoring of anticoagulation therapy. Despite its indispensible role in fibrin formation in the aPTT assay, FXII initiated coagulation was believed to have no important function *in vivo*. This notion is based on the clinical observation that FXII deficiency in humans and animals is not associated with abnormal bleeding despite causing a marked prolongation of the aPTT.[110,111] In contrast, deficiency of the extrinsic pathway trigger factor VII results in severe bleeding in humans, whereas complete tissue factor (TF) deficiency in mice is not compatible with life due to intrauterine bleeding.[112] Similar to FXII-deficient individuals, humans lacking the other contact proteins, PK or HK, do not have impaired hemostasis and do not show signs of any symptoms of pathologic spontaneous or injury-related bleeding. Contact factors can assemble and activate *ex vivo* when blood is exposed to bioincompatible surfaces, contributing to the systemic inflammatory response that occurs when blood is passed through an extracorporeal circulation system, such as during cardiopulmonary bypass surgery.

Contact activation-independent pathways for FXII activation have been suggested. Several proteinases including elastase, trypsin, bacterial proteases, and plasmin, convert FXII to FXIIa (aFXIIa form). Activation of the contact proteases by bacterial surface proteases is important for tissue invasion by the organism. The pathogens utilize the host contact system to form BK on their surfaces. Local BK activity increases vascular permeability and facilitates the invasion of bacteria from the blood into the surrounding tissues.[113]

Contact Activators

FXII can be activated by macromolecular constituents of the subendothelial matrix such as glycosaminoglycans and collagens, nucleotides, sulfatides, soluble polyanions, or nonphysiologic



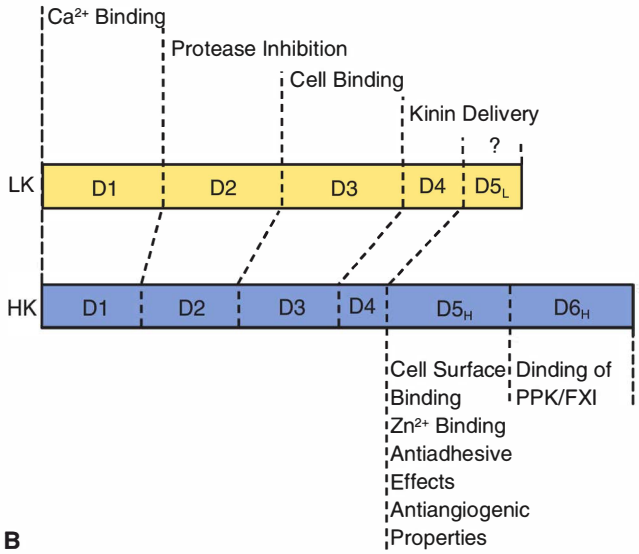


FIGURE 15B.2 Kininogen gene and structure–function relationships. **Left**: LK and HK are products of a single gene of 11 exons (E1 to E11). E1 to E9 encode domains D1 to D3 preceded by a signal peptide. Domain D4 contains the kinin moiety and is encoded by the 5′-terminal portion of exon 10 (E10a). The mRNAs for LK and HK are identical in their 5′-parts including exons 1 to 10a. They differ in their 3′-portions. The 3′-segment of exon 10 (E10b) encodes HK domains $D5_H$ and $D6_H$, and exon 11 codes for LK domain $D5_L$. Abbreviations: SP, signal peptide; LK consists of five domains (D1 to $D5_L$), and HK contains six domains (D1 to $D6_H$). **Right**: The domain structures of human kininogens are shown (not drawn to scale). Their common domains D1 to D4 bind Ca^{2+} (D1), inhibit cysteine proteinases (D2, D3), mediate cell binding (D3), and contain the kinin segment (D4). The biologic function, if any, of LK-specific domain $D5_L$ is unknown: HK-specific domain D5H contains a major cell binding site, Zn^{2+} binding site(s), and mediates antiadhesive effects of kininogens: Domain $D6_H$ exposes overlapping binding sites for FXI and PPK.

materials such as glass or polymers (reviewed by[9]), but the physiologically relevant mechanism for FXII activation has remained enigmatic for decades. Just recently, physiologic FXII contact activators have been identified (see below).

Glass was one of the first substances identified to activate FXII. The white clay minerals kaolin and celite, two other silica-rich compounds, are the most commonly used FXII activators for coagulation diagnostics. Kaolin is also used to terminate blood loss after serious injury in combat victims.[114] Although the idea of employing the contact system to seal injuries is interesting, exposing flowing blood to kaolin triggers thromboembolic events[115] and produces excessive hydratization energy causing burn necrosis at the wound site. Another classical FXII activator is ellagic acid (2,3,7,8-tetrahydroxy-chromeno[5,4,3-cde] chromene-5,10-dione). Ellagic acid triggers FXII-driven coagulation in plasma,[116] and the substance is commonly used as the starter for the aPTT assay. Infusion of ellagic acid into humans is prothrombotic.[117] However, it remains unclear whether the hypercoagulant response is a direct result of FXII activation or ellagic acid effects on platelet aggregation, or a combination of both. Ellagic acid also activates the fibrinolytic system possibly involving PK activity[118] and when administered *in vivo* reduces blood pressure presumably involving BK activity.[119]

A well-characterized FXII contact activator is high molecular weight dextran sulfate (DX500.000). Dextran sulfate is a polysulfated polysaccharide of glucose moieties. DX-mediated FXII activation is critically dependent on the chain length and degree of sulfation of the polyanion.[120] High molecular weight DXS (500 kDa) is a potent stimulator of FXII, whereas shorter DXS polymers fail to activate FXII. When injected in large animals, long-chain DXS induces BK-mediated hypotension,[121] but does not trigger intravascular coagulation. Polysaccharide-stimulated BK generation may have fatal effects. Starting November 2007, there was a dramatic increase in heparin-induced adverse reactions such as lethal acute hypersensitivity reactions in the United States and Germany in patients intravenously receiving commercial heparin of specific lots from a single manufacturer (http://www.fda.gov/cder/drug/infopage/heparin/adverse_events.htm). Greater than 150 patients deceased from anaphylactic hypotension, associated with intravenous heparin treatment. Comprehensive analyses identified a nonnatural contaminant occurring in suspect preparations of heparin that was characterized as oversulfated chondroitin sulfate (OSCS).[122] OSCS-contaminated heparin has greatly increased potency for activating FXII and triggering PK-mediated BK formation in human plasma and in a model of

experimental hypotonic shock *in vivo*.[123] Additionally, infusions of OSCS-contaminated heparin were associated with complement activation indicated by elevated plasma levels of C3a and C5a. These catastrophic reactions in patients are reminiscent of experimental shock models induced by DX-stimulated BK formation in pigs. Infusion of DX500.000[120] induced transient systemic hypotension, and icatibant (a B2R antagonist) blocked the drop in blood pressure.[121] BK-forming activity seems to be dependent on negative charge density of the polysaccharide rather than on a defined structure. OSCS activates the kallikrein–kinin and complement systems as potently as does DXS.

Charge-dependent contact system activation is not restricted to polysaccharides. It is known for decades that FXII binds to insoluble collagen, enhancing coagulation.[124] The interaction is dependent on a repetitious presentation of negative charges in the collagen fiber.[124] However, later reports argued against a direct activation of FXII by collagen. Recent studies have reevaluated the importance of collagen for FXII activation.[125] FXII was shown to bind to collagen fibrils of various origins. When added to plasma (equine), type I collagen promoted thrombin formation and plasma clotting in an FXII-dependent manner. FXII activity is critical for collagen-stimulated thrombus formation in flow chambers.[126] Additionally, collagens may stimulate the contact system indirectly.[127]

Dextran sulfate may have physiologic analogues. It was believed that mast cell-triggered leakage is predominantly if not exclusively mediated by histamine release, and targeting histamine signaling is widely used therapeutically to treat edema formation associated with aberrant mast cell activity.[128] Mast cell secretory granules also contain highly sulfated polysaccharides, with heparin as a major constituent. Addition of mast cell-derived heparin initiated BK formation in plasma in an FXII-dependent manner and triggered the FXII/PK cascade resulting in HK procession. Consistent with *ex vivo* data,[129] topical heparin application increased vascular permeability in an FXII-dependent manner in mice. Intravital microscopy and tracer extravasation experiments identified BK as the active mediator for increased leakage in heparin-driven plasma extravasation in mice.[130] Under these conditions the FXII substrate FXI was not activated. The detailed mechanism for selective activation of the FXIIa substrate PK over FXI is not entirely clear but may reflect a higher plasma concentration of PK *versus* FXI and higher specificities of heparin-dependent plasma inhibitors such as AT III for activated FXI *versus* PK. Similarly mast cell–derived chondroitin sulfates have been proposed as activators of the kallikrein–kinin system *in vitro*.[129] However, the physiologic relevance of this mechanism has not been elaborated so far.

Based on the experimental data, targeting heparin-initiated BK formation may represent a promising strategy to protect against defective barrier function attributed to mast cell activation in a broad variety of diseases. Indeed, FXII gets activated on particulate matter that is a component of air pollution.[131] BK formed by the FXII-driven contact pathway may contribute to intestinal pulmonary edema in allergic responses to air pollution. A similar mechanism contributes to bacterial infections. Contact system proteins assembled on the surface of *E. coli* and *Salmonella* through their specific interactions with fibrous bacterial surface proteins, curli and fimbriae, induce proinflammatory reactions *via* BK release.[113] Pharmacologic inhibitors of contact system–driven BK formation interfere with Salmonella-mediated pneumonia and pulmonary leakage in rodent models.[132] BK liberation from HK contributes to the host defense response to infection; however, high BK levels can contribute to hypotension and vascular leak associated with septic shock. Furthermore, BK generated on the bacterial membrane contributes to tissue invasion of the pathogen by opening endothelial cell–cell contacts. Plasma levels of contact factors are reduced in septic shock, and low factor XII and HK levels are predictors of fatal outcome during the systemic inflammatory response syndrome that is a feature of sepsis. Contact factor activation has been noted during meningococcal sepsis and in toxic shock syndrome. The importance of contact activation to the sepsis syndrome is shown by studies of *E. coli* sepsis in baboons, where FXII inhibition prevented hypotension (Table 15B.1).

Contact Activation in Vivo

A series of recent studies have identified candidates for physiologic or pathologic initiators of contact activation that include collagen, nucleotides, polyphosphate, and several proteoglycans.[5,125,134,135] Polyphosphates, inorganic nonbranched polymers of 60 to 100 orthophosphate residues that are released from platelet dense granules have procoagulant and proinflammatory effects that are mediated by FXII. Factor XII binding to polyphosphates initiates fibrin formation on procoagulant platelets with critical importance for thrombus formation. The biologic function of polyphosphate-triggered contact activation is discussed below. FXII activation may also be triggered by RNA in plasma,[136] and infusion of RNAse (an enzyme that degrades RNA) is thromboprotective in a mouse arterial thrombosis model.[135] Consistently, a synthetic RNA homologue (polyIC) that is not degradable by plasma RNAses is prothrombotic in a FXII-dependent manner. Misfolded protein aggregates, such as those found in plasmas of patients with amyloidosis, have been shown to trigger FXII activation.[137] Similarly to heparin, misfolded protein aggregates specifically initiate BK formation *via* activation of the kallikrein–kinin system and do not trigger activation of the intrinsic pathway of coagulation.[130]

One possible explanation for the selective activation of PK could be that local concentrations of PK molecules exceed those of FXI.[138] However, both zymogens are surface-bound *via* HK and share a conserved HK-binding site.[50,139,140] Moreover, negatively charged surfaces like kaolin do support FXII-dependent FXI activation under the same circumstances. Factor XII differs in binding to negatively charged surfaces and misfolded protein aggregates with possible implications for substrate preferences. Surface binding is mediated through the fibronectin type 2, second EGF, and kringle domains,[25,26] whereas interaction to aggregates is mediated by the fibronectin type 1 domain.[137] Differences in FXII binding may also modulate the conversion of α-FXIIa to β-FXIIa by kallikrein and shift FXII activity toward kinin formation.

Activated (procoagulant) platelets support FXII activation, dependent on integrin α_{IIb}-β_3 signaling,[141] and enhance activation of the kallikrein–kinin system in plasma.[142] Activated platelets promote fibrin formation in an FXII-dependent manner *in vitro*.[143] However, based on normal hemostasis in FXII deficient individuals, platelet-driven FXII activation was neglected. Cumulatively, the classical data suggest that FXII is activated on or by procoagulant platelets. Moreover, platelets

support the activation of FXII and factor XI in the presence of thrombin (feedback) and TF inhibition,[142,144] showing that platelets specifically trigger the intrinsic coagulation pathway.[141,143,145] Recent studies identified the platelet-derived FXII activator: polyphosphate, an inorganic polymer of 60 to 100 phosphate residues. Polyphosphate was originally identified in nonmammalian cells[146] but was later shown to be enriched in platelet dense granules.[147] Synthetic polyP is used as water softener in technical processes and has been shown to be a potent modulator of plasma clotting, affecting the intrinsic pathway, the fibrinolytic system, factor V activation, and the fibrin structure.[134,148] Platelet polyphosphate activates FXII in reconstituted systems and in plasma[134] *via* directly binding.[127] Polyphosphate-stimulated FXIIa initiates thrombin and BK formation in an FXI- and PK-dependent manner, respectively. In mice, platelet-secreted endogenous polyP induces pathologic thrombus formation (platelet-driven pulmonary embolism) and BK-driven edema. Targeting polyphosphate with phosphatases, which degrade polyphosphate, almost completely abolished procoagulant platelet activity and largely protected animals from activated-platelet driven thrombosis *in vivo*. Together, the data highlight the importance of polyphosphate as endogenous activator of the FXIIa-driven contact system on platelets *in vivo*. Synthetic polyphosphate restored defective clot formation in platelet-rich plasma from Hermansky-Pudlack patients, who suffer from hereditary polyphosphate deficiency[127] suggesting that polyphosphate may be utilized as hemostatic agents.[149] In contrast to heparin[130] and misfolded protein aggregates,[137] polyphosphate initiates FXII-dependent clotting and potently activates the kallikrein–kinin pathway

generating BK. Bacterial polyP initiates lethal hypotonic reactions in a FXII-dependent manner[127] and platelet-derived polymers initiate skin edema *via* BK signaling. The inorganic polymer presents the long sought link of primary and secondary hemostasis.[150,151] Interrupting polyphosphate-driven activation of the FXII-driven contact system efficiently and selectively interferes with thrombosis and edema formation *in vivo* and thus may present a new paradigm to fight thromboembolic and proinflammatory disease.[152]

THE CONTACT SYSTEM IN THROMBOSIS AND HEMOSTASIS

FXII in Thrombus Formation

Injury to a blood vessel triggers activation of blood platelets and the plasma coagulation system, leading to formation of a blood clot consisting of platelets and fibrin. Formation of fibrin is mediated by a group of tightly regulated plasma proteases and cofactors, the blood coagulation cascade. In the original waterfall models, fibrin formation is initiated by two distinct pathways, triggered by exposure of blood to a damaged vessel wall (extrinsic) or to blood-borne (intrinsic) factors.[1] Fibrin formation *via* the intrinsic pathway of coagulation is triggered by FXII and contact system activation. Despite its function for initiating coagulation *in vitro*, numerous patients lacking FXII have undergone surgery with no apparent excess bleeding, despite abnormal results on *in vitro* clotting assays.[153] Since deficiency in FXII is not associated with increased spontaneous or injury-related bleeding tendency, FXII was considered to play no role in blood coagulation *in vivo*, and subsequent revisions of the coagulation cascade usually exclude FXII.[154] The absence of a bleeding phenotype in FXII deficiency, in contrast to deficiencies of other components of the extrinsic coagulation cascade such as factor VII, TF, and factor IX (deficiency causes the bleeding disorder Hemophilia B), has lead to the reasonable hypothesis that fibrin formation *in vivo* is initiated largely, if not exclusively, through the extrinsic pathway of coagulation by factor VIIa/TF.[112] The factor VIIa/TF-driven model for hemostasis is supported by the observation that FXI, a major substrate for activated FXII (FXIIa) during contact-initiated clotting, can be activated by thrombin independently of FXII. The FXII-independent "revised model of coagulation" had been widely accepted.[154]

FXII-deficient ($FXII^{-/-}$) mice were generated and phenotyped to study the function of coagulation FXII *in vivo*.[155,156] Similar to FXII deficient humans, $FXII^{-/-}$ mice have a normal hemostatic capacity as assessed by a tail-bleeding assay.[157] Completely unexpected, intravital fluorescence microscopy and blood flow measurements in three distinct arterial beds revealed a severe defect in FXII-deficient mice in thrombus formation induced by different methods of injuries.[157] The data with FXII null mice challenge the "revised model of coagulation" and demonstrate a crucial role of FXII for fibrin formation *in vivo* (FIGURE 15B.3).

Reconstitution of FXII null mice with human FXII restored the prolonged aPTT found in untreated animals and fully restored the capacity of infused animals for thrombus formation. The reconstitution experiments suggest that FXII operates similarly in mice and humans. Indeed, the contact system is highly conserved among mammalian species.[158] Thrombus formation in FXII heterozygous mice—having 50% of normal plasma levels—was similar to wild type control mice (100% FXII), indicating that half of normal plasma concentration is sufficient for vessel occlusive clot formation. *Vice versa*, drugs that target FXII activity need to substantially reduce activity of the protease to provide thromboprotection. The essential role of FXII for thrombus formation has implications for thromboembolic disease. FXII gene–deficient mice are protected from the effects of cerebral ischemia in an experimental stroke model.[159] This protective effect is related to impaired fibrin formation in the microvasculature of the ischemic tissue. Mice lacking FXI are similarly protected from vessel occlusive fibrin formation, suggesting that FXII impacts only on pathologic clotting *via* the intrinsic pathway.[160,161] Despite the striking protective effect in these models, FXII-deficient mice, like their

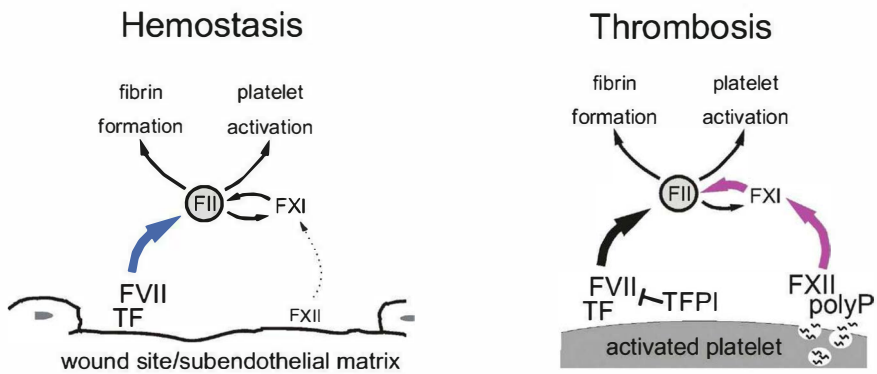

FIGURE 15B.3 Role of FXII in coagulation. *Hemostasis*: Thrombin (FII) formation at sites of lesions is predominantly due to TF exposed in the subendothelial matrix. TF in complex with factor VII (FVII) initiates thrombin formation, which promotes fibrin formation and platelet activation. The contribution of factor XII (FXII) for hemostasis is minor. *Thrombosis*: Additional fibrin forming activity is necessary to form a thrombus when TF/FVII-driven coagulation is blocked by TF pathway inhibitor. FXII is activated by platelet polyphosphate on activated platelet surfaces contributes to thrombin generation and additional platelet activation, propagating thrombus growth. Accordingly, FXII as well as factor XI (FXI) deficiency severely impairs thrombus formation, but have no function for hemostasis. (Reprinted with permission from Maas C, Renné T. Regulatory mechanisms of the plasma contact system. *Thromb Res* 2012;129(Suppl 2):S73–S76.)

human counterparts, do not have spontaneous or injury-related hemorrhage. Pharmacologic inhibition of FXII activation using the peptide-based inhibitor PCK in wild type mice also provides protection from cerebral ischemia, without causing excessive bleeding at the surgical injury site.[159,162] Consistently, a recombinant infestin-4–based inhibitor that specifically targets FXII activity provided protection from cerebral ischemia in experimental stroke models albeit did not affect the hemostatic capacity in inhibitor-treated mice.[163] These results demonstrate that FXII-driven fibrin formation is specifically important for pathologic thrombus formation but has no function for fibrin formation during normal hemostasis. This raises the possibility that targeting FXII may offer a strategy for prevention or treatment of pathologic thrombosis that is not associated with the high rate of hemorrhage that accompanies currently used anticoagulants.[153,164,165] Furthermore, given the results found in mouse models, the concept that pathologic thrombus formation represents disequilibrium of the processes that normally produce a clot at a site of injury likely needs revision (FIGURE 15B.3). The FXII-driven intrinsic pathway seems to be specifically important on activated platelet surfaces propagating thrombus formation when the initial procoagulant activity provided by TF/FVII is not sufficient.

The importance of the contact system for thrombosis is not restricted to animal models. Proteins of the contact system are highly conserved between mice and humans, and results from animal models can easily be transferred to human disease states; for example, FXI appears to participate in thrombosis in humans similarly to its role in mouse models.[166] Together the new data from contact system deficient mice and patients challenge the concept that pathologic thrombus formation represents a dysregulation of normal hemostatic mechanisms and suggest that the dogma of the coagulation balance is in need for revision.[167]

In test tubes, plasma FXI can be activated both by FXIIa and by thrombin according to the classical or revised model of coagulation, respectively. A comparison of mice with deficiency in FXI, FXII, or combined deficiency in the two clotting factors did not reveal additional thromboprotection in FXI/FXII-double deficient mice in a model of lethal pulmonary embolism.[127] The data indicate that FXII is predominantly, if not exclusively, operating *via* its substrate FXI in pathologic thrombus-forming mechanisms in mice. Consistently, antibodies that specifically block FXIIa-mediated FXI activation interfere with thrombus formation in baboons.[168] However, FXI may also be activated by thrombin independently of FXII.[169] The latter study strongly supports the existence of FXI feedback activation *in vivo*.[170] The relative importance of FXIIa versus feedback activation for generating active FXI *in vivo* are not completely understood and may have different importance depending on injury type, vascular bed, and site of activation.

Functions of the Contact System for Thromboembolic Disease in Humans

As today, there is a lack of clinical case controlled studies that systematically compare the incidence or severity of thromboembolic events such as stroke, myocardial infarction, or pulmonary embolism in humans with severe FXII deficiency and normal individuals. The first reported FXII deficient individual, John Hageman, died from a pulmonary embolism,[171] and several subsequent small clinical studies suggested an increased risk of thrombosis in FXII deficient humans.[172–174] However, as noted by Mr. Hageman's physician, Dr. Oscar Ratnoff, the patient had sustained a hip fracture a few days prior to his death,[175] and the trauma and subsequent immobilization were clear FXII-independent risk factors for venous thromboembolism.[109] The observation that deficiency in FXII interfered with polyphosphate-driven fibrin meshwork formation in the thrombus[127] suggests that severe FXII deficiency might increase risk for secondary embolic disease. Consistently, studies showed that thromboses in FXII-deficient patients were probably related to other risk factors, and not to FXII deficiency.[176] However, the detailed association of FXII deficiency and risk for thrombosis is probably more complex. Defective thrombus stability in FXII$^{-/-}$ mice revealed by intravital microscopy,[157] reports of pulmonary emboli in humans with congenital FXII deficiency,[177] and reduced clot firmness in FXII inhibitor–treated blood[127] raise an intriguing hypothesis. FXII deficiency interferes with thrombus propagation apart from the vessel wall and provides thromboprotection. However, FXII-deficiency may also have adverse effects. As in the case of John Hageman, thrombi may develop under some circumstances by FXII-independent mechanisms, especially when thrombosis is driven by massive TF exposure. These thrombi are unstable,[127] and easily embolize causing secondary embolic events. An interesting study from Austria supports the Janus-sided function of FXII for thrombosis in humans. Endler et al. analyzed the correlation between FXII levels and mortality in almost 10,000 patients and found a peculiar inverted U-shaped association. Overall mortality and mortality from cardiovascular disease increase as FXII levels decrease; however, the mortality of patients with severe FXII deficiency (<10% of normal) was similar to mortality for individuals with normal FXII levels (70% to 130%).[178] A C/T polymorphism at residue 46 of the human FXII gene promoter modulates expression levels of the protein. Homozygosity for 46T is associated with lower plasma FXII levels,[179] with an average plasma factor XII level of 53 U/dL (42 to 67) for 46TT, 87 U/dL (77 to 99) for 46CT, and 132 U/dL (97 to 151) for 46CC.[173] A clear association of the 46TT genotype and arterial disease remains to be demonstrated,[180] however, various studies associated the 46 C/T SNP with increased thromboembolic risk.[181–183]

In contrast, large clinical studies in Switzerland and the Netherlands clearly failed to demonstrate any correlation between severe FXII deficiency and an increased risk of thrombosis.[184,185] None of these studies analyzed thromboprotection conferred by FXII deficiency. In contrast, a recent clinical study has analyzed incidence of ischemic stroke in humans with severe FXI deficiency. Similarly to factor XI-null mice, FXI deficient humans are protected from cerebral ischemia[186] supporting the decisive role of the intrinsic pathway for arterial thrombosis in humans.

The data suggest a fundamental difference between individuals with severe or with mild to moderate deficiency in FXII and indicate that FXII may trigger different pathways depending on its activity. These findings are consistent with results from the SMILE project, involving patient from the Leiden thrombophilia study. In the SMILE project, an inverse relationship between plasma FXII and risk of myocardial infraction, with an odds ratio for the highest quintile of FXII levels of 0.4 compared to the lowest quintile, was seen.[187] In contrast, other groups have shown that levels of FXIIa activity were increased in studies of patients with myocardial infarction[188] or

unstable angina.[189] The discrepancies in the literature may be due to the fact that FXII behaves as a negative acute phase protein, with FXII levels decreasing following a thromboembolic event.[190] Additionally, age and ethnic background may influence FXII levels. For example, Orientals have lower plasma levels of FXII than whites.[191] In the second Northwick Park Heart Study, FXIIa was found to be an independent risk factor for coronary heart disease in middle-aged men. Men in the upper third of the study population for FXIIa level had a higher risk compared to those in the middle third. In a second analysis of this data, an increased incidence of coronary events was only found for men with high FXIIa.[192] In contrast, in the West of Scotland Coronary Prevention Study, factor FXIIa levels were not associated with an increased risk of coronary events.[182,193] When evaluating the clinical data on FXII, it is important to note that antibodies to FXII and reduced FXII levels have been associated with antiphospholipid antibodies (APA) and the APA syndrome, a known prothrombotic risk factor. Thus, 50 years after the first description of hereditary FXII deficiency in humans,[111] FXII and the contribution of the contact phase system to thrombosis in patients remain a topic of research.[184] Clearly, patients with deficiency of other contact system proteins such as PK or HK, like FXII deficient patients, do not suffer from abnormal bleeding despite significantly prolonged aPPTs.[194] So far there are no large clinical studies that analyze thromboembolic events in these individuals; however, some case reports associate PK deficiency and thrombosis.[195]

Deficiency in Contact Factors Protects from Thrombosis

Formation of an occlusive arterial thrombus can be divided into two phases: (a) the initiation phase, which results in formation of a "hemostatic" thrombus covering a site of endothelial injury or atherosclerotic plaque rupture, and (b) the propagation phase, which culminates in formation of a three-dimensional occlusive thrombus.[196] Both FXI and FXII deficient animals were largely protected as compared to wild type animals from arterial thrombus formation induced by chemical ($FeCl_3$-induced vascular injury), mechanical damage, or ligation types of vessel injury.[157,160,197] Infusion of human FXI or FXI into FXI or FXI deficient mice, respectively, restored the prolonged aPTT found in plasma of the animals and completely restored thrombus formation in arterial and venous pulmonary embolism models. The reconstitution experiments support the premise that FXI and FXII function similarly in mice and humans. The findings in genetically altered mice data strongly indicate that FXII is essential for thrombus propagation, and that the FVIIa/TF complex is not sufficient for formation of stable occlusive thrombi. The conundrum of normal hemostasis and abnormal pathologic thrombus formation is not restricted to FXII deficient mice. Mice lacking FXI also have relatively normal hemostasis and are protected from thrombus formation.[197] A comparison of FXI null mice and FIX-null (hemophiliac) mice revealed similar levels of protection from carotid artery[161] and *vena cava* thrombosis,[160] in stark contrast to the corresponding impacts of FXI and FIX deficiency on hemostasis. FXI null mice have normal hemostasis following injury to the tail, while FIX-null animals (a model of hemophilia B) bleed to death when challenged in the same manner.[161]

HK deficient mice also have an antithrombotic phenotype, although a different vascular injury model was used other than for the FXI and FXII deficient mice. The mouse has two kininogen genes (kininogen 1 and 2), which account for about 50% of kininogen plasma concentration each.[74] Targeted inactivation of kininogen 1 was sufficient to prolong the aPTT and to impair thrombus formation in the carotic artery induced by the Rose Bengal photothrombosis model.[198] Using the same experimental system, FXII deficiency in mice did not confer protection from cerebral ischemia.[199] The data suggest that Rose Bengal-induced fibrin formation is rather initiated by the "extrinsic" TF /factor VII pathway than the FXII-triggered contact system and indicate the need for experimental thrombosis model in mice that are more indicative for human disease.

HEREDITARY ANGIOEDEMA

The contact system has the capacity of activating the classical pathway of the complement system,[200] and simultaneous activation of the contact and complement system may often occur under pathologic conditions. HAE (MIM #106100) is a rare autosomal dominant disorder, life threatening swelling disorder, that develops in individuals, who are deficient in C1INH (HAE type I) or have a dysfunctional C1INH protein (HAE type II). Urticaria (itching) is not a feature, indicating that histamine is not important to the pathology of the disease. C1INH is the major inhibitor of the classical complement pathway proteases C1r and C1s and regulates generation of the inflammatory mediator BK by the plasma contact system.[5] Deficiency in functional C1INH facilitates excessive activation of the complement and contact system cascades and the development of edema in HAE type I and II patients.[201,202] In addition to these two classical HAE types, a third variant exists that almost exclusively affects women. HAE type III (C1INH HAE type) patients have normal biochemical C1INH functions and plasma concentration, but similarly to other patients suffer from edema.[203] Clinically, all types of HAE are characterized by recurrent episodes of acute swelling involving the skin or the oropharyngeal, laryngeal, or gastrointestinal mucosa. The pathophysiology of increased vascular permeability in HAE has remained controversial. Elegant studies with genetically modified mice demonstrated that edema formation in C1INH-dependent HAE forms is due to pathologic contact system activation. In mice, inactivation of C1INH using a "gene-trap" approach increases vascular leakage. Crossings of C1INH null mice with kinin B2 receptor deficient animals "rescued" the edema phenotype suggesting that vascular leak in HAE is predominantly if not exclusively mediated by BK. Consistently, pharmacologic inhibition of B2R blocked edema formation in C1INH deficient animals.[204] Inactive C1INH increased FXII and PK activity and resulted in excessive PK-mediated release of BK in humans[205] and mice.[204] BK has been shown to be elevated in acute swelling attacks strongly suggesting that increased BK activity mediated elevated vascular leakage.[206] Hence, HAE types I and II are treated by infusion of plasmatic or recombinant C1INH[207] or B2R-receptor antagonists (Icatibant).[208] Alternatively, recombinant PK inhibitors (Ecallantide) may be used to interfere with acute swelling attacks in HAE patients.[209] In contrast to C1INH-dependent HAE forms, the pathomechanism and therapy of HAE type III have remained enigmatic. Using genome-wide linkage analyses in families from France, Switzerland, and Germany, HAE type

III was shown to be an autosomal dominant disease and association with a single missense mutation (c.1032CrA) in the gene of coagulation FXII.[210] A later study involving other families confirmed the original findings and showed that HAE type III could also be associated with a different mutation that affects the same nucleotide of the FXII gene, c.1032CrG.[211] Both point mutations translate into amino acid exchanges Thr328Lys and Thr328Arg, respectively, on protein level. In plasma of HAE type III patient, the enzymatic activity of FXII is elevated as compared to healthy controls.[210] Of note, the aPTT assay results in normal values in HAE type III patients and fails to detect affected individuals.[212] Indeed, the aPTT assay starts fibrin production by preactivated FXII. FXII is activated by exposure to strong contact activators such as kaolin for about 120 to 180 seconds. This time period is sufficient for generating maximal FXII activity independently on presence or absence of the endogenous inhibitor C1INH or FXII-activating conformations (forms of FXII promoting its active potential) such as found in the FXII-Thr328 mutants.[213] Recently, a FXII deletion (residues 324 to 340) was identified in a family with HAE.[214] It remains to be demonstrated, by which mechanism a deletion in the proline rich region of FXII increases BK levels.

Estrogens regulate FXII expression,[215] which might be responsible for the women's specificity of HAE type III.[216] However, FXII plasma levels in HAE type III patients are in the normal range,[210] suggesting that yet unknown mechanism trigger edema predominantly in women. Diagnosis of HAE is difficult as the clinical symptoms are highly variable regarding localization, frequency, triggering factors, and severity of swellings. In contrast to HAE types I and II that are diagnosed by analysis of C1INH plasma levels and function, diagnosis for HAE type III is elaborate and needs FXII gene sequencing that is available in only few diagnostic laboratories. The clinical symptoms suggest that edema in HAE type III is due to aberrant BK formation; however, other FXII-driven pathways such as the intrinsic pathway of coagulation, the complement system, or the fibrinolytic system may contribute.[153] HAE patients experience recurrent attacks of swelling, but the stimuli that trigger these periodic episodes of excessive vascular leakage are poorly defined.[201,202] BK is generated in allergic disease and contributes to increased vascular permeability.[209,217,218] *In vitro*, the mast cell–derived polysaccharide, heparin liberates BK by triggering contact system activation.[129,219,220] The data obtained in plasma samples suggest a role of heparin for triggering swelling episodes in HAE patients *in vivo*. Consistently using a mouse model for HAE type I, mast cell derived heparin as identified as potential trigger for edema attacks *in vivo*.[130]

TARGETING CONTACT SYSTEM PROTEINS FOR ANTICOAGULATION

Current anticoagulation therapy is based primarily on heparins, vitamin K antagonists, or indirect inhibitors of FXa like the synthetic pentasaccharide Fondaparinux. The need for regular monitoring and dose adjustments for some of these drugs (unfractionated heparin and warfarin) or for parenteral administration (heparins, fondaparinux) are inconvenient. Furthermore, use of these drugs is associated with an increased risk of life-threatening bleeding. New oral anticoagulations with lower, but still significant, bleeding risk that include direct inhibitors of thrombin (e.g., Dabigatran etexilate) or FXa (e.g., Rivaroxaban) are entering the market. The antithrombotic effects and bleeding risks for these drugs have been assessed in several clinical trials.[221] Bleeding is an expected consequence with these compounds, because they all target proteins that are critical components of the hemostatic mechanism. In contrast, the limited roles of FXI and FXII in hemostasis[164] suggest that agents targeting these proteases should not increase the incidence of major bleeds.

Wild type mice treated with the peptidergic FXIIa inhibitor D-Pro-Phe-Arg chloromethylketone (PCK), similar to FXII$^{-/-}$ deficient mice, are protected from pulmonary embolism and ischemic stroke without increased bleeding.[127,159] While PCK is not highly selective for FXIIa, recombinant FXIIa inhibitors based on the fourth domain of infestin (infestin-4, a nonclassic Kazal-type serine protease inhibitor protein from *Tryatoma infestans*)[222] fused to human albumin (rHA-infestin-4) have been developed. rHA-infestin-4 is a potent FXIIa inhibitor in human, mouse, and rat plasmas, but does not prolong bleeding times in rodents, even after infusion of large doses. Pretreatment of mice with rHA-infestin-4 resulted in markedly reduced cerebral infarction in the tMCAO model.[163] Similarly, the recombinant contact phase inhibitor Ir-CPI, a Kunitz-type protein from the salivary glands of the tick *Ixodes ricinus*, blocks FXIIa, FXIa, and α-kallikrein and protects mice from venous thromboembolism.[223] A nonpeptidic 3-carboxamide-coumarin (COU254) inhibitor selectively blocked FXII activity in plasma, but was not effective in the tMCAO model in mice.[224] Other protein inhibitors with some degree of selectivity for FXIIa, including cabbage seed protease inhibitor,[225] the pumpkin seed inhibitor CMTI-V,[226,227] trypsin inhibitor from corn (CTI),[228] inhibitors from hematophagous insects,[229] and Ecotin (an inhibitor found in the periplasm of *E.coli*),[230] are effective FXIIa inhibitors in plasma, but also inhibit other coagulation proteases including thrombin, FXIa, and α-kallikrein. A monoclonal antibody against FXIIa that interferes with the FXIIa–FXI interaction has antithrombotic properties and might be useful to prevent thrombosis in patients (United States Patent Application 20090304685, Pritchard D.).

A new and exciting method to inhibit FXII is based on antisense technology.[56] Highly specific antisense oligonucleotides (ASOs) bind complementary sequences on the mRNA of a protein of interest by base pair hybridization. Subsequent selective cleavage and degradation of the target mRNA leads to a reduction in target protein level. In a phase III trial to treat hypercholesterolemia, ASOs directed against the mRNA of apolipoprotein B were potent, selective, and safe[231] (Table 15B.2).

EVOLUTION OF THE CONTACT SYSTEM

The contact system is a young protease cascade in terms of evolution. Orthologs for FXII and PK are not found in fish and birds (or other "primitive" organisms). An ortholog for the FXII gene first appears in amphibians, and is found in mammals, but is missing from the chicken genome.[233,234] An analysis of the region surrounding the FXII homologous protein, hepatocyte growth factor activator (HGFA), and the FXII gene locus sheds some light on this situation. In frogs and mammals, the genes flanking HGFA are paralogs of those flanking FXII, demonstrating that the FXII gene is the result of duplication of the chromosomal segment containing the HGFA gene. The duplication events were followed by translocation to a different

Table 15B.2

Thromboprotective effects of contact system inhibitors *in vivo*

Target	Inhibitor	Arterial Thrombosis	Venous Thrombosis	Ischemic Stroke
FXIIa	Infestin 4 from *Triatoma infestans* fused to recombinant human albumin (rHA-Infestin-4)[163]	x	x	x
	Nonpeptidic inhibitor (3-carboxamide-coumarin, COU254)[224]			—
FXIIa/PK	Peptide-based inhibitor (D-Pro-Phe-Arg chloromethylketone, PCK)[159,127]	x	x	x
FXIIa/FXIa/PK	Recombinant *I. ricinus* inhibitor (Ir-CPI)[223]	x	x	
FXII/PK	ASOs[232]	x	x	

chromosome. Of note, the duplicated region is similar in chicken as compared to mammalians, except that the FXII gene is missing in that specific gene cluster. Comparison of whole genomes shows that the FXII gene was lost during evolution along the lineage leading to birds.[235] This is consistent with the observation that plasma from birds lacks FXII activity and does not clot in aPTT assays.[236] Factor XII gene expression has also been lost in *Cetaceans* (whales and porpoises) due to mutations that converted the gene into a pseudogene in a common ancestor of this order.[233,234] In contrast, kininogens and kinin receptors are ubiquitous in vertebrates.[237] Kininogen genes in amphibians appear to be related to an original kininogen gene in early vertebrates, which has been lost in other modern vertebrate groups. Kininogens in fish, birds, and mammals are related to this original gene that has been transformed into a pseudogene in amphibians.[158]

In summary, FXII predecessor first appeared in tetrapods and may represent an adaptation to a terrestrial environment. While FXIIa may have been an activator of the PK/factor XI predecessor, and subsequently PK and factor XI, the absence of FXII (and contact activation) in birds and *Cetaceans* suggests alternative mechanisms for activation of the contact system that await further analysis.

CHAPTER

16 Fibrinogen Structure and Function

JOHN W. WEISEL AND CARL-ERIK H. DEMPFLE

Fibrinogen, originally factor I (FI) in the clotting cascade, is a fibrous adhesive glycoprotein, present in the plasma at a concentration of approximately 2.5 g/L, which is essential for platelet aggregation and for fibrin gel formation in hemostasis, wound healing, inflammation, angiogenesis, and other biologic processes. This chapter reviews basic and clinical aspects of fibrinogen's structure and functions, focusing on fibrinogen's role in hemostasis and thrombosis; other roles are covered in other chapters.

AMINO ACID SEQUENCE AND DISULFIDE BONDING

Fibrinogen is a large complex glycoprotein made up of three pairs of polypeptide chains, designated as Aα, Bβ, and γ, with molecular masses of 66.2, 54.5, and 48.4 kDa, respectively, for a total mass of about 340 kDa, including the posttranslational addition of asparagine-linked carbohydrate to the Bβ- and γ-chains.[1–3] The unusual nomenclature for fibrinogen—(Aα, Bβ, γ)$_2$—arises from the inclusion of "A" and "B," representing the small peptides that are cleaved from fibrinogen by thrombin to yield fibrin monomer, which is designated as (α, β, γ)$_2$.

In the most common forms of the polypeptide chains, there are 610, 461, and 411 amino acids in the Aα-, Bβ-, and γ-chains, respectively (FIGURE 16.1). The numbering for the amino acid sequence has been based on the mature product, but the numbering from the primary translation product is now used frequently. The amino acid sequences of the three chains are homologous, but there are also important differences that are discussed at the appropriate sections of this review. The evolutionary implications of these homologies are also be summarized.

Fibrinogen has 8, 11, and 10 cysteines in each Aα-, Bβ-, and γ-chain, respectively, for a total of 58, all of which participate in disulfide bonds.[1,2] The *N*-termini of all six chains are held together by disulfide bonds, with five interchain bonds linking the two halves of the molecule, including one between the Aα-chains, two between the Aα- and Bβ-chains, and two between the γ-chains (FIGURE 16.1). There are two pairs of disulfide rings linking all three chains at either end of the coiled-coil regions. There are also several intrachain disulfides.

THREE-DIMENSIONAL STRUCTURE

Overall Molecular Organization

Rather than describing the historical steps in the elucidation of the structure of fibrinogen, the most important aspects of the structure itself will be outlined, starting with general features. On the other hand, some of the early work will be mentioned where it is still important for current studies and understanding functional aspects of this protein.

Fibrinogen is a fibrous protein about 45 nm in length and consists of a central nodule linked to two end nodules by rod-like α-helical coiled coils (FIGURE 16.2).[3] The central nodule contains the disulfide bonds mentioned above that hold the two halves of the molecule together. There are at least two domains in the central nodule: *N*-terminal portions of both γ-chains meet at the center to form the γ*N*-domain, and portions of two Aα- and Bβ-chains that meet to form what is called the funnel-shaped domain.[4,5] In addition, the *N*-terminal Bβ-chain, which is longer than the others, has been called the Bβ-domain. Each end nodule consists of a β-module and a γ-module, which are each made up of the *C*-termini of β- and γ-chains, respectively, and are homologous to each other. The β-module and the γ-module each consist of three domains, the *N*-terminal A-domain, central B-domain, and *C*-terminal P-domain. The *C*-terminal Aα-chain, which is not homologous to the other two chains, is called the αC region and is made up of a compact *C*-terminal portion called the αC-domain and a flexible tether called the αC-connector that is variable in different species of fibrinogen. The two α-helical coiled coils are made up of all three polypeptide chains, and the distal portions are four stranded, with the addition of a part of the Aα-chain that runs antiparallel to the other three strands.

Visualization of Individual Molecules by Electron Microscopy

Aspects of the overall shape of fibrinogen have been deduced from a variety of physicochemical and structural methods. A diverse array of structures were proposed over many years, and it should be remembered that crystallographic structures do not capture the molecular flexibility and other potential structures that may be present in solution.

One of the first proposals for fibrinogen's shape arose from transmission electron microscopy of rotary shadowed molecules.[6–10] Fibrinogen appeared to have an elongated, 46 nm long trinodular shape (FIGURE 16.3A). A variety of artifactual images of negatively contrasted fibrinogen were then published, in retrospect suggesting that the protein reacts adversely to the low pH of most common heavy metal stains. Subsequent studies revealed that fibrinogen carefully prepared by this method shows the same basic shape.[7,10] Electron microscopy continues to be useful for observations of binding interactions, aspects of fibrin polymerization, and visualization of parts of the molecule that are not seen in crystal structures.

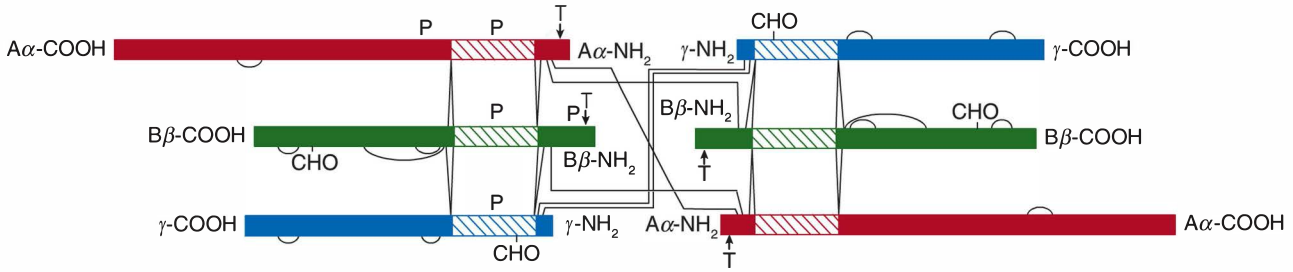

FIGURE 16.1 Schematic diagram of the three pairs of polypeptide chains and disulfide bonding. The Aα-, Bβ-, and γ-chains are represented by bars with lengths approximately proportional to the number of amino acids in each chain. The *N*- and *C*-terminal ends of the chains are labeled and disulfide bonds are shown. The coiled-coil regions are shown as diagonally striped boxes. The carbohydrate locations are shown as CHO. The sites of cleavage of Fps by thrombin are indicated by T and the major sites of plasmin cleavage by P. (From Weisel JW. Fibrinogen and fibrin. *Adv Protein Chem* 2005;70:247–299.)

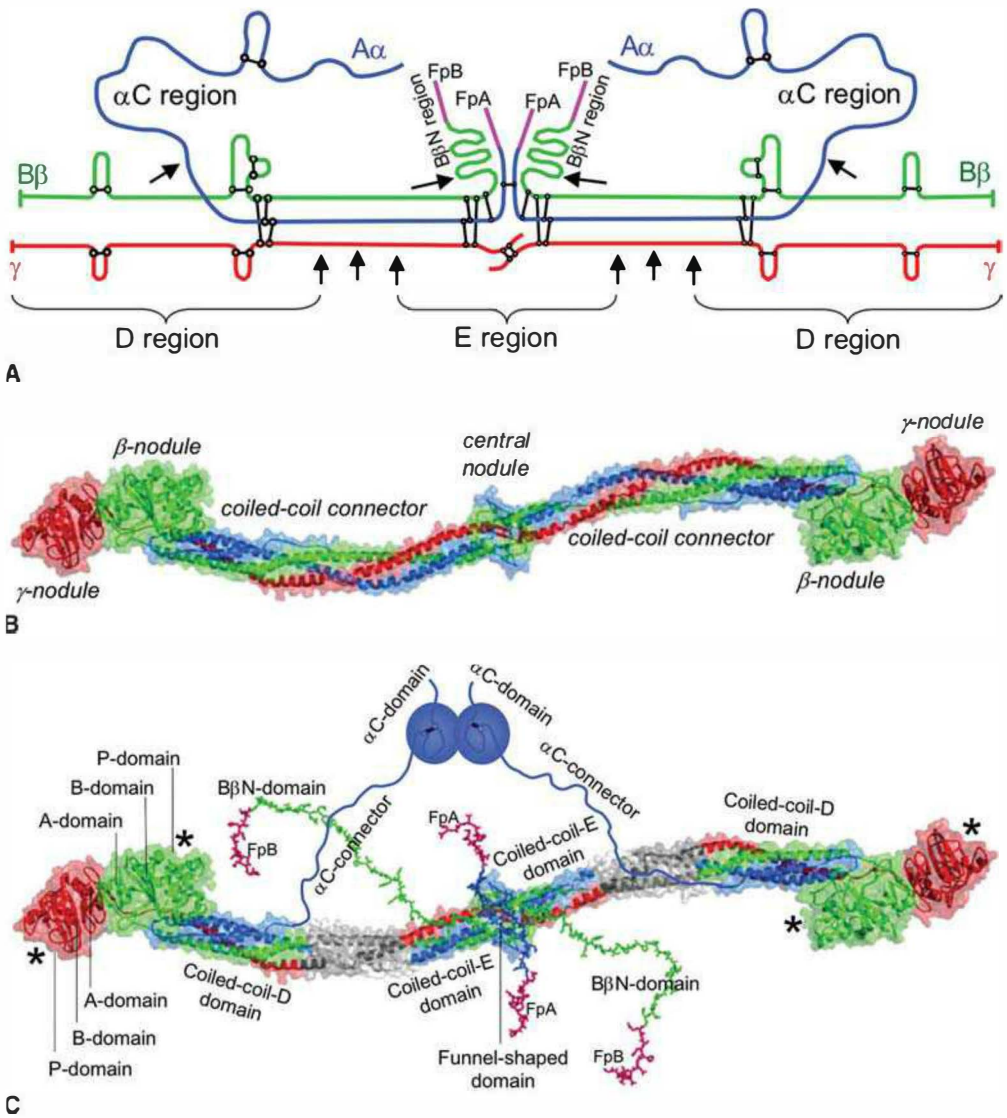

FIGURE 16.2 Structure of fibrinogen. The Aα-chains are *blue*, the Bβ-chains are *green*, and the γ-chains are *red*. **A:** Schematic diagram to show locations of the disulfide bonds and the major regions of fibrinogen, D, E, and αC regions. Major plasmin cleavage sites are indicated by *arrows*. **B:** X-ray crystallographic structure of fibrinogen, with some regions indicated. **C:** The same crystallographic structure with the parts of the molecule that are missing added and labeled. (From Medved L, Weisel JW. Recommendations for nomenclature on fibrinogen and fibrin. *J Thromb Haemost* 2009;7:355–359.)

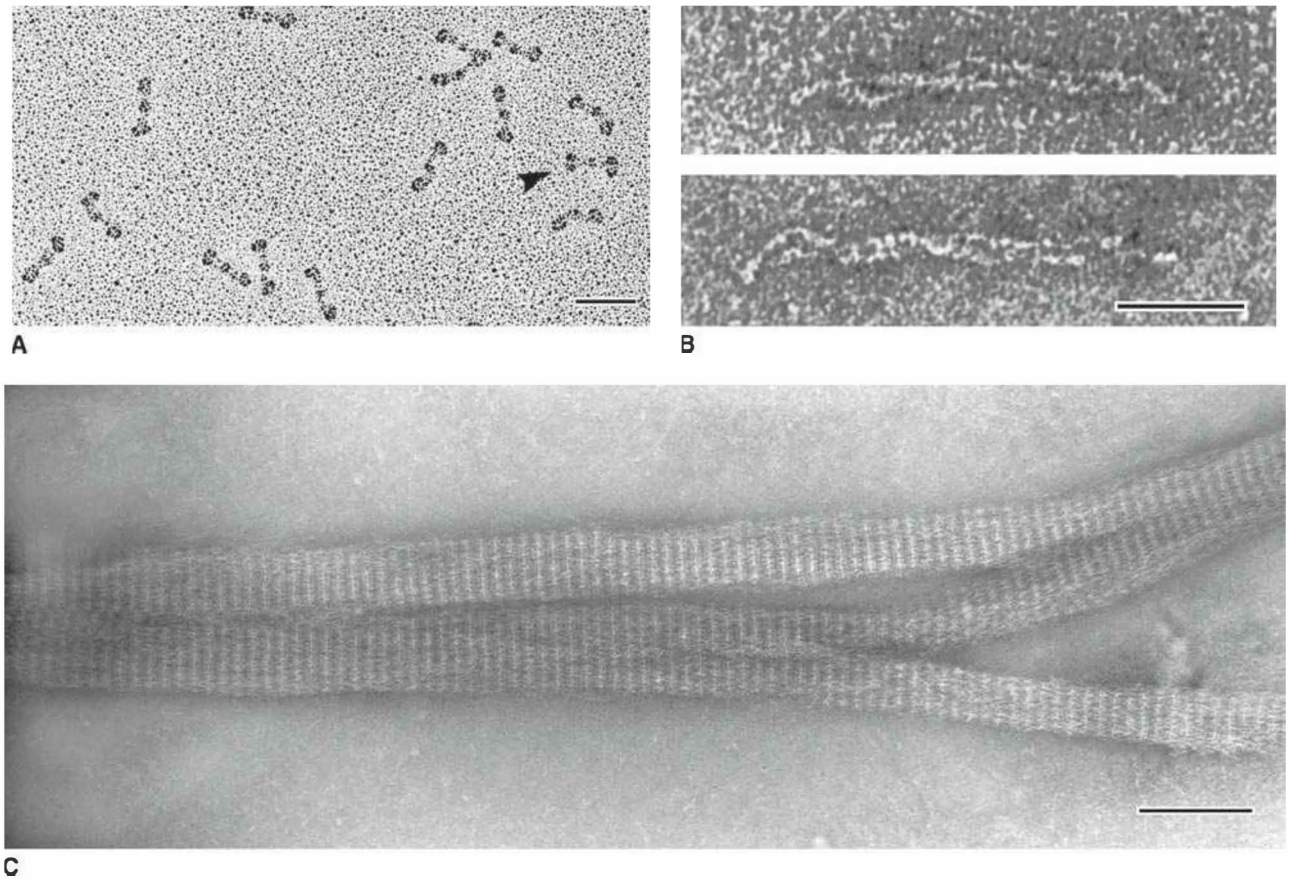

FIGURE 16.3 Transmission electron microscope images of fibrinogen molecules, protofibrils, and fibers. **A:** Individual fibrinogen molecule rotary shadowed with a thin layer of tungsten, showing the 45-nm-long elongated protein molecules with a central region and two nodules at each end, connected by thin rods. Magnification bar, 50 nm. **B:** Negatively contrasted fibrin protofibrils, showing the half-staggering of fibrin monomers and the twisting of the two filaments of the protofibril. **C:** Negatively contrasted fibrin fibers, which have a 22.5-nm repeat, and a distinctive band pattern that arises because areas with high protein density exclude stain and appear bright, while areas with less protein allow stain to penetrate and appear darker. Magnification bar, 200 nm. (From Weisel JW. Fibrinogen and fibrin. *Adv Protein Chem* 2005;70:247–299.)

Structural Insights from Limited Proteolysis of Fibrinogen

Before the crystallographic structure of fibrinogen was determined, the enzymatic degradation products of fibrin(ogen) were extensively analyzed to decipher the structure of the molecule.[11] The nomenclature originally developed has persisted, with the main parts of fibrinogen that remain significant being fragments X, Y, D, and E. These proteolytic fragments are still extensively used in research, are important to understand fibrinolysis (see Chapter 20), and are used in some clinical assays.

Fibrinogen is first converted by plasmin to a clottable derivative, called fragment X, which is missing the *N*-terminal end of the Bβ-chains 1 to 42 and the *C*-terminal ends of the Aα-chains. Fragment X is then cleaved asymmetrically into fragment D and fragment Y, the latter in turn cleaved into another fragment D and fragment E. Fragment D is made up of Bβ-modules and a γ-module and approximately the distal half portion of the coiled-coil region. D-dimer (or double D) consists of two D fragments covalently cross-linked by FXIIIa. Fragment E is made up of the central domain and the proximal portion of both coiled coils. It is important to note that each of these fragments is made up of multiple domains, so the older practice of calling them domains is inappropriate, and they should be called D and E regions.

Carbohydrate

Each fibrinogen molecule contains two pairs of biantennary oligosaccharides attached *via* *N*-glycosyl bonds at Bβ364 and γ52. The amino acid motifs at these two sites are NXT and NXS, respectively, typical of *N*-glycosylation. The Aα-chains contain two NXS sequences but no attached carbohydrate, although extended AαE-chains do. Circulating fibrinogen is variably desialated, leading to heterogeneity, with about equal amounts of mono- and disialyated chains, but generally no asialo chains.[12,13]

The presence of carbohydrate on fibrinogen has important functional consequences. The most striking example comes from patients with cirrhosis and other liver disease who have hypersialated fibrinogen that forms clots with thin fibers and many branch points.[14] Conversely, if all sialic acid on fibrinogen is removed with neuraminidase, fibrinogen makes clots consisting of thicker fibers with fewer branch points.[15] Further, complete

removal of all carbohydrate has more extreme effects, leading to clots with extremely thick fibers and even fewer branch points.[16] These results indicate that the carbohydrate on fibrinogens modulate clot structure through effects of both charge and mass on polymerization, probably particularly lateral aggregation.

Circulating fibrinogen also contains variable amounts of nonenzymatic glycation. Patients with uncontrolled diabetes have increased levels of fibrinogen glycation due to the high concentrations of sugar in their blood, but even nondiabetics have several sugar residues attached. The effects of nonenzymatic glycation have not been fully elucidated, but higher levels of glycation appear to result in clots made up of thinner fibers and more branch points.[17–24]

Structure of the End Regions of Fibrinogen

The homologous β- and γ-modules are each made up of three domains, the *N*-terminal A-domain, central B-domain, and *C*-terminal P-domain,[25] but the two modules are oriented quite differently (FIGURE 16.4).[26] The β-module is folded back about 130 degrees with respect to the γ-module, as predicted from analysis of the molecular packing in fibrinogen crystals.[9]
