A useful tool to gain insight into the totality of evidence for specific clinical endpoints is the systematic review and meta-analysis process. It is noteworthy that the number of human studies assessing health effects of probiotics has increased to the point that it is possible to use these techniques for an unbiased approach to reviewing the totality of evidence. Hundreds of such studies have been published, addressing a range of clinical effects. Some considerations should be brought to bear, however, when considering meta-analyses of probiotics (52). Most importantly, there must be a scientifically sound basis for combining evidence on different strains, species, or genera. Such a rationale is possible, especially when effects are expected to be based on common, underlying mechanisms.

A novel application of probiotics for health is their use to deliver vaccines and other biotherapeutics to the mucosal immune system

of the intestine. An optimized probiotic carrier could increase antigen potency and reduce the potential side effects incurred through other, more traditional delivery routes. Oral ingestion of proteins (vaccines or enzymes) results in denaturation, degradation, and loss of biological activity. In contrast, these bioactive molecules can be protected by viable microbial cells during passage through the stomach and then released into the intestine. Bioactive molecules targeted for delivery by probiotics include vaccine antigens against viral and bacterial pathogens, digestive enzymes for humans, and growth-promoting enzymes in animals. Probiotics are an attractive choice for mucosal delivery vehicles because of their ability to survive intestinal passage, record of safety, and ease of genetic manipulation (53). Wells et al. (54) pioneered the development and use of lactic acid bacteria as vaccine delivery vehicles, and developed recombinant strains designed to treat a number of conditions, including HIV infections. Klaenhammer and colleagues successfully developed effective oral vaccine delivery platforms in the probiotic species *L. acidophilus* and *Lactobacillus gasseri* for protection from anthrax and botulism challenges in mice (55–57).

Earlier it was demonstrated in a mouse model that a genetically modified *Lactococcus lactis* designed to produce and secrete the cytokine interleukin 10 in the gastrointestinal tract could decrease inflammation associated with colitis (58). This group also addressed the important issue of biocontainment of the recombinant microorganism by devising an elegant solution of replacing the *L. lactis thyA* gene with the interleukin 10 gene. ThyA is responsible for the synthesis of the nucleic acid thymidine. Once the gene is removed, *L. lactis* requires an exogenous source of thymidine that must be provided in the culture medium. Thymidine is scarce in the environment, thereby preventing growth and spread of the microorganism outside laboratorycontrolled culture conditions (58). This recombinant microorganism was tested in a phase I clinical trial for Crohn's disease, as well as the effectiveness of the engineered biocontainment system (59). The clinical study

demonstrated the feasibility of the approach but was unsuccessful, and no further human trials have been published.

There are many exciting opportunities to employ probiotic bacteria as vehicles to deliver bioactive molecules to targeted locations in the gut. This is likely to be one of the most important areas for practical application of probiotic cultures that are derived through recombinant-DNA technologies.

Probiotics for Animal Health

Considerable effort has been directed toward the development of probiotic cultures for both agricultural and companion animals. Important health targets for agricultural animals are enhancing animal growth, promoting weight gain, and reducing carriage of human enteric pathogens. Reduced pathogen carriage is of significant interest because control of enteric pathogens at the farm level can greatly reduce the risk of foodborne illness. While antibiotics have been used extensively as prophylactics in animal feeds since the 1950s to improve growth and feed conversion, concerns over the development, transmission, and spread of antibiotic resistance determinants through this practice have led to its ban by some regulatory agencies [regulation (EC) no. 1831/2003 of the European Parliament and of the Council on additives for use in animal nutrition; https://eur-lex.europa.eu/legal-content/EN/TXT/?uri=CELEX%3A32003R1831] and has revived interest in developing probiotic cultures for livestock and poultry. Decades ago, Nurmi and Rantala (60) discovered that newly hatched chicks could be protected from *Salmonella* infection by exposure to a suspension of gut contents from the adult chicken. This concept was later revived in a probiotic mixture composed of 29 species of nonpathogenic bacteria isolated from the chicken gut. The probiotic mixture is sprayed over the chicks so that as they preen, their intestinal tract is seeded with microbes which occupy this ecological niche to provide colonization resistance against *Salmonella*, *Campylobacter*, and *Listeria* (61). This seeding mimics the colonization that occurs naturally in small flocks, where mothers

are in close contact with the hatchlings. Generally, it has been shown that undefined competitive exclusion mixtures (e.g., mixtures derived from gut contents) perform better than simpler defined mixtures (e.g., a single strain or defined mix of strains) (62). Similarly, Zhao et al. (63) specifically targeted colonization of *E. coli* O157:H7 in cattle by creating a probiotic cocktail of 17 isolates of *E. coli* and one *Proteus mirabilis* strain. These were isolated from cattle on the basis of their ability to inhibit *E. coli* O157:H7 *in vitro*. In challenge studies with *E. coli* O157:H7, the probiotic mixture reduced the level of pathogen carriage in most of the probiotic-treated animals. Probiotics have been studied for their role in reducing *Campylobacter jejuni* colonization in poultry (64). In the animal probiotic field, host specificity, animal age, and targeted benefit are critical in selecting cultures for specific probiotic applications. There are currently a number of commercially available competitive exclusion products available for agricultural animals (65).

Probiotic use in companion animals has largely focused on cats and dogs (66, 67). Study endpoints include reduction of diarrhea, treatment of gastrointestinal disorders, prevention or treatment of allergies, treatment urinary tract infections, and treatment of bad breath.

Safety

Live microorganisms of many species have been consumed safely by humans in various forms and in high numbers for centuries. Safety assessments of the commonly used and studied probiotic genera *Lactobacillus* and *Bifidobacterium* document a low potential for adverse health effects in these species (68). However, proposed probiotic strains are not limited to these genera and can include members of the genera *Bacillus*, *Enterococcus*, and *Escherichia*, which contain species that are foodborne pathogens. Novel probiotic strains must be assessed for safety before addition to foods and supplement products. Safety review of potential probiotics generally

involves, but may not be limited to, the strainlevel assessment of four criteria:

- identity of the microorganism
- history of safe use of the microorganism
- fermentation and processing conditions for the microorganism
- the microorganism's potential for pathogenicity, toxigenicity, and resistance to clinically relevant antibiotics

Although reviews conclude that the infective and toxigenic potential of lactobacilli and bifidobacteria is low (68), case studies have described opportunistic infections caused by lactobacilli in the immunocompromised or elderly. With extended survival of chronically immunocompromised individuals and an aging Western population, increased scrutiny must be given to strains that may be administered to these individuals. In particular, some intestinal isolates, such as *L. rhamnosus*, have warranted increased surveillance due to a higher correlation with secondary infections. Ongoing genome sequencing projects have not revealed any identifiable pathogenic determinants for probiotic cultures. However, genome sequencing projects have identified genes in probiotic species that are annotated as antibiotic resistance genes or multidrug resistance transporters (69). This is not surprising, given the widespread use of antibiotics in agriculture and medicine and the apparent widespread distribution of antibiotic resistance genes among commensal and food bacteria (70). When these are identified in probiotic cultures, it will be important to determine whether any antibiotic resistance determinant is functional, is clinically relevant, and has any reasonable probability for genetic transfer to other microbes.

Taxonomy and Molecular Identification of Probiotic Strains

The correct identification of probiotic strains is critical to a number of activities associated with these microorganisms, including product labeling, safety assessment, scientific communication, and attribution of beneficial effects. Historical problems with phenotypic classification of probiotic microbes led to misidentification of many commercial strains prior to 1995, and therefore the genus and species names found in older probiotic literature should be viewed carefully. Further, some product manufacturers persist in using old nomenclature. The advent of molecular techniques and efficient and costeffective whole-genome commercial sequencing facilities has made bacterial species identification by genome sequencing and phylogenetic analysis commonplace. The availability of molecular-analytic tools has enabled proper identification of probiotic species and individual strains over the last decade and has helped dispel confusion over species identity and ancestry. Phylogenetic analysis can be conducted in varying degrees of depth and combined with information on other phenotypic characteristics (e.g., microscopic morphology and carbohydrate fermentation profile) as needed to gain a complete view of taxonomic classifications.

A number of DNA sequence-based typing systems have been used to analyze conserved regions of the ribosomal DNA operon or other conserved genes in probiotic strains. These include the following:

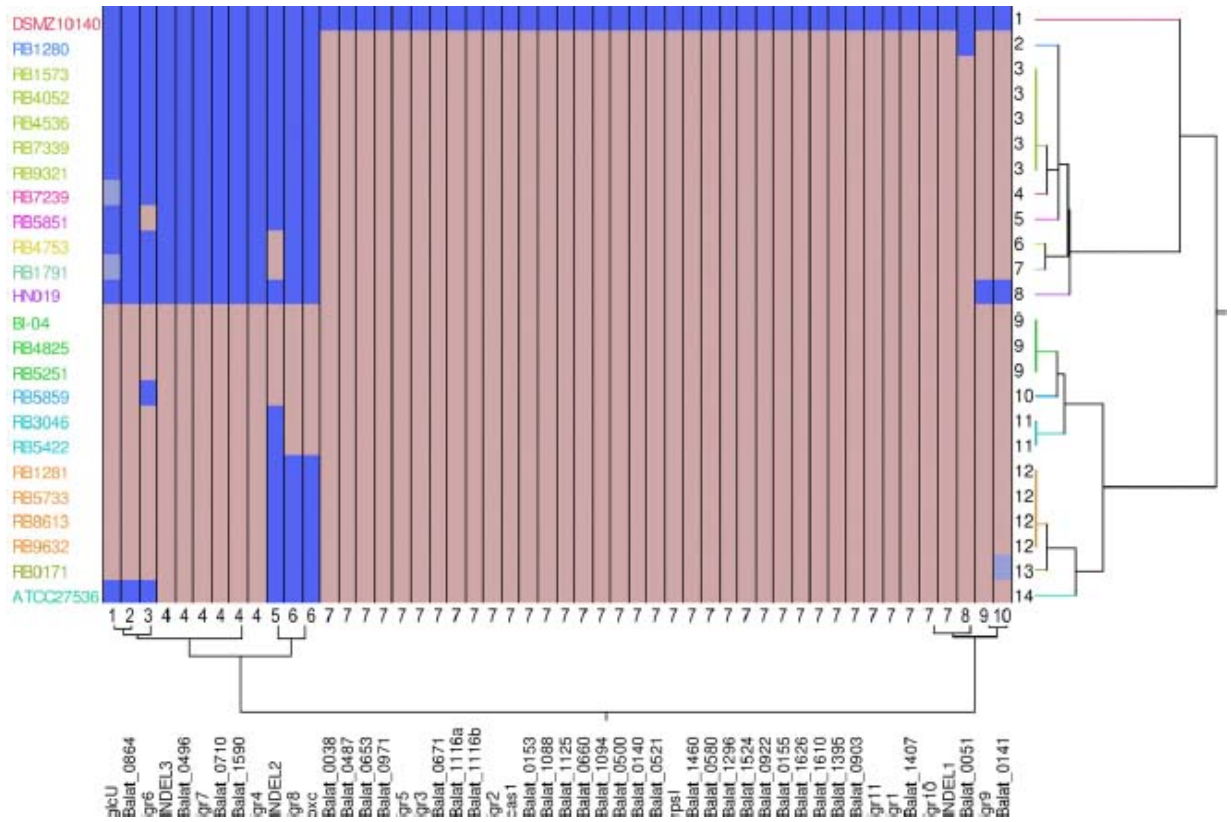
- PCR amplification and sequencing of the 16S rRNA gene (1,500 bp) or the □450 bp of the internal transcribed spacer region between the 16S and 23S rRNA genes were used to identify members of the *L. acidophilus* complex (71).
- Modern phylogenetic trees are being constructed based on whole-genome sequencing, as is the case for the genus *Lactobacillus*, which is undergoing a major taxonomic upheaval (72).
- PCR amplification and sequencing of alternative genes that are universally present and highly conserved, e.g., the *recA* gene of

bifidobacteria (73)

- Whole-genome sequencing for comparative genomic analysis (74, 75)

The ability to properly identify probiotic species provides the first giant step toward eliminating confusion over strain identity and ancestry. The practice is expected to also uncover new probiotic species that have been hidden below the surface of traditional taxonomic descriptions. DNA sequence analysis of the rRNA operons of strains loosely classified as *L. acidophilus* revealed six closely related species that comprise the *L. acidophilus* complex: *L. acidophilus*, *Lactobacillus crispatus*, *Lactobacillus amylovorus*, *Lactobacillus gallinarum*, *L. gasseri*, and *Lactobacillus johnsonii*. All of these are considered to have probiotic potential, but the specific roles and benefits of each species remain to be determined.

Lactobacillus is a member of the phylum *Firmicutes*, class *Bacilli*, order *Lactobacillales*, and family *Lactobacillaceae*. This genus was identified by Beijerinck in the early 1900s, and members were first classified by their optimal growth temperatures and sugar fermentation pathways. Later, the species were classified based on physiological assays such as the homo- and heterofermentation profiles of the members (76). However, identification and classification utilizing 16S rRNA gene sequences is now the most widely accepted method for species-level typing of microorganisms and offers a fast, reproducible, and an inexpensive method for discrimination. Beyond phylogenetic analysis, the most detailed recent examination of probiotic and commensal microbes was whole-genome analysis of the lactobacilli. Complete genome sequencing of representative strains across 213 species comprising lactobacilli revealed the complexity of the genus and the precise taxonomic relationships between the numerous species that occupy diverse ecological niches in plants, animals, humans, and fermented foods (75).



Bifidobacterium, another widely studied genus of probiotic microorganisms, belongs to the phylum *Actinobacteria*, class *Actinobacteria*, order *Bifidobacteriales*, and family *Bifidobacteriaceae*. Similar to the lactobacilli, historic methods of species identification relied on phenotypic differences, including the origin or host from which the species was isolated (e.g., *B. longum* subsp. *infantis*, isolated exclusively from infants, or *B. longum* subsp. *longum*, isolated from adults), as well as their sugar fermentation profiles (77). The taxonomic classification of bifidobacteria was significantly improved through use of 16S rRNA gene sequencing. Whole-genome sequencing shows that multiple, commercial *B. lactis* strains are highly similar (74) (Fig. 32.5), yet specific strains can be distinguished (78). A current list of all recognized bacterial species, including *Bifidobacterium* and *Lactobacillus* species, can be found in the Approved List of Bacterial Names at http://www.bacterio.net.

Comparative Genomics

Comparative genomic analysis is a powerful tool for discerning the relationships between microbes and identifying key similarities and differences. Alignment of whole genomes has illustrated the overall synteny between the closely related members of the *L. acidophilus* complex and substantial differences with *Lactobacillus plantarum* (79). Moreover, genomic content can be compared between strains of the same species, allowing an inventory of genetic content or deficiencies. Molenaar et al. (80) compared the genomic content of 20 *L. plantarum* strains using DNA microarrays based on the *L. plantarum* WCFS1 genome. Remarkably, considerable variation was observed among strains, notably in properties considered important for probiotic activities, such as exopolysaccharide synthesis, bacteriocin production, and carbohydrate utilization.

Genomic analysis has revealed important differences and similarities within these probiotic bacteria (81). First, these bacteria are rich in transporters for uptake of sugars and amino acids, emphasizing their dependence on importing, rather than

synthesizing, nutrients from the gastrointestinal tract. In this regard, members of the *L. acidophilus* complex (*L. acidophilus*, *L. gasseri*, and *L. johnsonii*) are largely deficient in their ability to synthesize amino acids and other essential nutrients. This is consistent with the evolution of these bacteria within the small intestine, where nutrients are abundant and can be acquired via transporters. In contrast, *B. longum* encodes complete pathways for synthesis of all amino acids and nucleotides, reflecting the more nutrientcompetitive environment of the colon, where bifidobacteria naturally reside. In addition, *B. longum* harbors a surprisingly large number of genes predicted to encode proteins required for catabolism of complex carbohydrates and plant polymers (43). Such compounds, like fructooligosaccharides (FOSs), are considered prebiotics which can promote the growth of bifidobacteria and some lactobacilli.

pathways which are clustered in a 600-kb "lifestyle adaptation region." This metabolic capacity and flexibility explain why *L. plantarum* is found naturally in the intestinal tract and can also dominate microbial populations in fermenting plant materials.

Functional Genomics

As a result of genomics, correlations between gene function and mechanisms of probiotic activity are now rapidly emerging in this field, and the potential functionality and safety of probiotic cultures can now be rationally considered based on genome content. Genomic information also allows surveys for potentially problematic genes that might be harbored by probiotic strains, including antibiotic resistance genes. The tetracycline resistance determinant (*tetW*) was found by sequencing of the genome of *B. lactis* BB-12, a widespread commercial probiotic (82). This strain was subjected to an in-depth review by FDA and remains classified as "generally recognized as safe" due its long-term, safe use as a probiotic and the widespread distribution of *tetW* throughout the genus *Bifidobacterium*, in both commensal and probiotic strains (83).

Among probiotic lactobacillus strains, genes identified and confirmed to be involved in carbohydrate metabolism (lactose, sucrose, galactooligosaccharides, FOSs), bile tolerance, and host interaction (e.g., cell surface proteins) are common. There are other species of lactobacilli, however, that are primarily involved in the fermentation of milk that have markedly reduced gene content and genome size (84). Further approaches to validate the importance of probiotic genes include the use of transcriptomics and directed mutagenesis for gene knockouts to link gene to function. One landmark example examined the effects of the bacteriocin-producing *L. salivarius* strain UCC118 on infection challenges by *L. monocytogenes* in a mouse model. This study unequivocally demonstrated that wild-type *L. salivarius* prevented infection, while a mutant strain unable to produce the listeria-active bacteriocin did not prevent infection and death of the mice (35) (Fig. 32.6). More

recently, cell surface pili (Fig. 32.7) were discovered via genomic screening of both lactobacilli and bifidobacteria and linked to the ability of these bacteria to bind mucin (85, 86).

Establishing mechanisms that link *in vitro* phenotypic criteria to *in vivo* functionality remains one of the major scientific challenges for probiotics in the future (5). In this regard, this field is poised perfectly to further exploit the recent progress in high-throughput sequencing capacity and functional genomics toward the investigation of these bacteria and their probiotic capabilities. There remains a myriad of possible probiotic strains, representing a diverse set of phenotypes, which are being linked increasingly to a variety of benefits. Defining and screening genetic traits important for functional probiotic activities promise to identify superior strains and allow the construction of strain combinations that elicit unique or multiple effects.

PREBIOTICS

The human diet is generally rich in complex plant carbohydrates, but the human genome encodes fewer than 20 carbohydrate-hydrolyzing enzymes capable of breaking down the disaccharides sucrose and lactose and, to some extent, starch polysaccharides (87). It is now established that most of the indigestible carbohydrates pass through our small intestine and reach the colon intact. There they nourish the microbiota, which possesses specialized carbohydrate-scavenging machinery to harvest nutrients from these dietary glycans. In fact, the “bifidus factor” in human milk, discovered during the 1950s (88) and later identified as human milk oligosaccharides (HMOs), has long been observed to influence the gut microbiota composition in breast-fed infants by stimulating the growth of bifidobacteria. Based on this specialized host-microbiota mutualistic relationship, certain indigestible carbohydrate ingredients that mimic bifidogenic effects have been exploited as dietary interventions to modulate gut community structure and enrich health-promoting microorganisms.

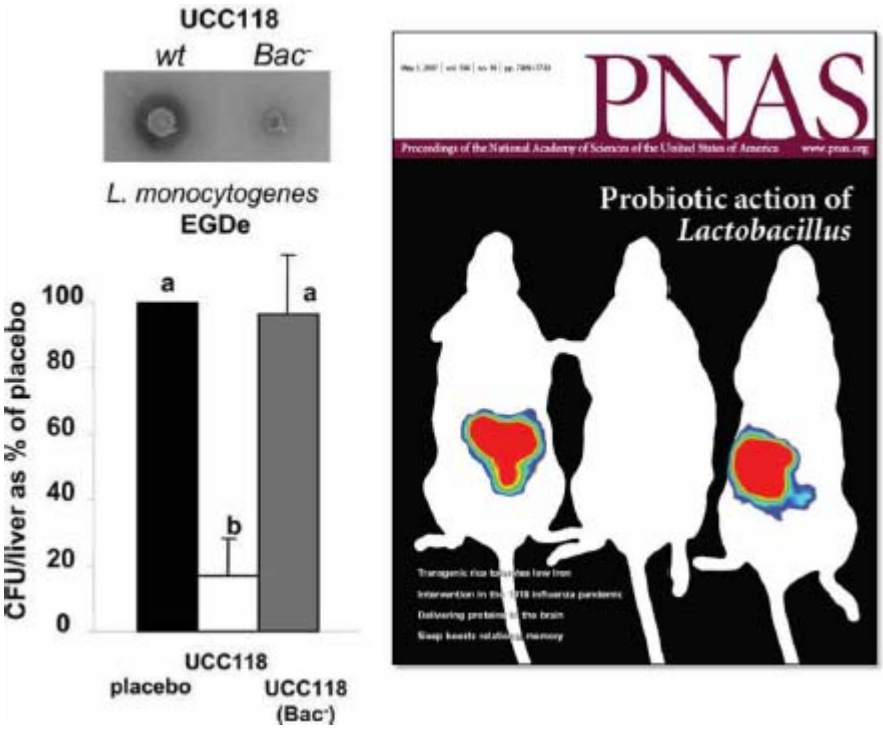

Figure 32.6. Bacteriocin production by *L. salivarius* UCC118 protects against *L. monocytogenes* EGDe infection of mice. (Top left) Bacteriocin production by wild-type (wt) UCC118 and the non-bacteriocin-producing mutant. (Bottom left) Bars represent mice fed placebo (black), UCC118 (white), or a non-bacteriocin-producing mutant of UCC118 (gray). (Right) Image on the cover of *Proceedings of the National Academy of Sciences* shows livers of mice that are colonized with luminescent *L. monocytogenes* EGDe, in red. Prebiotic Definition and Composition

The term “prebiotic” was formally conceptualized in the mid-1990s by Gibson and Roberfroid (89) and was recently updated by a consensus panel of experts convened by ISAPP. A prebiotic is currently defined as a substrate that is selectively utilized by host microorganisms conferring a health benefit (3). Gibson and Roberfroid also proposed the synbiotic approach, where a prebiotic ingredient is combined with a probiotic culture, often the prototypical probiotics bifidobacteria and lactobacilli, to enhance

their retention and efficacy in the host (89). Well-documented prebiotic ingredients are long- and short-chain β-fructans (inulin and FOSs [also called oligofructose]), the HMO-mimetic β-galactooligosaccharides (GOS), and lactulose disaccharide. FOSs are linear fructose oligomers (Fig. 32.8) naturally found in Jerusalem artichoke, chicory roots, and onion and are commercially either produced from hydrolysis of inulin or synthesized using sucrose as the starting substrate by the transfructosylation action of β-fructofuranosidases or β-fructosyltransferases. Originally developed to simulate HMOs, GOSs are typically linear galactose oligomers (Fig. 32.8), most often contain a terminal lactose moiety at the reducing end, and are commercially synthesized by the transgalactosylation activity of β-galactosidases using high concentrations of lactose as starting substrates. Other promising prebiotic candidates include raffinose trisaccharide, isomaltooligosaccharides, xylooligosaccharides, pectin oligosaccharides, resistant starch, and selected dietary fibers. Also included recently as potential prebiotics are noncarbohydrate compounds such as polyphenols, other phytochemicals, and polyunsaturated fatty acids, which have demonstrated positive impacts on the microbiota and health outcomes. The present definition expands prebiotic applications beyond the gut to include administration to extraintestinal sites such as the vaginal tract and skin (3).

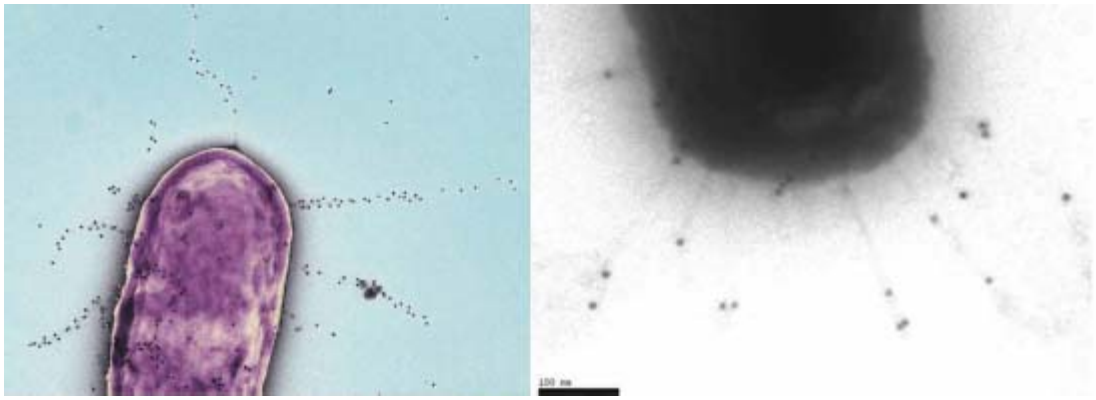

Figure 32.7. Pili expressed by *L. rhamnosus* (left) (85) and *B. breve* (right) (86).

Next-Generation Prebiotics

The prebiotic concept continues to evolve, as gut microbiome and -omics studies have revealed that other indigenous genera in the gut, such as *Faecalibacterium*, *Akkermansia*, *Roseburia*, *Bacteroides*, *Ruminococcus*, and *Eubacterium*, are also stimulated by prebiotics. Metabolism of these nondigestible compounds apparently involves protocooperative efforts and substrate crossfeeding among a broad consortium of the resident microbiota, challenging the initial selectivity criterion for prebiotic ingredients. Studies have also demonstrated metabolic cross-feeding among the beneficial taxa; for example, lactate and the SCFA acetate produced by bifidobacteria during carbohydrate fermentation serve as growth factors for the beneficial members of *Faecalibacterium*, *Roseburia*, *Eubacterium*, and *Anaerostipes* (90–92). Collectively, these recent findings highlight cross-feeding as a key mechanism for which prebiotics exert their effects on the gut microbiota and indicate that the concept should emphasize the overall ecological and functional attributes of the microbiota (93, 94). Most importantly, the core of the prebiotic concept remains conferring health-promoting physiological effects to the host, specifically via prebiotic-stimulated modulation of the beneficial microbiota composition and activities (95).

In one recent example, feeding GOS to lactoseintolerant subjects resulted in a significant modification of the microbiome (96) and concurrent improvement of clinical symptoms and tolerance to lactose (97). The studies documented the ability of a prebiotic to modify the microbiome, leading to a health benefit for lactoseintolerant individuals.

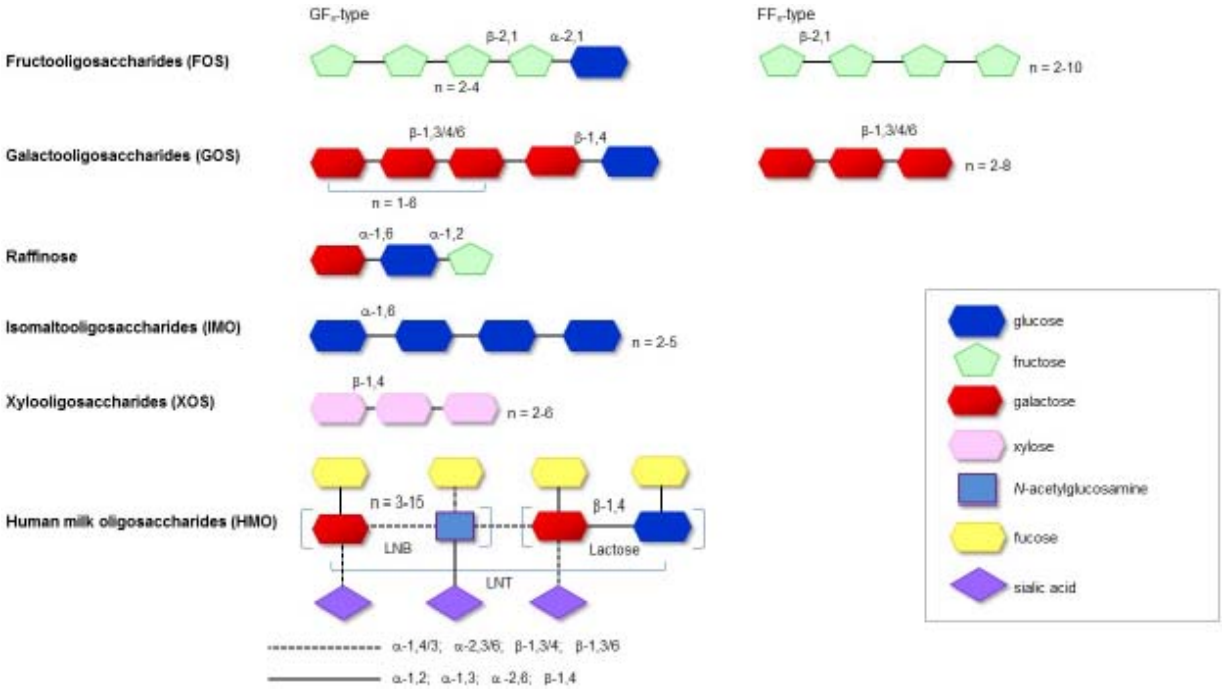

Figure 32.8. Examples of prebiotic oligosaccharides with demonstrated health effects through modulation of beneficial microbiota. FFn, FOS generated from partial hydrolysis of inulin; GFn, FOS synthesized from sucrose; LNB, lacto-*N*-biose I; LNT, lacto-*N*-tetraose. The structure of HMO is modified from reference 121; figure modified from reference 107.

Prebiotic Mechanisms of Action

In an effort to distinguish prebiotics from other dietary components or antimicrobial agents that may also impact the microbiota and host health (e.g., some nonfermentable dietary fibers, antibiotics, etc.), scientists proposed that the classification be restricted to compounds that are utilized (fermented or metabolized) by the microbes as nutrients, leading to modulation of the microbiota and subsequent health effects (3, 94). Accumulating evidence has shown that intestinal and systemic health benefits elicited by a microbiota shift are achieved via some of the following proposed mechanisms (Fig. 32.9):

- decrease in colonic pH resulting from SCFA production during prebiotic fermentation, such as acetate (C2, mainly by bifidobacteria), propionate (C3, by propionibacteria and *Bacteroidetes*), and butyrate (C4, by *Faecalibacterium*, *Roseburia*, *Eubacterium*, and *Anaerostipes*) (98–100)
- improvement in mucosal immunity from production of anti-inflammatory cytokines stimulated by beneficial microbial members (reviewed in reference 101)
- improvement in intestinal barrier function and mucosal epithelial development
- promotion of colonization resistance by commensal microbiota and enhanced protection against enteric infections
- production of secondary metabolites and bioactive compounds, including bacteriocins (reviewed in reference 102), vitamin B (e.g., biotin, cobalamin, folate, nicotinic acid, pantothenic acid, pyridoxine, riboflavin, and thiamine), vitamin K (reviewed in reference 103), and neurochemicals (e.g., gammaaminobutyric acid and serotonin) (104; reviewed in reference 105)
- bioconversion of dietary glycosylated polyphenols/phytochemicals, leading to the potential release of bioactive components (e.g., anti-inflammatory, anticarcinogenic, antimicrobial, and antioxidant substances) from the prebiotic substrates, thus improving their bioavailability in the host (106)

In order to develop effective prebiotic and synbiotic interventions, it is essential to understand how the prebiotic compounds are metabolized by the targeted microbiota and probiotic microbes, especially under *in vivo* conditions. High-throughput genome sequencing and transcriptome analyses coupled with genetic studies in some of these microbes have gradually unraveled the molecular mechanisms involved in the uptake and catabolism of prebiotic substrates. The depolymerization of these substrates often relies on the interplay of multiple glycosyl hydrolases, located intra- and/or

extracellularly, and dedicated transport systems for the uptake of intact or intermediate substrates. For example, the genome sequences of *Bifidobacterium*, *Lactobacillus*, *Bacteroides*, and several other gut commensal genera reveal broad repertoires of transporters and enzyme machinery to metabolize a wide range of complex carbohydrates (reviewed in references 107, 108). These genome features are key determinants for survival in the gastrointestinal tract and reflect the specialized adaptation of these microorganisms to the lower small-intestinal (e.g., lactobacilli) and colonic niches (e.g., bifidobacteria and *Bacteroides*), where complex oligosaccharides and plant polymers, as well as host-derived glycans (e.g., mucin, glycogen, HMOs, etc.), are abundant.

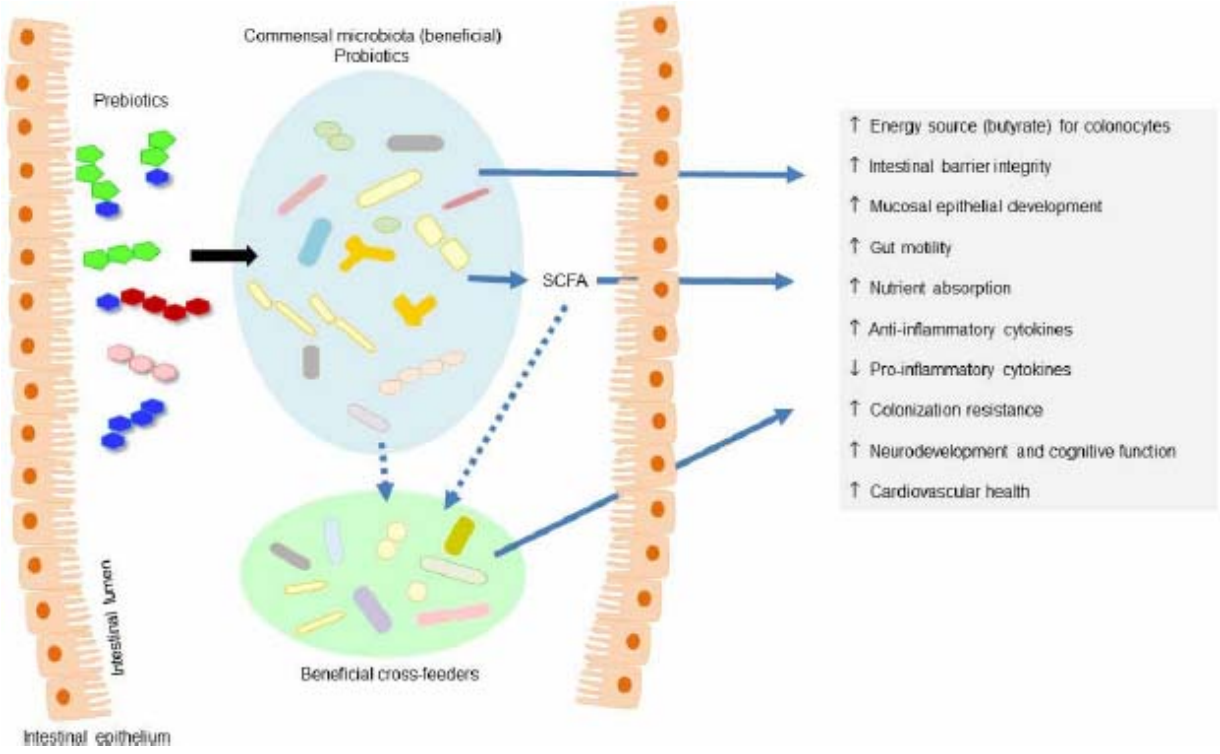

Figure 32.9. Metabolism of prebiotic compounds by beneficial gut microbiota and probiotic microorganisms, by which the resulting population is enhanced directly and indirectly (via substrate cross-feeding and metabolic cross-feeding) and which has health-promoting effects on the host. SCFAs are an essential energy source for colonic epithelial cells and serve as growth factors for some beneficial bacteria. These metabolites have also been associated with maintenance of gut barrier integrity, immunomodulatory functions, and host signaling (39, 100). Dashed arrows indicate cross-feeding of hydrolyzed prebiotic substrate intermediates and SCFA metabolites.

The genetic mechanisms for metabolizing FOSs, GOSs, and HMOs have been studied extensively among lactobacilli and bifidobacteria. The majority of the FOSfermenting species of *Lactobacillus* and *Bifidobacterium* possess specific transporters (e.g., ATP-dependent binding cassette [ABC] transporter, phosphotransferase system [PTS], and sugar permeases) for the uptake of mainly short-chain FOSs, followed by intracellular hydrolysis of the substrates by cytoplasmic β-fructofuranosidases (109–112) (Fig. 32.10). On the

other hand, species in the *Lactobacillus casei-Lactobacillus paracasei* group are capable of utilizing FOS and larger fructan polymers, such as inulin and levan, owing to the presence of a cell wallanchored β-fructosidase (113, 114). This enzyme hydrolyzes the fructan polymers externally, generating substrate intermediates (consisting mainly of fructose moieties) that are subsequently imported by the cells via dedicated fructose PTS transporter.

Overall, the internal sequestering of FOS in its intact form allows inclusive intracellular catabolism and confers a competitive advantage to the microbe in a nutrient-rich environment (109). In contrast, the unique extracellular FOS degradation strategy demonstrated by the *L. casei-L. paracasei* group provides cross-feeding of hydrolytic products from FOS and allows some versatility to catabolize more complex fructan substrates (114). This strategy could be viewed as logical for establishing a mutually beneficial relationship with other resident microbiota sharing the same niche where complex fructoside substrates are readily degraded and made generally available to the entire microbial ecosystem. The molecular mechanisms of GOS utilization were first identified in the commercially ubiquitous probiotic organism *L. acidophilus*, which involves a lactose permease (LacS) and two cytoplasmic β-galactosidases that are induced by GOS (115). Separate studies further reported upregulation of this GOS catabolic system upon exposure to bile *in vitro* (116), revealing intertwined gut-adaptive traits for bile tolerance and oligosaccharide utilization in the small-intestine environment. These observations support the strategy for delivering *L. acidophilus* with GOS as a synbiotic. When the probiotic microbes transit through the intestine, GOS metabolism would be induced by both GOS and an environmental signal, bile.

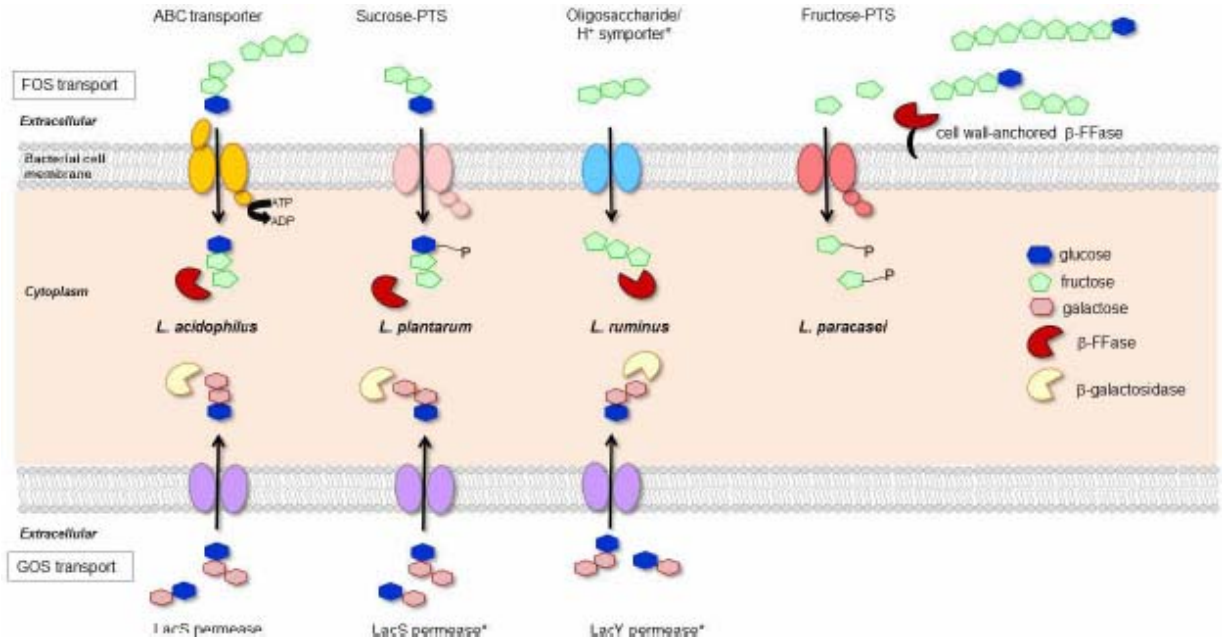

Figure 32.10. Molecular mechanisms of prebiotic FOS and GOS uptake and catabolism identified among intestine-associated lactobacilli. A diverse array of transport systems (ABC transporter, sucrose and fructose PTSs, symporter) and hydrolytic pathways (intracellular versus extracellular) have evolved for FOS utilization in these organisms (top). Uptake of GOS is mainly mediated by lactose permeases and is hydrolyzed by cytoplasmic β-galactosidases (bottom). Note that no LacS permease ortholog was identified in the *L. casei-L. paracasei* group. FFase, β-fructofuranosidase or β-fructosidase; ~P, phosphorylation of the substrate intermediate during the uptake process via PTS; an asterisk indicates that the transporter system was predicted based on *in silico* analysis.

Among bifidobacteria, certain strains of *B. longum* and *Bifidobacterium breve* encode a cell membranebound endogalactanase (GalA) that degrades GOS and plant-derived galactan. The enzyme liberates galactotriose from GOS and galactan polymers in an exo-type fashion (117). The resulting galactotriose is imported via an ABC transporter and hydrolyzed by a cytoplasmic β-galactosidase (118). In *B. longum*, the same catabolic system is also associated with the utilization of lactose and FOS (112). Meanwhile, glycoprofiling of GOS consumption among bifidobacteria revealed

that infant isolates of *B. breve* and *B. longum* subsp. *infantis* metabolized longer-chain pure GOS more efficiently than the adult isolates of *B. adolescentis* and *B. longum* subsp. *longum* (119). This differential GOS consumption phenotype reflects specific GOS catabolic systems that evolved through adaptation to host nutrient environments and provides a framework for targeted GOS enrichment of bifidobacteria in specific host populations.

As the third most abundant solid component in human milk after lactose and lipids, HMOs are a complex mixture of nondigestible oligosaccharides composed of glucose, galactose, *N*-acetylglucosamine (GlcNAc), l-fucose, and sialic acid (*N*-acetylneuraminic acid), the latter two of which confer structural diversity to the HMOs (120). Not surprisingly, the ability to metabolize HMOs or lacto-*N*-biose (LNB; Galβ1-3GlcNAc), the main building block of HMOs, is a common trait among infant-derived species of *B. longum* subsp. *infantis* and *Bifidobacterium bifidum* but is not observed among bifidobacteria found in adults, i.e., *B. adolescentis* and *Bifidobacterium catenulatum*. Regarded as the archetypical HMO phylotype, *B. longum* subsp. *infantis* possesses a unique 43-kb gene cluster that encodes an array of glycosyl hydrolases, ABC transporters and oligosaccharide-binding proteins dedicated to HMO utilization (43). This gene cluster, along with several other HMO utilization loci, is conserved among all HMO-positive *B. longum* subsp. *infantis* strains but is absent in strains of the closely related organism *B. longum* subsp. *longum*, which are specialized degraders of plant glycans derived from their adult host diet. In *B. longum* subsp. *infantis*, short-chain HMOs (degree of polymerization of ≤7) are transported via a dedicated HMO ABC transporter and are subsequently disassembled by a series of cytoplasmic β-galactosidase, fucosidases, sialidase, and β-*N*acetylhexosaminidase (121). By comparison, in *B. bifidum*, another specialized HMO degrader, hydrolysis of HMOs occurs extracellularly prior to uptake and is initiated by membrane-bound fucosidases and sialidases that remove the decorated fucose and sialic acid moieties, followed by liberation of LNB by a membrane-

associated lacto-*N*biosidase and subsequent uptake of LNB intermediates by an LNB ABC transporter (122–124). This extracellular catabolic strategy is thought to circumvent transporter capacity limitation and provide a competitive advantage by enabling the organism to metabolize a wider range of HMO structures.

In general, the majority of gut commensals and probiotic microorganisms of intestinal origin are equipped with a remarkably diverse glycobiome for efficient utilization of complex carbohydrates in the hosts. Compared to lactobacilli and bifidobacteria, *Bacteroides* and *Ruminococcus* possess more elaborate cell membrane-bound enzyme complexes—the starch utilization system (Sus) and the cellulosome/amylosome, respectively—for the degradation of starch and insoluble fibers (108). The carbohydrate gene repertoires among the gut members dictate their substrate preference based on chain length, glycosidic linkages, monosaccharide constituents, and the overall structural complexity of the substrates. These genetic capacities in turn are shaped by adaptation to nutrient availability, and consequently, niche differentiation and resource partitioning within the microbiota, presumably to minimize nutrient competition while promoting metabolic syntrophy (cross-feeding) to sustain a mutualistic community and host symbiosis.

The inherently complex and dynamic nature of the human microbiota is magnified by a variety of host factors (e.g., diet, environmental influences, host genetics, and health status), which undoubtedly pose challenges to designing effective prebiotics for targeted host populations. Increasing research efforts in recent years have focused on understanding the precise molecular mechanisms of how prebiotics and dietary glycans are metabolized and consequently modulate the microbiota and impact host health. For example, *in vitro* mixed-culture models, metagenomics and metatranscriptomic studies, *in vivo* animal models, and comprehensive clinical studies are aimed at comprehending how the metabolic fate of prebiotic substrates can positively impact and shape the microbiota. The mechanistic insights into this causal

effect will provide the molecular framework for the development of next-generation prebiotics and synbiotics with tailored specificity and enhanced effectiveness.

CONCLUSIONS

The probiotic field has offered considerable promise since the early observations by Metchnikoff about the importance of limiting putrefactive metabolism in the gut. The associated prebiotic concept proposed by Gibson and Roberfroid in 1995 launched efforts to understand how to manipulate colonizing and probiotic microbes through rationally designed, selective substrates. Today, microbiological and molecular methods provide new insights into prebiotics, probiotic bacteria, the microbiota, and the interactions that may be responsible for eliciting beneficial outcomes realized through probiotic and prebiotic consumption. Advancing our understanding of the probiotic and prebiotic concepts provides a worthy challenge to scientists due to the complexity of the host, dynamic interactions within microbial ecosystems, and the multifaceted impacts of our associated microorganisms on health and well-being. Key issues and important challenges for food microbiologists working on probiotics and prebiotics in the years ahead will include the following:

- clarifying mechanisms of action of both probiotics and prebiotics
- characterizing responders and nonresponders to probiotic or prebiotic interventions
- clarifying how structure relates to function of prebiotic substances and correlating that function to health outputs
- matching expression of probiotic mechanisms with specific clinical benefits and understanding the strain specificity of clinical benefits

- deepening our understanding of the impact of probiotics and prebiotics on the composition and expression patterns of normal colonizing microbiota
- understanding how manufacturing or harvesting conditions and delivery matrices influence clinical outcomes for probiotics and prebiotics
- stabilization of probiotics for effective delivery in expanded applications
- developing next-generation probiotics (novel microbes) and prebiotics (novel structures)
- developing the use of probiotic cultures for oral delivery and expression of vaccines and biotherapeutics to the gastrointestinal tract and associated mucosal immune system
- translation of scientific discoveries into commercial development • identification of physiologically relevant biomarkers that can assess parameters of probiotics and prebiotic effectiveness
- epidemiological and long-term studies in target hosts to determine the impact of probiotic and prebiotics on long-term health and chronic disease

We acknowledge helpful discussions with Bruno Pot regarding terminology related to probiotics. His suggestions for components of Table 32.1 are gratefully appreciated. We acknowledge Alexandra Mannerings for producing Fig. 32.4. Research and scholarly works by Y.J.G. and T.R.K. on probiotics and prebiotics have been supported, in part, by the North Carolina Agricultural Foundation.

Fermented Foods

DIVERSITY OF FERMENTED FOODS AND TECHNOLOGICAL AIMS OF FOOD FERMENTATIONS

In fermented foods, microbial and enzymatic conversions determine and maintain food safety and quality. Fermentation is one of the oldest methods of food processing, and a substantial proportion of contemporary foods are processed by fermentation (Fig. 33.1). The intentional use of food fermentations likely predates agriculture. The case was made, although not undisputed, that Neolithic hunter-gatherer societies in the Fertile Crescent generated sufficient surplus to create a demand for festivities and ritual or recreational drugs, which was met by cultivation and fermentation of (yet-undomesticated) cereals (1, 2). Whether or not human desire for mind-altering drugs during ritual or social festivities represents “ground zero” for agriculture and food fermentations, many of the fermented foods are produced to meet that demand (Fig. 33.1, groups 1 to 4 and spirits).

A second motivation for food fermentations is the detoxification of raw agricultural commodities. Owing to their compact structure, cereal grains and legumes are poorly digestible without processing. Cereals and legumes also contain inhibitors of digestive enzymes—proteins as well as phenolic compounds—and lectins (3, 4). These compounds are reduced or removed by soaking, milling, fermentation, and cooking or baking, unit operations that have been used for processing of cereals since the onset of agriculture (5). Fermentation also removes toxic or bitter-tasting phytochemicals, e.g., linamarin in cassava or oleuropein in olives. Fermentation of tubers, cereals, pulses, and some other plant material thus primarily aims to improve palatability and nutritional value of raw agricultural commodities (Fig. 33.1, groups 5 to 10). The

current debate concerning the role of FODMAPs (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) and amylase/trypsin inhibitors in wheat and their role in wheat (or gluten) intolerance demonstrates that this aspect remains relevant even in societies with an abundant and diverse food supply (6).

Fermentation with lactic acid bacteria preserves perishable raw materials such as vegetables, fish, meat, and milk (Fig. 33.1, groups 12 to 18). In climates with long winters, fermentation is a straightforward way to preserve vegetables and to supply vitamins until the following spring. This was exemplified by the British explorer James Cook (1728 to 1779), who used sauerkraut to prevent scurvy during long voyages by ship, which allowed him to boldly go where no Europeans had gone before (7). Lactic fermentation of milk or vegetables achieves a storage life of several days or weeks. When combined with drying, lactic fermentation converts meat and milk to tradable commodities with a storage life that is comparable to that of dry cereal grains or canned foods.

Last but not least, fermented foods please the palate. Tea, coffee, chocolate, and condiments such as vinegar are fermented for no other purpose. The unique sensory properties of other fermented foods have ensured their popularity, although the initial aim of their production—detoxification or preservation—could be readily achieved by other unit operations in food production. For example, the use of sourdough has rebounded as the default fermentation step in bread production after a century of almost exclusive use of baker's yeast in wheat baking. This recurrence is largely attributable to the superior sensory quality of sourdough bread.

Most fermented foods are based on tradition and artisanal fermentation processes and are deeply rooted in the culture and the economy of specific regions. This strong connection to specific locations is brought about by climatic conditions that determine the availability of specific crops which require fermentation, e.g., rye, sorghum, or cassava; by economic constraints, e.g., preservation of crops that are harvested only once a year or the preservation of milk that is produced on pastures that are remote from the consumers; or by (religious) festivities that are celebrated with specific (fermented) food items. Most fermented foods are, or originate from, "indigenous" or "ethnic" foods, even though a few are available worldwide.

The discovery of yeasts and bacteria as food-fermenting organisms in 1857 by Louis Pasteur enabled the industrialization of food fermentations (8). Baker's yeast and starter cultures for dairy fermentations were commercialized less than 30 years after Pasteur's discovery; lactic starter cultures for fermentation of cereals (1910), meat (1966), and wine (1985) were commercialized in the 20th century. Industrial food production allows global production of fermented foods with a relatively standardized quality. New food product developments also employ fermentation processes that are unrelated to traditional procedures; examples include the use of *Gluconobacter* in lemonade production, the fermentation of yogurt-like oat products with probiotic lactobacilli (9), and fermentation processes for imitation cheese products from plant proteins.

SCOPE AND LIMITATIONS OF THIS CHAPTER

This chapter focuses on major categories of fermented foods and fermentation organisms (Fig. 33.1). For additional information on fermented foods and for information on the fermentation of wine, beer, vinegar, coffee, and cocoa, the reader is referred to more comprehensive textbooks that are dedicated to fermented foods and to the respective chapters of the fourth edition of this book (10–15).

Fermented foods are a major contributor to the dietary intake of viable bacteria: a meal that includes 100 g of cheese, salami, kimchi, or yogurt contains 10^{11} viable lactic acid bacteria. Food-fermenting bacteria interact with human intestinal microbiota and with the gut-associated immune system. Accordingly, the concept of probiotics, "live bacteria that, when administered in adequate amounts, confer a health benefit on the host," was developed by Metchnikoff in the early 20th century with yogurt as the conceptual template. Owing to the conceptual link between fermented foods, viable bacteria, and health, the supplementation of food initially focused on fermented dairy products, particularly yogurt. The list of bacterial species with probiotic activity and that of species that reliably occur at high cell counts in fermented foods overlap significantly. Several authors have made the case that specific fermented foods may have probiotic activity; however, others excluded fermented foods from the probiotic concept because, in

addition to the presence of viable probiotic bacteria, health effects of fermented foods are inextricably linked to other food components. This chapter does not explore the link of fermented foods and the probiotic concept further; the reader is referred to two opinion papers that make the case in favor (16) and against (17).

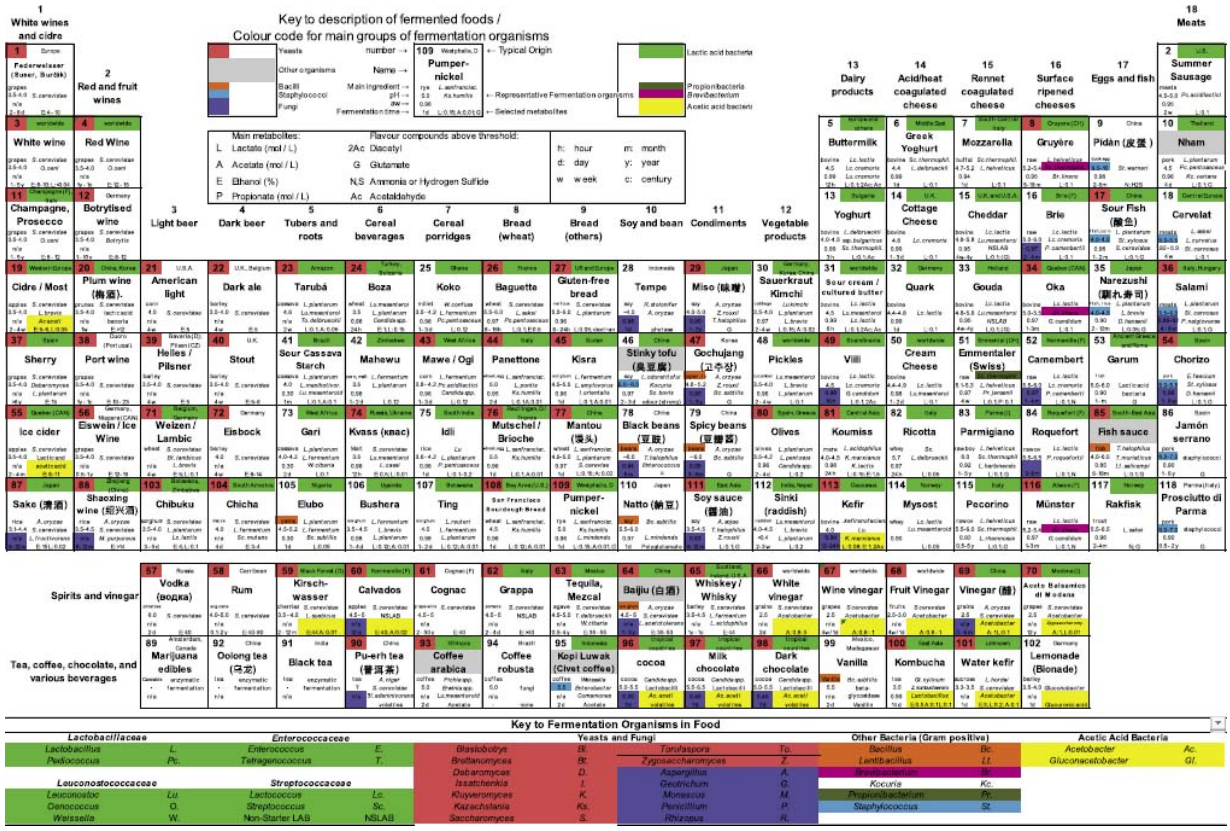

Figure 33.1. Periodic table of fermented foods, indicating the diversity of products, fermentation organisms, and raw materials. Fermented foods are grouped by product category and ranked within a group by flavor intensity or ripening time, if applicable. Fermentation organisms that contribute to fermentation are indicated by color coding of specific fields (see the key at the top of the table). Typical organisms, the concentration of relevant metabolites, and the ripening or fermentation times are also indicated. Genus abbreviations used in this chapter are introduced in the figure. Food products are generally listed in the language of origin. The figure is formatted for large-scale (A0) printing; a high-resolution image file is available as "Document" under the Activities tab of the author's homepage at https://www.ualberta.ca/agriculture-life-environment-sciences/about-us/contact-us/facultylecturer-directory/michael-gaenzle. Modified from reference 36.

COMMUNITY ASSEMBLY IN FOOD FERMENTATIONS

Traditional food fermentations are not controlled by starter cultures; the assembly of microbial communities is controlled by selection of raw materials, product formula, control of the fermentation process, and backslopping, which is the practice of inoculating with a previous batch. Generally, the assembly of animal, plant, or microbial communities is explained by four concepts: diversification/speciation, drift, dispersal, and selection (Table 33.1) (18, 19). Speciation, however, is unlikely to occur in food fermentations. Food fermentations are less than 14,000 years old, and the longest documented continuous use of fermentation microbiota, pit muds for production of baijiu by Luzhou Laojiao in Luzhou, China, is less than 500 years (20). In contrast, bacterial speciation occurs on a time scale of millions of years (21, 22); intraspecies differentiation and host adaptation of pathogens and commensals occur on time scales ranging from dozens to thousands of millennia (22, 23). Accordingly, sourdough isolates of *Lactobacillus reuteri* that have a history of more than 20 years of food use were genetically and physiologically indistinguishable from intestinal representatives of the same species (24). *Lactobacillus delbrueckii* evolved in lactose-rich environments by reduction of genome size, which particularly relates to the silencing of carbohydrate-active enzymes that are active on substrates other than lactose. This was interpreted as adaptation to dairy, but the presence of *L. delbrueckii* in the intestines of suckling but not of weanling piglets suggests that it has adapted to suckling mammals rather than dairy fermentations (25, 26). Comparative genomic analysis of food-fermenting *Aspergillus oryzae* and *Saccharomyces cerevisiae* indicates intraspecies domestication. Both species have been used for several hundred years in koji and brewing, respectively (27, 28). Domestication or speciation is thus of only limited relevance for food fermentations.

Drift, or random events, may shape community assembly in individual fermentation batches (α-diversity) (29), particularly if contamination by microorganisms that have no stable association with the ingredients or the processing environment impacts the fermentation microbiota. Food fermentations are carried outon a much smaller scale and with a much shorter generation time than communities of plants or animals; therefore, β-diversity and γ-diversity are not impacted by drift (Table 33.1). Contamination of fermentation batches with competitive

fermentation organisms is frequent—and then no longer random—or rare and with low impact on overall diversity.

Dispersal limitation is a main factor in community assembly of spontaneous fermentations, and organisms that have a stable association with the raw material, ingredients (including water), or animals or humans that reliably are in contact with the fermentation batch are likely to dominate. The small scale and short fermentation time of food fermentation all but eliminate dispersal limitation in back-slopped fermentations; even an unlikely contamination event will occur eventually if fermentation microbiota are propagated daily under septic conditions for several weeks, months, or years (Table 33.1) (30).

Selection is an important determinant for community assembly of spontaneous fermentations; microbiotas of spontaneously fermented milk, vegetables, and cereals differ substantially from the microbiotas of the raw materials from which the fermentation organisms originated. It is the major determinant of the composition of back-slopped fermentation, because competitive microbes will contaminate the fermentation and outcompete other organisms eventually, even if they have only an indirect association with the raw material, humans, or the processing environment (30) (Table 33.1).

Why are fundamental considerations related to community assembly important? In the section above, the case was made that fermented foods are produced in a virtually unlimited regional variety. The shared patterns of community assembly, however, lead to very similar fermentation microbiotas in comparable products and processes globally. Spontaneous fermentations are dominated by organisms that have a stable association with the raw material or with ingredients. Spontaneous fermentation of raw milk or meat at ambient temperature very likely results in growth of *Lactococcus lactis* and *Lactobacillus sakei*, respectively, as major members of fermentation microbiota. Likewise, spontaneous plant fermentations are initially fermented by plant-associated members of the *Enterobacteriaceae*, including *Enterobacter*, *Cronobacter*, *Klebsiella*, and *Pantoea*¸ followed by *Leuconostoc*, *Weissella*, and *Enterococcus*, until eventually the acid-tolerant organisms *Lactobacillus plantarum* and *Lactobacillus brevis* or *Lactobacillus fermentum* (in cereals) dominate (30, 31). This succession of fermentation microbiotas—referred to here as “the usual suspects”—

reliably occurs in sauerkraut, kimchi, and carrot juice fermentations worldwide but also in spontaneously fermented cereals.

Back-slopped fermentations exert a more stringent selective pressure than spontaneous processes and often select for microbiota that converge at the species level. For example, bakers around the world exert a uniform selective pressure on fermentation microbiota if they use sourdough as the sole leavening agent; the need for dough leavening necessitates rapidly growing and metabolically active organisms. Although the steamed or baked products look, taste, and smell very different, fermentation microbiota are consistently dominated by *Lactobacillus sanfranciscensis* and *Kazachstania humilis* (*Ks. humilis*) or *S. cerevisiae* (Fig. 33.1). Likewise, red smear microbiotas on surface-ripened cheeses are highly comparable worldwide; competitive microorganisms contaminate from human skin wherever red smear cheese is made and are maintained by back-slopping in the dairy. In short, “terroir,” referring to local differences, is relevant with respect to the choice and quality of the raw material, the product formula, and the production processes but not with respect to the composition of fermentation microbiota.

Table 33.1. Concepts in community assembly in food fermentations[a]

Concept	Description	Relevance for food fermentations
Diversification/Speciation	Generation of genetic variation	Speciation of bacteria occurs on a time scale of 1–20 million years and is not relevant for microbiota of fermented foods (21–23). Intraspecies adaptation to food fermentations was proposed for *S. cerevisiae* and *A. oryzae* (23, 24, 28).
Drift	Random events that impact fermentation microbiotas	Drift may shape the α-diversity (diversity in a single sampling unit, e.g., a fermentation batch) but not β-diversity (diversity at a regional level or in a subtype of a food fermentation) or γ-diversity (global microbial diversity in a specific food fermentation).
Dispersal	Movement of fermentation organism across space	Contamination or inoculation of food fermentations from raw materials, the environment, or animals, pests, and humans (30)
Selection	Selection of fermentation organisms with the highest ecological fitness	Together with dispersal, selection shapes community assembly of spontaneous food fermentations. In back-slopped fermentations, selection is the main factor for community assembly (30).

MAJOR GROUPS OF FERMENTATION ORGANISMS AND METABOLIC PATHWAYS

A catalogue of microorganisms in fermented foods was compiled on the initiative of the International Dairy Federation. The most recent version lists 195 bacterial species representing 18 families and 3 phyla; fungi are represented by 69 species representing 3 phyla (32). The most relevant organisms are lactic acid bacteria, yeasts, acetic acid bacteria, and fungi. The presence of these groups of organisms is highlighted by color coding in Fig. 33.1, and their most relevant properties are briefly presented in this section.

Lactic Acid Bacteria

Lactic acid bacteria are facultative anaerobic Gram-positive bacteria that produce lactic acid as a major product of carbohydrate metabolism (33). Most organisms that are referred to as lactic acid bacteria are classified in the order *Lactobacillales*. Lactic acid bacteria comprise human and animal pathogens, commensal members of human and animal microbiotas, and environmental organisms. Organisms with a safe tradition in food use include only a small fraction of lactic acid bacteria, i.e., *Lactobacillaceae*, *Leuconostocaceae*, *Lc. lactis*, *Streptococcus thermophilus*, and *Tetragenococcus halophilus*. Enterococci are part of fermentation microbiotas in cereals, dairy products, and fermented meats. These organisms do not cause foodborne disease; however, they can cause life-threatening hospital-acquired (nosocomial) infections and contribute to the transmission of antibiotic resistance genes from farm animal microbiota to human pathogens (34). Their safety and their deliberate use in food fermentations are thus subjects of an ongoing debate.

The ecological fitness of lactic acid bacteria in food fermentations relates to their rapid but inefficient metabolism of fermentable carbohydrates (35). An overview of lactic metabolism is provided in Fig. 33.2 (36). Consumption of sugars and oxygen and acidification by accumulation of lactate, acetate, and formate inhibit and eventually kill competing bacteria. Homofermentative lactic acid bacteria metabolize glucose via the Embden-Meyerhof pathway with pyruvate as the central metabolic

intermediate (Fig. 33.2) (36). Heterofermentative lactic acid bacteria convert glucose via the phosphoketolase pathway with pyruvate and acetyl coenzyme A (acetyl-CoA) as central intermediates (Fig. 33.2) (36). Fermentation pathways of lactic acid bacteria relate to their phylogeny: *Leuconostocaceae* and 7 of the 24 phylogenetic groups in the genus *Lactobacillus* are heterofermentative (37), while all other lactic acid bacteria are homofermentative. The metabolic, ecological, and phylogenetic diversity in the genus *Lactobacillus* is equivalent to the diversity that is typically observed in a bacterial family; current efforts toward clarification of the taxonomy of the genus will likely elevate many or most of its phylogenetic groups to the taxonomic rank of genus (37, 38). Many lactic acid bacteria are conditionally respiring; respiratory metabolism is of only limited relevance in food fermentations but is exploited industrially for high-density fermentation of bacterial biomass (36). Organic acids are metabolized to achieve regeneration of reduced cofactors or to contribute to pH homeostasis through intracellular decarboxylation reactions (Fig. 33.3) (36, 39). Organic acid metabolism profoundly impacts the quality of wine and fermented dairy products (36).

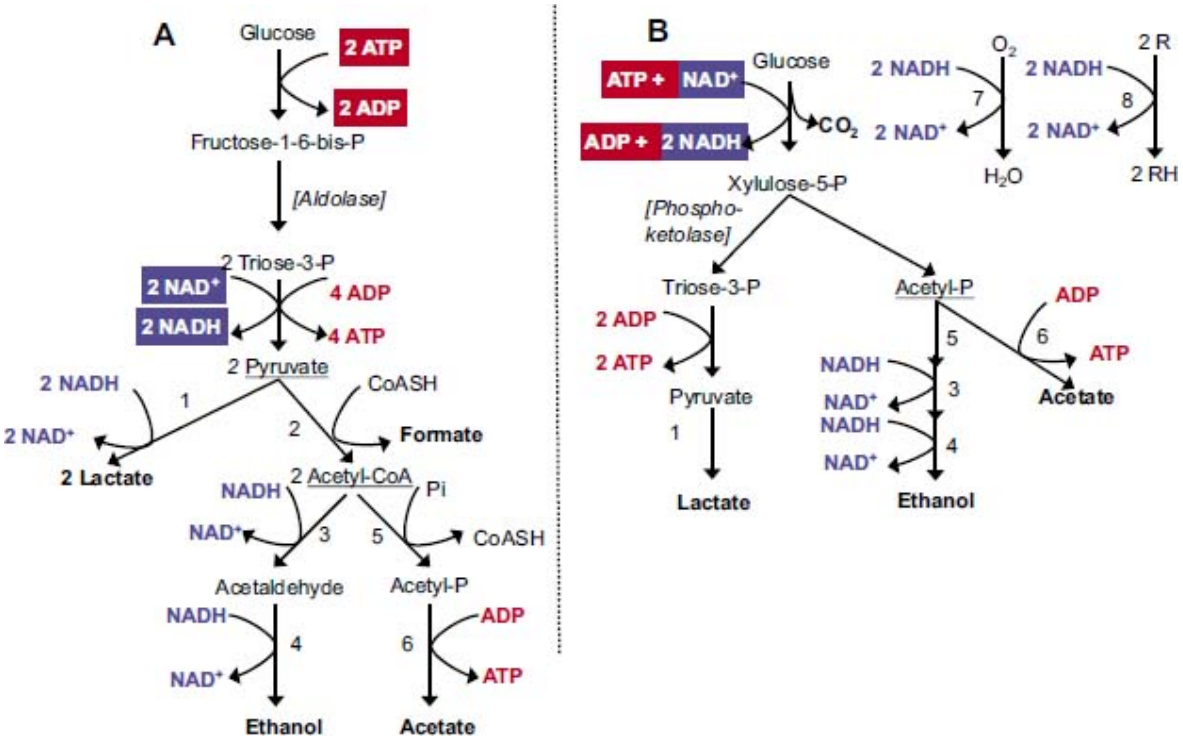

Figure 33.2. Overview of carbohydrate fermentation in lactic acid bacteria. Major end products of metabolism are in boldface type; branching points of metabolism, or metabolic switches, are underlined. The formation of reduced and oxidized cofactors (in white on a blue background and in blue, respectively) is indicated if it occurs upstream or downstream of relevant metabolic branching points; ATP consumption (in white on a red background) and synthesis (in red) are shown to indicate the ATP yield of the metabolic pathway. (A) Homofermentative metabolism of hexoses via the Embden-Meyerhof pathway and alternative fates of pyruvate. The alternative fate of pyruvate depends on the substrate availability, the availability of oxygen, and the pH. (B) Heterofermentative metabolism of hexoses via the phosphoketolase pathway and alternative routes of acetylphosphate. Conversion of acetylphosphate to acetic acid is dependent on alternative routes for regeneration of reduced cofactors (upper right, steps 7 and 8). Enzymes are indicated by numbers as follows: 1, lactate dehydrogenase; 2, pyruvate formate lyase; 3, acetaldehyde dehydrogenase; 4, alcohol dehydrogenase; 5, phosphotransacetylase; 6, acetate kinase; 7, NADH oxidase or NADH peroxidase; 8, mannitol dehydrogenase, glutathione reductase, or alcohol reductase. Modified from reference 36.

Yeasts

Yeasts are unicellular, facultative anaerobic fungi. For yeasts that reproduce sexually, the name referring to the teleomorph state (sexual reproduction) is used, but for many yeasts, only the anamorphic state (asexual reproduction) is known, or the name referring to the anamorphic state remains in use (32). Most food-fermenting yeasts, e.g., *Candida*, *Debaryomyces*, *Kazachstania*, *Pichia*, and *Saccharomyces*, are in the family *Saccharomycetaceae*. Yeasts, in particular *S. cerevisiae*, are responsible for ethanol and CO_2 formation in food fermentations. Glucose is metabolized to pyruvate as central metabolic intermediate by the Embden-Meyerhof pathway. Pyruvate is shunted to the Krebs cycle for respiratory metabolism if oxygen is available or converted to ethanol and CO_2 via pyruvate decarboxylase in fermentative metabolism.

Figure 33.3. Metabolism of organic acids in lactic acid bacteria: alternative fates of citrate and malate in lactic acid bacteria to support pH homeostasis or cofactor regeneration. Major end products of metabolism are in boldface type. The formation of oxidized cofactors is indicated by blue type; ATP synthesis is in red; proton-consuming decarboxylation reactions are on a gray background. Dashed arrows indicate chemical conversions. Tartrate is converted by tartrate dehydratase; citrate is converted to succinate to achieve regeneration of two reduced cofactors or to acetoin to achieve proton consumption and proton motive force generation by two decarboxylation reactions. Tartrate metabolism has been observed only in *L. plantarum*. Citrate conversion to lactate or acetate and ethanol combines oxidation of 1 mol of NADH and one decarboxylation reaction. Lactobacilli convert citrate to succinate or lactate; *T. halophilus* converts citrate preferentially via pyruvate formate lyase acetate and ethanol; *Lc. lactis*, *Leuconostoc* spp., and *Oenococcus oeni* convert citrate to the alternative end product acetoin or lactate. Enzymes are indicated by numbers as follows: 1, tartrate dehydratase; 2, citrate lyase; 3, malate dehydrogenase; 4, fumarate hydratase, 5, succinate dehydrogenase; 6, oxaloacetate decarboxylase; 7, malolactic enzyme; 8, lactate dehydrogenase; 9, acetolactate synthase; 10, acetolactate dehydrogenase; 11, pyruvate formate lyase; 12, acetaldehyde dehydrogenase; 13, alcohol dehydrogenase; 14, phosphotransacetylase; 15, acetate kinase. Modified from reference 36 with information from reference 39.

The competitiveness of *S. cerevisiae* in alcoholic fermentations relates to the specific regulation of fermentative versus respiratory metabolism. In *S. cerevisiae*, respiration is inhibited in the presence of less than 1 g of glucose per liter, even if oxygen is available (Crabtree effect); moreover, sugar is used faster anaerobically than aerobically (Pasteur effect) (40). The regulation of carbohydrate metabolism results in rapid but ineffective conversion of glucose and the accumulation of ethanol as a toxic by-product which inhibits other yeasts and bacteria. After hundreds of years of back-slopping, brewer's yeasts show signs of domestication and exhibit reduced sexual reproduction but more rapid use of maltotriose compared to wild yeasts or wine yeasts that are not back-slopped or are back-slopped on longer (annual) fermentation cycles (28).

A second important metabolic activity of yeasts is the production of diverse flavor volatiles (41). Major pathways for flavor production include the transamination of amino acids (Ehrlich pathway), conversion of phenolic compounds and fatty acids, and synthesis of floral esters (Fig. 33.4). Ester synthesis by yeasts is strain specific and serves the ecological role of attracting insects to overcome dispersal limitation (41). The formation of flavor volatiles by yeasts is a major determinant of the quality of alcoholic beverages but also of soy sauce, bread, and surface-ripened cheeses and meats.

Acetic Acid Bacteria

Acetic acid bacteria are strictly aerobic, Gram-negative members of the *Alphaproteobacteria*. *Acetobacter* and *Gluconacetobacter* are used in vinegar fermentation, in the fermentation of coffee and cocoa, and in kefir or water kefir grains (Fig. 33.1), but they also spoil alcoholic beverages. Metabolism of acetic acid bacteria is characterized by rapid but incomplete oxidation of alcohols to the corresponding aldehydes or organic acids; the resulting low pH and high organic acid concentration create an inhospitable environment for most other microorganisms, including yeasts and fungi (42, 43). The conversion of ethanol to acetic acid is most relevant in food applications, but mannitol and other sugar alcohols or glucose are also oxidized. Acetic acid bacteria also produce exopolysaccharides, including acetan and cellulose (44). These exopolysaccharides form the matrix for the bacterial biofilm on the surfaces of vats used in traditional production of vinegar (“mother of vinegar”) or kombucha and contribute to formation of the exopolysaccharide matrix in kefir grains.

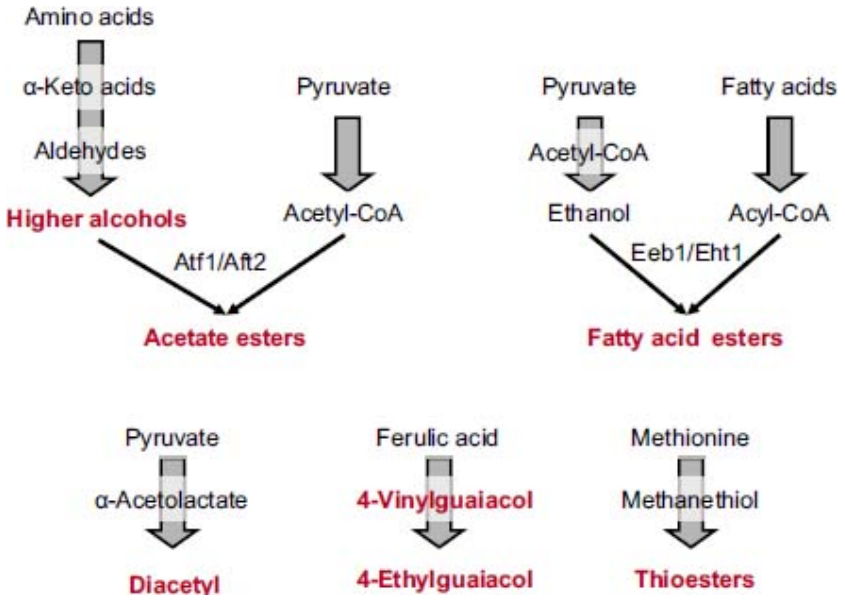

Figure 33.4. Overview of pathways for formation of flavor volatiles by yeasts. Flavor volatiles are shown in red. Drawn using data from reference 41.

Mycelial Fungi

Mycelial fungi are decomposers of organic material that play a critical role in global nutrient cycles. Their extensive array of hydrolytic enzymes is a main motivation for their use in food fermentations. In cereal and soy fermentations in East Asia, fungi are employed as the primary saccharification and proteolytic cultures to degrade starch and proteins prior to fermentation with yeasts, lactic acid bacteria, and/or acetic acid bacteria (27, 45). Fermentations in the European tradition employ fungi as secondary ripening cultures on fermented meats and cheeses to accelerate proteolysis, lipolysis, and flavor formation. Spontaneous fermentations of meats or cereals are brought about mainly by members of the *Ascomycota* in the genera *Aspergillus* and *Penicillium* (32). The Japanese koji mold, *A. oryzae*, has been domesticated by hundreds of years of cultivation on starch substrates. Although it shares a high degree of genetic similarity to its ancestor, *Aspergillus niger*, *A. oryzae* is characterized by a higher expression of amylases and differential expression of asparaginase and glutaminase (27).

Mycelial fungi also are capable of production of secondary metabolites, particularly mycotoxins. Domestication of *A. oryzae* led to silencing of gene clusters that are responsible for mycotoxin production in the ancestral *A. niger* (27). *Penicillium roqueforti* and *Penicillium camemberti* produce the mycotoxins roquefortin C and cyclopiazonic acid, respectively, although their concentrations in cheese are too low to present a food safety risk (32). The formation of red and orange pigments by *Monascus purpureus* is a main reason for its use in production of angkak, or red yeast rice, a red rice produced in Southeast Asia, and in production of red or yellow rice wine (Fig. 33.5) (46). *M. purpureus* also produces monacolin K, or lovastatin, a potent competitive inhibitor of cholesterol synthesis in humans, and citrinin, a nephrotoxic and hepatotoxic mycotoxin. Citrinin, monacolin K, and pigments are synthesized by different polyketide synthases, but their production is regulated by the same signal protein, Mga1; pigment production by wild-type strains is thus generally associated with citrinin production. The level of citrinin in *Monascus* products is regulated in Japan and South Korea; owing to citrinin contamination, *Monascus* products are not used as food colorants in the European Union or the United States (47).

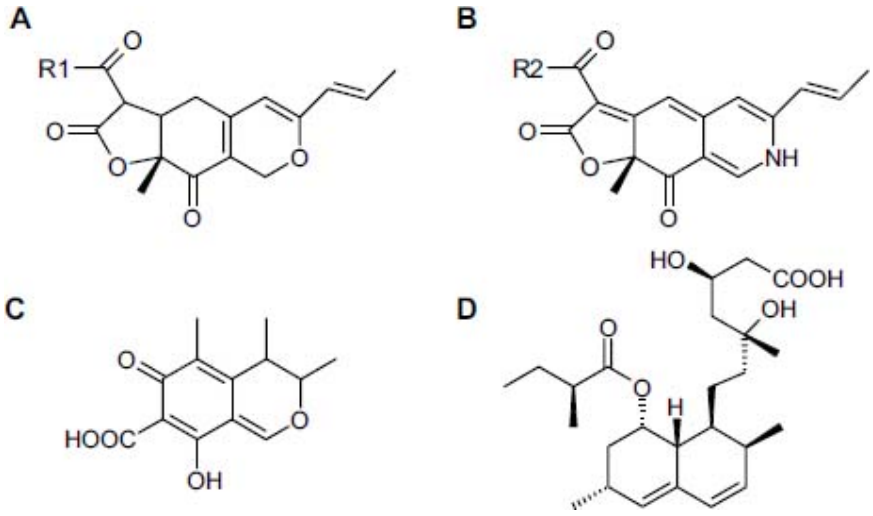

Figure 33.5. Examples of bioactive secondary metabolites of *M. purpureus*. (A) The yellow pigments monascin (R_1 = C_5H_{11}) and ankaflavin (R_1 = C_7H_{15}); B, the red pigments rubropunctamine (R_2 = C_5H_{11}) and monascorubramine (R_2 = C_7H_{15}); C, the mycotoxin citrinin; D, monacolin K (lovastatin), a potent inhibitor of cholesterol synthesis in humans. Drawn with data from references 46 and 47.

In addition to the four major groups of fermentation organisms, members of several other bacterial taxa, including staphylococci, bacilli, and propionibacteria, are relevant in specific food fermentations (Fig. 33.1); their properties and contribution are discussed in the sections related to specific food fermentations.

CEREAL WINES, SPIRITS, AND VINEGAR PRODUCED IN EAST ASIA

Production Processes and Products

In East Asia, alcoholic beverages—" wines" and spirits—as well as vinegar are produced from unmalted cereals. These products belong to very different product categories (Fig. 33.1) but are produced via comparable processes (Fig. 33.6) and fermentation microbiotas (Table 33.2) and are thus presented in the same section. Amylolytic fungal and bacterial cultures are used to produce enzymes for starch saccharification; the alcoholic fermentation is carried out with yeast and lactic acid bacteria in mash (sake and shochu) or in solid-state

fermentations (baijiu and rice vinegar). In Japan, *A. oryzae* has been maintained in solid-state fermentations on cooked rice as a relatively pure saccharification culture for 500 to 700 years, a time span that was sufficient for domestication (27, 48). The term "koji" refers both to the mold and the molded rice cake that is used for hydrolysis of starch and proteins in cereal, soy, and fish fermentations. The Chinese term for all saccharification cultures is "jiuqu." Daqu is most widely used and obtained by spontaneous fermentation (Fig. 33.6); xiaoqu and fuqu are back-slopped (49–51).

In a Japanese fermentation, the succession of fermentation microbiota that is required to convert cooked cereals to vinegar is achieved in a single fermentation vessel that is inoculated with koji (52). Initial growth of *A. oryzae* is followed by alcoholic fermentation with *S. cerevisiae* and lactic fermentation by *Pediococcus acidilactici* (*Pc. acidilactici*), *Lc. lactis*, *L. plantarum*, and *L. fermentum*, and by growth of *Lactobacillus acetotolerans* and *Acetobacter pasteurianus* in the final stages of fermentation (Table 33.2). The fermentation process is completed in 5 months and followed by aging for 1 year. Sake is also brewed with koji as a saccharification culture; *S. cerevisiae* and lactic acid bacteria are maintained as separate starter cultures. Addition of *M. purpureus* to koji allows production of yellow or red rice wines such as Shaoxing wine, which is produced in Zhejiang Province in China (53). *M. purpureus* is a slowly growing organism and is thus grown in association with *A. oryzae* to prevent contamination (53).

Daqu, the saccharification starter for wine, baijiu, and vinegar production, is produced by spontaneous fermentation of ground cereals. Barley, wheat, rice, or sorghum flour is mixed with water to a moisture content of 40%, shaped into bricks, and stacked in fermentation rooms (50, 51). Fermentation microbiotas are controlled by control of the temperature, which increases to 45 to 50°C (low-temperature daqu), 50 to 60°C (mediumtemperature daqu), or 60 to 65°C (high-temperature daqu). During fermentation and subsequent drying, the moisture content is reduced to 14% or less, and daqu is stored dry for up to several months (50).

Figure 33.6. Flow chart for production of cereal wines and spirits. (A) Flow chart for production of Japanese rice wine (sake). Rice is polished, washed, and steamed. A part of the raw material is inoculated with koji, the saccharification starter composed of *A. oryzae*; a second part is used with koji for production of the starter containing yeasts and lactic acid bacteria (LAB). Both are combined for the mash fermentation. After completion of the fermentation, the mash is filtered, pasteurized, and aged. (B) Flow chart for production of daqu, the saccharification starter used in Chinese rice wines, spirits, and vinegar fermentations. Cereals are ground, mixed with water to a water content of 40%, and shaped into blocks about 6 by 20 by 30 cm. The blocks are stacked in a fermentation room, and the spontaneous fermentation is controlled by control of the temperature to produce low-temperature daqu (45 to 50°C), medium-temperature daqu (50 to 60°C), or high-temperature daqu (60 to 65°C). After fermentation, daqu is dried, ground, and stored dry. (C) Alcoholic fermentation for production of baijiu. Ground cereals are soaked, cooked, cooled, and fermented after the addition of daqu. Fermentation occurs at ambient temperature in earthen jars or in mud pits that are inoculated with part of the material from the previous batch. For some products, such as sauce-flavored baijiu, a 4- to 5-day aerobic fermentation is conducted prior to anaerobic fermentation in pits. After fermentation, the mash is distilled and the distiller's grains undergo a second fermentation which is again inoculated with daqu and part of a previous batch. The cycle of distillation and fermentation is repeated two to seven times. Drawn with information from references 49–52 and 54.

Alcohol and, where applicable, acetic acid fermentation is performed in earthen jars, or in pit muds with a volume of 5 to 10 m^3. Fermentation microbiota are usually back-slopped or maintained by continuous use of the same pit muds (20). Some products, such as "sauceflavored baijiu," include an aerobic, high-temperature stacking fermentation prior to the anaerobic mash fermentation (49). Chinese liquors are fermented in two to seven cycles of (stacking and) mash fermentation and distillation; after each distillation step, the distiller's grains are mixed with daqu (Fig. 33.6). Traditional vinegar fermentations employ surface aeration with occasional mixing to induce the acetic acid fermentation (12).

Fermentation Microbiotas and Their Impact on Product Quality

An overview of the fermentation microbiotas in Japanese and Chinese wine and spirit fermentations is provided in Table 33.2. In Japan, sake, spirit, and vinegar fermentations are typically controlled by back-slopped (starter) cultures; *A. oryzae* is the main saccharification starter, while *S. cerevisiae* together with lactobacilli dominates the mash fermentation and *A. pasteurianus*, *Gluconacetobacter xylinus*, and *Gluconacetobacter europaeus* carry out the acetic acid fermentation. In sake starters, *Lactobacillus fructivorans* and *Lactobacillus homohiochii* are the dominant lactic acid bacteria (54). Of note, the type strain of the homofermentative *L. homohiochii* has been lost; the current type strain clusters with the heterofermentative *L. fructivorans* group (54).

Table 33.2. Microbiota in Asian wine, liquor, and vinegar fermentations[a]

Product (origin)		Succession of fermentation microbiotas	
Sake (Japan)	*Aspergillus oryzae*	*S. cerevisiae*, *L. fructivorans*, *L. acetotolerans*[b]	
Rice vinegar (Japan)	*Aspergillus oryzae*	*S. cerevisiae*, *Lc. lactis*, *L. casei*, *L. plantarum*, *L. fermentum*	*L. acetotolerans*, *A. pasteurianus*
Rice vinegar (China)	Daqu: *Aspergillus* spp., *Rhizopus* spp., *Bacillus* spp., *Weissella*, *Leuconostoc*, *Enterobacteriaceae* including *Cronobacter* and *Enterobacter*, *Saccharomyces*, *Saccharomycopsis*	Mash: *S. cerevisiae*, lactobacilli	*Acetobacter* spp., *Gluconacetobacter* spp.

wine (Japan and China)			

[a] With data from references 20, 50, 53, and 55–57.

[b] The original isolates were classified as homofermentative *L. homohiochii*. The type strain of this species has been lost but likely represented an organism closely related to *L. acetotolerans* (54).

Baijiu and Chinese rice vinegar are fermented by a succession of two to five different microbial communities representing the aerobic saccharification starter, the anaerobic mash fermentation, and, where applicable, the microbiotas of an aerobic stacking fermentation, the mud of the pit walls, and acetic acid fermentation. This succession likely represents the most diverse fermentation microbiota of any fermented food. Because of this exceptional diversity and because most studies characterized the fermentation microbiota only by sequence-based techniques, current knowledge on the microbial diversity and the key contributors to product quality is still preliminary.

The composition of the Chinese saccharification starter daqu is controlled by the temperature and moisture content (50). Daqu microbiotas are very diverse; bacilli, members of the *Enterobacteriaceae* including *Enterobacter* and *Cronobacter*, and lactic acid bacteria are part of the bacterial microbiota, while the mycobiota is represented by *Aspergillus* spp., *Monascus* spp., *Mucor* spp., and a wide variety of yeasts (50, 55–57). Bacilli and *Enterobacteriaceae* from daqu carry mobile genetic elements that confer heat resistance, suggesting that temperature control is a key factor in community assembly (49, 50, 58). Bacilli as well as fungi produce amylolytic and cellulolytic enzymes that are required for starch saccharification during later stages of the fermentation (59).

Microbiotas of mash fermentations are back-slopped and thus more uniform; *S. cerevisiae* and host-adapted lactobacilli, including *L. acetotolerans*, *Lactobacillus helveticus*, and *Lactobacillus panis*, are dominant organisms. Aerobic stacking fermentation that is included prior to the mash fermentation in sauce-flavored baijiu includes metabolic activity of bacilli, plant-associated lactic acid bacteria, and *Pseudomonas* spp. (Table 33.3). Fermentation in pit muds brings the

mash into contact with strictly anaerobic microbiotas in the mud walls that include *Clostridia*, *Bacteroidetes*, and other strict anaerobes (57, 60).

Fermentation of vinegar is performed in earthen jars to achieve surface aeration with occasional mixing of the mash. Comparable to other vinegar fermentations, *Acetobacter* spp. and *Gluconacetobacter* spp. are the main organisms converting ethanol to acetic acid.

Although the contribution of individual members of daqu microbiotas, particularly bacilli, to the production of amylases and proteases has been demonstrated, the metabolic activities of individual members of the diverse fermentation microbiota involved in production of spirits and vinegar remain unknown. The different process variables—low-, medium-, or high-temperature daqu fermentation, fermentation in mud pits or earthen jars, the number of fermentation and distillation cycles, and the inclusion of an aerobic stacking fermentation—result in a large diversity of products with different flavor characteristics (49). The very diverse fermentation microbiota results in a very intense flavor that is mediated by a diverse set of flavor compounds. In addition to fruity, floral, or malty higher alcohols, aldehydes, and esters that likely result from yeast metabolism and are also found in other yeast-fermented products (Fig. 33.4), baijiu flavor is complemented by sweaty, cheesy, and rotten cabbage odors that are present with high odor activity values (61).

Table 33.3. Representatives of microbiota of cereal porridges and beverages[a]

Organisms	Example(s)
Spontaneous fermentation (the usual suspects)	Ogi, mawe, mahewu, koko, bushera, idli
Early fermentation: *Enterobacteriaceae* including *Enterobacter* spp., *Cronobacter* spp., *Pantoea* spp., and *Klebsiella* spp.	
Intermediate fermentation: *Leuconostoc* spp., *Weissella* spp., *Lc. lactis*, *Enterococcus* spp., *Pc. pentosaceus*, and *Pc. acidilactici*	
Late fermentation: *L. plantarum*, *L. fermentum*, and *L. brevis;* yeasts including *S. cerevisiae*, *I. orientalis*, and *C. glabrata*	
Back-slopped fermentations	
L. paracasei, *Lu. mesenteroides*, and *S. cerevisiae*	Kvass
L. reuteri, *L. vaginalis*, *L. fermentum*, *L. plantarum*, and *L. harbinensis*	Ting, kisra
L. plantarum, *L. paracasei*, *L. brevis*, *Lu. mesenteroides*, *W. confusa*, and *S. cerevisiae*	Boza

TUBERS AND ROOTS

Products and Production Processes

Tubers and roots, including cassava, yams, and sweet potato, are major crops in Africa and, to a lesser extent, in South America and South and East Asia (62). Sliced cassava are fermented in spontaneous solid-state fermentations, e.g., for production of gari and fufu in West Africa, or the whole roots are spontaneously fermented after submersion in water, e.g., for production of lafun in Nigeria. The products are consumed as a paste or after drying and reconstitution to porridges (62). Some cassava

products and elubo (fermented yam roots) are spontaneously fermented after boiling of the tubers (62, 63).

Fermentation Microbiotas and Their Contribution to Product Quality

Cassava and yam fermentations are dominated by the usual suspects, i.e., a succession of fermentation microbiotas initiated by *Enterobacteriaceae* and by acid-sensitive lactic acid bacteria, including *Leuconostoc* spp., *Weissella* spp., and *Enterococcus* spp., followed by *Lactobacillus* spp., particularly *L. plantarum* and *L. brevis* (62–64). In addition to the usual suspects, *Lactobacillus manihotivorans* and *Bacillus* spp. were identified in some of the fermentations. Tubers and roots have a low content of fermentable carbohydrates and low amylase activity; many *Bacillus* spp. and cassava isolates of *L. manihotivorans* and *L. plantarum* express extracellular amylase activity. Extracellular amylases are exceptional in lactobacilli but frequently found in isolates from tubers or cereal fermentations in tropical climates (35, 65). Extracellular amylases of lactobacilli are homologous to intracellular α-glucosidases in other lactobacilli but differ by the presence of a signal peptide directing protein export (35). Although several species of lactobacilli were named after amylolytic strains, the expression of extracellular amylases is strain specific rather than species specific.

A second key metabolic activity of lactic acid bacteria in cassava fermentations is β-glucosidase activity, which hydrolyzes the toxic cyanogenic glycoside linamarin to acetone and hydrogen cyanide (Fig. 33.7) (66), which can be washed away or evaporates prior to consumption. Cassava also exhibits linamarase activity, but fermentation and permeabilization of the plant cell wall are required to give the enzyme access to the substrate.

CEREAL FOODS

Nonalcoholic Beverages and Porridges

Production Processes and Products

Fermented porridges and nonalcoholic beverages are widely produced in Africa from corn, millet, or sorghum. A majority of the products are produced by spontaneous fermentation at the household level with a corresponding diversity of production processes; an overview is provided by Nout (67), Sekwati-Monang (68), and Franz et al. (69). Cereal beverages in Europe include kvass (Russia) and boza (Turkey and Balkan countries); lactic acid-fermented oat porridges are produced in Scotland (sowans) and Finland (9). Comparable to cultured dairy products, nonalcoholic cereal beverages often contain viable fermentation organisms and are a suitable carrier for probiotic bacteria (9, 69).

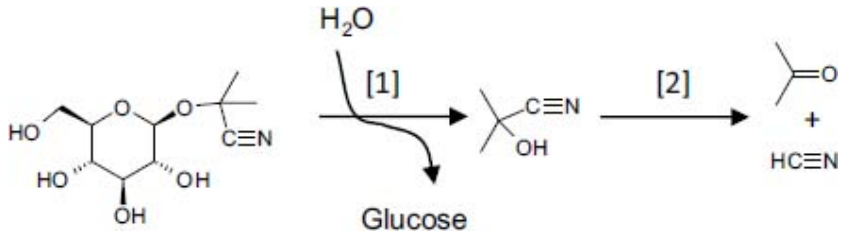

Figure 33.7. Degradation of linamarin in cassava fermentations. Linamarin is a toxic cyanogenic β-glucoside that is degraded by linamarase activity of the raw material or by β-glucosidases of lactobacilli (1). The degradation product decomposes spontaneously (2) to the volatile compounds hydrogen cyanide and acetone.

Fermented cereal beverages have a solid content of about 10%; malt from millet, sorghum, or barley is added as saccharification agent and as source of fermentation microbes. The balance of sweet taste derived from starch hydrolysis, sour taste derived from lactic fermentation, and carbonation from yeast metabolism typically provides a refreshing beverage. If fermentation microbiotas are not inactivated, cereal beverages spoil by alcoholic fermentation. Boza is produced in Turkey and Bulgaria by boiling a thin slurry of wheat or millet flour; after boiling, the slurry is filtered, cooled, and fermented by addition of 20% sucrose and a portion of a previous batch (70). Kvass is produced from stale rye bread in Russia and other Eastern European countries (Fig. 33.8) (71). Commercial kvass production employs rye malt and boiled rye flour as alternative ingredients (71). The color and the balance of sweet and sour taste of kvass resemble those of cola products, and it has therefore also been referred to as “Russian cola.” Bushera is produced in

Uganda by boiling a thin slurry of flour from sorghum malt, followed by cooling, addition of sorghum malt, and spontaneous fermentation (Fig. 33.8) (72). Mahewu (Zimbabwe) and obiolor and kunun-zaki (Nigeria), kwete (Uganda), and togwa (Tanzania) are produced by comparable procedures with millet or sorghum malt (Fig. 33.8) (68).

Cereal porridges are produced by fermentation of thick slurries of cereal flour or by soaking of grains, followed by wet milling (Fig. 33.9). Soaking prior to milling of grains greatly reduces the energy input required for milling (9). Porridges are generally cooked or steamed prior to consumption and thus do not contain viable fermentation microbiota (68) (Fig. 33.9). Ting is produced in Botswana and South Africa from sorghum flour; the fermented slurry is boiled, diluted to a soft or stiff consistency, and eaten after addition of sucrose, milk, or condiments (73). Idli is produced in India and Sri Lanka by separate soaking of black beans and rice, followed by wet milling, mixing, and fermentation (74). Koko is produced in Nigeria by steeping, wet milling, and spontaneous fermentation of millet. After fermentation, the bottom layer is boiled to a porridge; the top layer, koko sour water, is added to adjust the consistency of the porridge or consumed as a beverage (Fig. 33.9). Ogi (Nigeria and West Africa), mawe (Benin), ben saalga (Burkina Faso), and kirario (Kenya) are produced from maize or pearl millet by similar procedures involving soaking, wet milling, spontaneous fermentation, and cooking prior to consumption (68, 69).

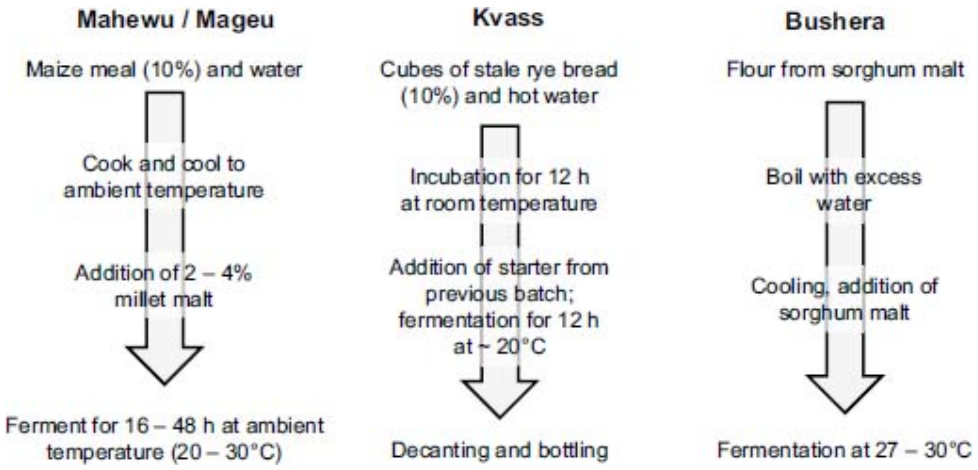

Figure 33.8. Flow charts for production of selected cereal beverages. Shown are processes for production of mahewu (Zimbabwe and South Africa), kvass (Russia), and bushera (Uganda). Kvass is alternatively produced with rye malt and boiled rye flour. Drawn with information from references 68, 71, and 72.

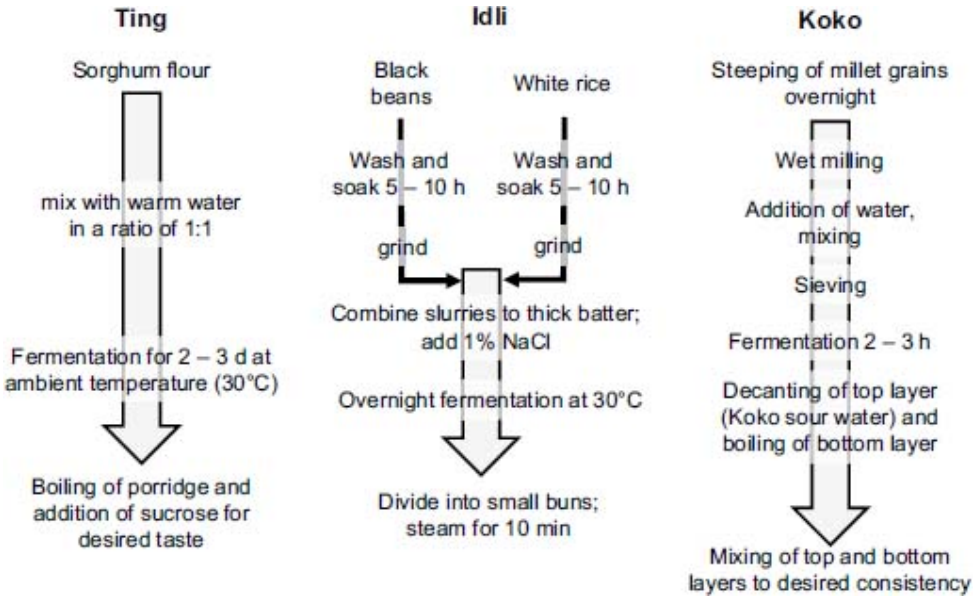

Figure 33.9. Flow charts for production of selected cereal porridges. Shown are processes for production of ting (Botswana and South Africa), idli (India and Sri Lanka), and koko (Ghana). Drawn with information from references 68, 73, and 74.

Fermentation Microbiotas and Their Impact on Product Quality

The microbiota of cereal fermentations used for production of beverages and porridges consists predominantly of lactic acid bacteria and yeasts; community assembly follows the same pattern as assembly of the sourdough microbiota, which has been studied in more depth (see below). The use of alternative cereal substrates—sorghum, millet, or maize—in many of the fermentations selects for strain-specific metabolic properties rather than specific species of lactic acid bacteria or yeasts. Spontaneous cereal fermentations are dispersal limited and reliably undergo fermentation by the usual suspects, i.e., a suc plant-associated *Enterobacteriaceae*, followed by plantassociated lactic acid bacteria, including *Leuconostoc*, *Weissella*, *Lactococcus*, and *Enterococcus*, which are displaced eventually by more acid-tolerant lactobacilli (Table 33.3) (25, 74–76). Because fermentations are carried out with different inocula and for different lengths of time, all representatives of this continuum of fermentation microbiota, including *Enterobacteriaceae*, have been isolated from cereal products (68, 69, 77). Malt that is used in production of fermented cereal beverages has a higher bacterial cell count than flour or grains and thus accelerates fermentation (78). Fully fermented products obtained by spontaneous fermentation are generally dominated by *L. plantarum* and *L. fermentum*. Back-slopping is practiced for production of kvass, boza, ting, and kisra, among others; in these fermentations, host-adapted lactobacilli, including *L. reuteri* and *Lactobacillus vaginalis*, occur (Table 33.3). The high ambient temperature in many African countries and South Asia favors thermophilic lactic acid bacteria over mesophilic organisms. Likewise, thermophilic yeasts, including the opportunistic pathogens *Candida glabrata* and *Issatchenkia orientalis*, contribute to the fermentation alongside *S. cerevisiae*.

The composition and endogenous enzymes of the fermentation substrates select for strain-specific properties of fermentation microbiota. Resting grains of C_4 cereals, including maize, millet, and sorghum, have low amylase activity compared to wheat, rye, and barley (79); accordingly, many lactobacilli from maize, millet, and sorghum fermentations express extracellular amylase activity (35).

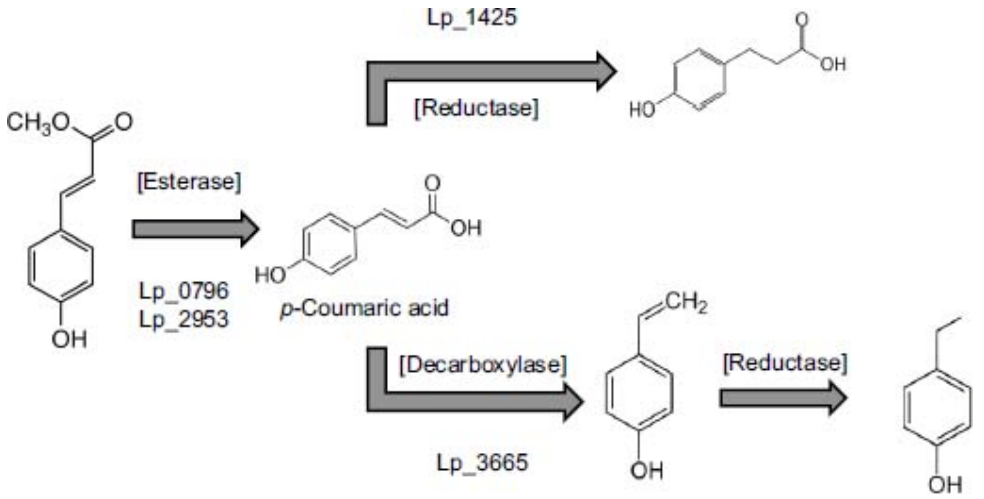

Figure 33.10. Metabolism of phenolic acids by lactic acid bacteria using the example of coumaric acid metabolism by *L. plantarum*. Protein numbers refer to the genome sequence of *L. plantarum* WCFS1 (GenBank accession number NC_004567.2).

Millet and sorghum also differ from wheat, rye, and barley by a high content of phenolic compounds, including tannins and phenolic acids. Phenolic compounds are of agronomic relevance, as they contribute to the drought and pest resistance of sorghum and millet varieties; however, they also decrease the nutritional value and impart a bitter taste (79, 80). Lactic acid metabolism in cereal fermentations modifies phenolic compounds through glycosyl hydrolases, which hydrolyze flavonoid glycosides, tannases, phenolic acid esterases, and phenolic acid decarboxylases or phenolic acid reductases with specific activity on hydroxyl benzoic and hydroxyl cinnamic acids (Fig. 33.10) (81). Metabolism of phenolic compounds in lactobacilli is strain specific and particularly frequent in *L. plantarum* (82, 83). Tannins and phenolic acids in sorghum and millet fermentations have antimicrobial activity, which selects for fermentation organisms with high resistance to phenolic acids (84). The conversion of phenolic compounds during sorghum and millet fermentations likely also improves the palatability of fermented porridges and beverages produced from these cereals.

Bread and Steamed Bread

Production Processes

Bread is generally fermented with mixed cultures of yeast and lactic acid bacteria. Traditional processes for production of bread and steamed bread use sourdough as the sole leavening agent. Sourdough is fermented by continuous propagation or back-slopping. The use of sourdough as the sole leavening agent requires multiple fermentation steps in bread production to ensure sufficient leavening capacity by sourdough yeasts and lactic acid bacteria (Fig. 33.11). The production of yeast biomass dedicated for use as a leavening agent in baking started in the 19th century; baker's yeast all but replaced sourdough as the leavening agent in wheat baking and supplemented the use of sourdough in rye baking. In rye baking, the use of sourdough remained necessary to improve water binding and gas retention through solubilization of rye pentosans and to inhibit endogenous amylases by acidification. The shift of technological aims also resulted in altered fermentation processes. Sourdoughs that are used as leavening agents are propagated frequently to maintain the sourdough microbiota in the exponential phase of growth; these doughs are referred to as type I sourdoughs (Fig. 33.11). Sourdoughs used for dough acidification are fermented for longer times and at higher temperatures to enhance acid and flavor production; these sourdoughs are referred to as type II sourdoughs (85) (Fig. 33.11).

Type I sourdoughs are fermented at the site of bread production; few bakeries manage to scale type I fermentation processes to a large industrial scale. In contrast, type II sourdoughs are produced at bakeries or at specialized ingredient suppliers for distribution in a stabilized form (dried, pasteurized, or refrigerated) (86). The fermentation of type II sourdoughs is readily scaled and integrated into automated processing lines. The scalability of type II sourdough fermentations and their beneficial impact on bread quality contributed to the widespread reintroduction of sourdough processes in industrial baking in recent decades. Sponge doughs represent an intermediate between straight doughs (fermentation with baker's yeast only) and sourdoughs. Sponge doughs are started only with baker's yeast; depending on the contamination of the yeast preparation and the flour, a lactic microbiota develops after 6 to 12 h and acidifies the dough. Freeze-dried starter cultures for use in baking are commercially available but are of little relevance compared to refrigerated sourdoughs containing active yeasts

and lactic acid bacteria or to dried or pasteurized sourdough products that do not contain viable microorganisms (86).

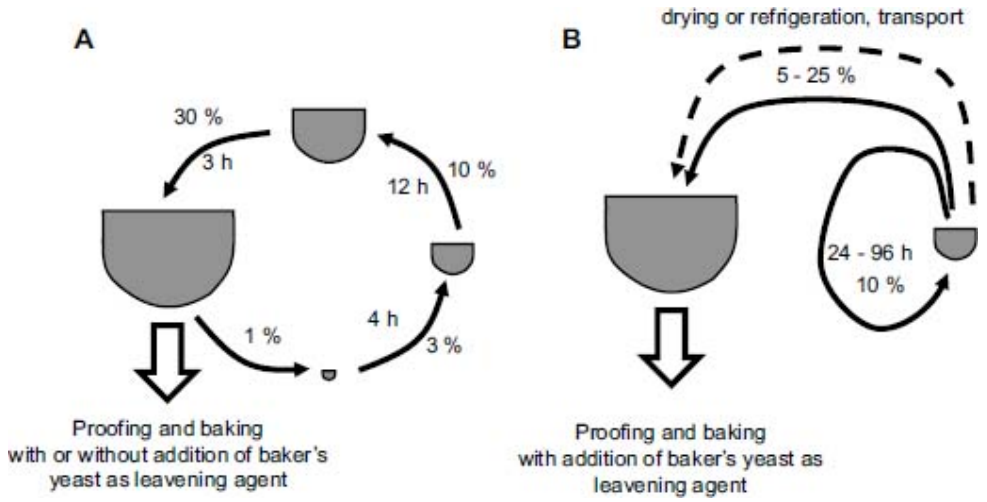

Figure 33.11. Schematic representation of type I (A) and type II (B) sourdough fermentation processes. Times indicate typical fermentation times for each fermentation step; the percentage values indicate the percentage of the flour in the bread recipe that is fermented at a specific step. Type I sourdoughs are propagated for use as the sole leavening agent; this necessitates the use of two to four fermentation cycles per batch of bread, which uses an increasing proportion of the flour. Fermentations are conducted at an ambient temperature of 15 to 30°C. Sourdoughs are maintained by use of a small proportion of the last sourdough or the bread dough as the inoculum for the next fermentation cycle. Type II sourdoughs are generally fermented at a higher temperature (30 to >40°C); if the fermentation is carried out by ingredient suppliers, type II doughs are pasteurized, dried, or refrigerated prior to use in the bakery.

Products

Bread or steamed bread is a staple of the diet in most regions of the world where wheat or rye is cultivated, including Europe, North America, China, and the Middle East. While fermentation processes (type I or type II sourdough) and the bulk raw material (wheat or rye) are comparable throughout the world (87), local differences in the use of ingredients and production processes account for a large variety of products. Examples are shown in Fig. 33.1 (groups 7 and 8). Baking of

bread in an oven or on hot stones heats the surface to tempera temperatures of more than 100°C, leading to crust formation and flavor generation in the Maillard reaction. Steamed bread is widely consumed in Southeast Asia (mantou) and in Central Europe (Dampfnudel or Germknödel); steaming of bread avoids crust formation during baking (88). Leavened flat bread (e.g., naan, pita, and kisra) is produced in Central Asia, the Middle East, eastern Mediterranean countries, and Sudan.

The most common cereal used in bread production is wheat. Wheat prolamins have the unique property of forming a polymeric protein network, the gluten macropolymer. The gluten macropolymer mediates dough hydration and gas retention during fermentation and baking (89) and supports production of bread with a much larger volume than bread from other cereals. The gluten proteins are polymerized by disulfide bonds. Additives, ingredients, or microbial metabolites that impact intramolecular disulfide cross-linking also impact the volume and texture of wheat bread (89).

Examples of wheat breads include the French baguette, which is produced with type I sourdoughs or by sponge doughs; San Francisco sourdough bread (type I sourdough); and the Italian panettone, the French brioche, and the Suebian Mutschel, which are produced with type I sourdoughs with the addition of eggs, butter, and sugar. In rye dough, dough hydration and gas retention are mediated by arabinoxylans (pentosans), which are solubilized by partial enzymatic hydrolysis of waterinsoluble pentosans during sourdough fermentation (90). Rye breads are darker and denser than wheat breads, particularly when whole flour and whole grains are the major ingredients. Rye bread is common in regions of Northern, Eastern, and Central Europe where the growing season is too short, cold, or wet for wheat; examples include the Westphalian pumpernickel, the Finnish reikäleipä, and crispbread (Fig. 33.1).

Cereals other than wheat and rye have a low content of structure-forming proteins or polysaccharides and do not allow the production of leavened bread unless structure-forming ingredients such as proteins or hydrocolloids are added. Traditionally, millet and sorghum are used for production of leavened flatbread. In recent years, gluten-free breads have become popular in North America and Europe. A gluten-free diet

that is free of prolamins of wheat, rye, and barley is the only treatment for celiac disease; gluten-free breads also cater to consumers with wheat or gluten intolerance (91). Commercial recipes for gluten-free breads are based on purified starches, structure-forming proteins, and hydrocolloids and gluten-free cereals or pseudocereals. The use of sourdough in gluten-free baking does not follow traditional procedures but generally follows type II technology to achieve improved flavor, texture, and shelf life (92).

The use of ingredients other than flour and water further contributes to the diversity of products. Examples of such ingredients are sugar, eggs, butter or other oils and fats, seeds, nuts, dried fruits, and insects; examples of products with a substantial proportion of noncereal ingredients are panettone, brioche, and hamburger buns.

Sourdough Fermentation Microbiotas

Sourdough microbiota have a high γ-diversity; more than 50 species of lactic acid bacteria and more than 20 species of yeasts have been identified in sourdoughs. However, the α-diversity (diversity in a single sourdough) is relatively low. Overviews of key organisms in sourdough are provided in references 87, 93, and 94 and in Table 33.4.

Type I sourdoughs used as sole leavening agents have a consistent composition of microbiota throughout the world. This uniformity relates to the technological aim of type I fermentations, which is leavening. In straight dough processes, the biomass of the added baker's yeast accounts for about 1% of the dough dry weight; type I sourdoughs achieve a comparable level of CO_2 production, although microbial biomass accounts for less than 0.1% of the dough dry weight. Dough leavening is achieved by fermentation protocols that maintain sourdough microbiotas perpetually in a metabolically active and exponentially growing state; this is achieved by multiple daily fermentation steps and uninterrupted propagation. Even short interruptions, e.g., by weekends or by extensive baking practices on farms or in households, reduce the leavening power and shift the fermentation microbiota (87, 95). Type I sourdoughs are continuously maintained over decades or centuries (95, 96). Anecdotal evidence dates

the origin of sourdoughs that are currently used in San Francisco to the 1849 gold rush.

Table 33.4. Composition of sourdough microbiotas[a]

Fermentation Type	Key organism(s)	Other organisms
Type I Sourdoughs	*L. sanfranciscensis*, *Ks. humilis*, *Ks. exigua*	*L. plantarum*, *L. brevis*, *L. alimentarius*, *Lu. mesenteroides*
Type II sourdoughs	*L. pontis*, *L. amylovorus*	*L. fermentum*, *L. panis*, *L. reuteri*, *L. crispatus*, *L. helveticus*, *I. orientalis*
Spontaneous sourdoughs and sponge doughs	*L. plantarum*, *L. fermentum*, *S. cerevisiae*	*Enterococcus* spp., *Pc. pentosaceus*, *Weissella* spp., *Lu. mesenteroides*, *L. casei*, *L. brevis*, *L. plantarum*, and *L. fermentum*

[a] Data are from references 87, 93, and 94.

The continuous use of type I sourdoughs eliminates dispersal limitation because contamination events, even from unlikely sources, will occur eventually. The consistent selective pressure in type I sourdoughs selects for the most rapidly growing organisms. Type I sourdoughs typically contain two to four strains; in over 90% of type I sourdoughs, *L. sanfranciscensis* is the most abundant organism. *L. sanfranciscensis* is often associated with organisms of the *Lactobacillus alimentarius* and *L. brevis* groups or with *Lactobacillus pontis* and *L. panis* (87). All isolates of *L. sanfranciscensis* described to date were isolated from type I sourdoughs, but the phylogenetic position of the strain, its metabolic features, and its detection in insects by culture-independent methods suggest an association with flowers or insects (21, 25). Comparable to other insect-associated lactobacilli, *L. sanfranciscensis* has a very small genome (1.3 Mbp), a very restricted metabolic potential, and a low acid tolerance but a high tolerance to oxygen (97). The prevalence of *L. sanfranciscensis* in type I sourdough is explained by its efficient use of sucrose and maltose, the main carbohydrate sources in sourdough, and the high coding density of rRNA operons, which support rapid growth

(36, 97). *L. sanfranciscensis* invariably coexists with sourdough yeasts, particularly *Ks. humilis* (previously *Candida milleri* or *Candida humilis*), *Kazachstania exigua* (previously *S. exiguous*), or *S. cerevisiae* (98). Yeasts and lactobacilli in sourdough do not compete for the main nutrients; *L. sanfranciscensis* preferentially metabolizes maltose over glucose, while *Ks. humilis* and *Ks. exigua* are maltose negative. Likewise, lactobacilli satisfy requirements for amino acids by uptake of peptides, while sourdough yeasts preferentially metabolize free amino acids (99). Yeast invertase activity supports growth of *L. sanfranciscensis* by releasing fructose from cereal fructans that are not accessible to lactobacilli (100).

The α-diversity and the β-diversity in type II sourdoughs are higher than those in type I sourdoughs, which reflects the fact that the technological aim, dough acidification, accommodates a higher variability in the fermentation processes (25, 85). Common characteristics of type II fermentation processes, which are often conducted on a large industrial scale, are long fermentation times, high levels of dough acidity at the end of the fermentation, and high fermentation temperatures (87, 101, 102). Type II sourdough microbiotas are dominated by vertebrate-host-adapted, acid-tolerant, and thermophilic organisms of the *L. reuteri* group (*L. pontis*, *L. panis*, and *L. reuteri*) in association with organisms of the *L. delbrueckii* group (*Lactobacillus amylovorus*, *Lactobacillus crispatus*, and *Lactobacillus acidophilus*). Yeasts are often absent in type II sourdoughs; in addition to yeast species that are also found in type I sourdoughs, thermophilic yeasts and particularly *I. orientalis* (anamorph: *Candida krusei*) and *C. glabrata* occur (98).

Sponge doughs and spontaneous sourdoughs are characterized by a larger diversity of fermentation organisms than that in the back-slopped type I and type II sourdoughs.

In spontaneous sourdough fermentations, fermentation is initiated by the usual suspects, the succession of fermentation microbiota that also occurs in other spontaneously fermented plants (25). The addition of baker's yeast in sponge sourdough suppresses the initial growth of *Enterobacteriaceae* that is observed in other spontaneous cereal fermentations, resulting in dominance of environmental and nomadic lactic acid bacteria, e.g., *L. plantarum*, *L. fermentum*, *Leuconostoc* spp., and *Pediococcus* spp. (25, 87, 98).

Impact of Sourdough Microbiotas on Product Quality

The beneficial impact of sourdough fermentation on bread quality is dependent not only on the metabolic activity of fermentation microbiota but also on the modulation of the activity of cereal enzymes (Table 33.5). Wheat and rye flours have amylase, protease, pentosanase, and phytase activities; of these, amylase activities are inhibited by low pH, while proteases, pentosanases, and phytases are more active at the pH of sourdough, 3.5 to 4.5, than at the pH of flour or yeast-fermented dough, 5.5 to 6.5. The extended time of sourdough fermentations compared to straight dough processes also supports conversion of proteins and polysaccharides by cereal enzymes (90).

Type I sourdough fermentations leave little room for optimization of product quality by strain selection because leavening power is the overriding selection criterion (87). Proteolysis during sourdough fermentation provides amino acids as flavor precursor compounds in yeast metabolism or the Maillard reaction during baking (103, 104) but also weakens gluten structure (104, 105). The negative impact of gluten hydrolysis and depolymerization is partially compensated for by the recruitment of pentosans as water-binding polysaccharides; solubilization of water-insoluble arabinoxylans during sourdough fermentation increases their water-binding capacity (90, 104, 105). Phytate hydrolysis during sourdough fermentation improves the mineral bioavailability (90). Sourdough yeasts improve bread flavor by conversion of amino acids to flavor volatiles and by strain-specific formation of volatile esters (28, 103). Specific contributions of *L. sanfranciscensis* to bread quality all relate to cofactor regeneration supporting rapid growth. Acetic acid is a main flavor volatile in bread and also a major contributor to the inhibition of fungal growth during bread storage (36, 103, 106, 107). Acetate formation by *L. sanfranciscensis* depends on the availability of fructose, oxidized glutathione, and aldehydes. These compounds are used to oxidize reduced cofactors (NADH) to NAD^+ with concomitant reduction to mannitol, reduced glutathione, and the corresponding aldehydes and thus enable acetate production in heterofermentative metabolism (36). The reduction of aldehydes originating from lipid oxidation by *L. sanfranciscensis* alters the flavor profile because the corresponding alcohols have a much lower flavor threshold (88, 103). The reduction of

oxidized to monomeric glutathione interferes with gluten polymerization and reduces bread volume (87, 105).

Type II sourdough fermentations leave more room for selection of cultures that improve bread quality through production of specific metabolites. An overview is provided in Table 33.5; examples include the production of exopolysaccharides for improved bread volume and reduced staling (108), the conversion of amino acids to taste-active compounds and flavor precursors (103, 109), and the formation of antifungal metabolites (107).

Table 33.5. Impact of sourdough fermentation on product quality[a]

Metabolite or metabolic pathway	Impact on quality	Organism(s)
Carbohydrate metabolism		
Formation of lactic acid	Dough acidification	All LAB
Formation of acetic acid	Flavor and enhanced mold-free shelf life	Heterofermentative LAB
Formation of CO_2	Leavening	Heterofermentative LAB and yeasts
Formation of exopolysaccharides by LAB	Improved bread volume, improved texture, and reduced staling	*L. reuteri*, *Leuconostoc* spp., and *Weissella* spp.
Formation of mannitol	Sweet taste	Heterofermentative LAB except *Weissella* spp.
Protein and amino acid metabolism		
Release of amino acids from peptides	Taste compounds and flavor precursor compounds	All LAB
Conversion of glutamine to glutamate by LAB	Umami taste	All LAB
Conversion of arginine to ornithine by LAB	Precursor to formation of 2-acetyl-2-pyrroline during baking	Species-specific trait of LAB, particularly in type II fermentations
Conversion of glutamate to γ-butyric acid	Bioactive	*L. reuteri*, *L. plantarum*, *L. brevis*, others
Reduction of oxidized glutathione	Reduced gluten quality and bread volume,	*L. sanfranciscensis*

	accelerated degradation of allergens	
Formation of γ-glutamyl peptides	Enhanced taste	*L. reuteri*
Conversion of amino acids to flavor volatiles	Improved flavor	Yeasts
Lipid metabolism		
Reduction of aldehydes originating from lipid oxidation to alcohols	Altered flavor	*L. sanfranciscensis*
Hydration of unsaturated fatty acids to hydroxyl-fatty acids	Enhanced mold-free shelf life	*Lactobacillus hammesii*
Others		
Conversion of phenolic acids	Flavor, bioavailability of bioactive compounds	*L. plantarum*, *L. brevis*
Ester synthesis	Flavor	Yeasts

[a] Modified from reference 90. LAB, lactic acid bacteria.

FERMENTED SOY AND BEAN PRODUCTS AND CONDIMENTS

Products and Production Processes

East and Southeast Asia have a rich tradition of fermented beans and soybeans (110–112). Beans and soybeans are typically fermented after a cooking step and without milling: examples include tempe, obtained by fermentation of cooked soybeans; natto, *Bacillus*-fermented soybeans; and stinky tofu, which is produced by fermentation of tofu (a curd prepared by precipitation of soy proteins) with lactic acid bacteria and bacilli. Beans and soybeans are also used for production of condiments.

The most widely known condiment is soy sauce, which is produced by fermentation of soy or soy and wheat (Fig. 33.12). Miso paste is produced in Japan and Korea from soybeans and wheat or rice and is used as a soup base. Dochi is a condiment obtained by fermentation of black beans in China (113). Gochujang, a condiment used in Korean cuisine, is produced by fermentation of hot chili peppers, soy, spices, and salt with *A. oryzae* and *Bacillus* spp. (112).

Fermentation Microbiotas and Their Contribution to Product Quality

The fermentation microbiotas in production of soy sauce are controlled by use of *A. oryzae* as a saccharification culture at the koji stage and by the addition of 17 to 25% NaCl to the moromi stage, which selects for the halophilic organism *T. halophilus* and yeasts (Fig. 33.12) (27, 110). During the 2- to 3-day koji fermentation, *A. oryzae* consumes about 20% of the starch and produces proteases, amylases, and glutaminase for hydrolysis of starch and proteins during the subsequent mash fermentation. *T. halophilus* produces lactate, while yeasts including *Zygosaccharomyces rouxii* and *Candida versatilis* produce flavor volatiles from amino acids and phenolic acids (Fig. 33.4) (27, 110). Pentoses are more reactive in the Maillard reaction than hexoses; therefore, pentose metabolism by *T. halophilus* indirectly impacts the color and flavor of soy sauce. The finished product contains 17 to 25% NaCl, 1% glutamate and lactic acid, and numerous additional umami and kokumi tastants and flavor volatiles that are produced by proteolysis, peptide conversion, or the Maillard reaction (109). Miso is produced from cooked soybeans and steamed rice; miso fermentations employ a lower salt concentration (10 to 12%) but they also use *A. oryzae* at the koji stage and salt-tolerant lactic acid bacteria, including *T. halophilus*. Dochi is produced by solid-state fermentation of cooked black beans with *A. oryzae*, followed by a high-salt (15%) mash fermentation (113).

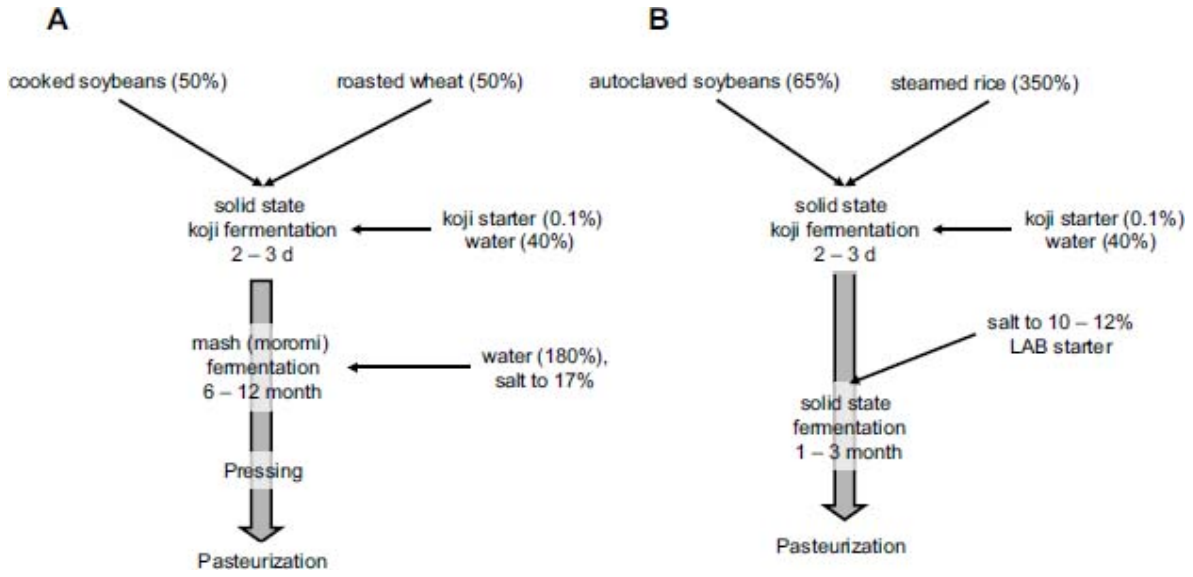

Figure 33.12. Flow chart for production of Japanese soy sauce (A) and miso (B). Koji fermentation by *A. oryzae* generates saccharolytic and proteolytic enzymes that hydrolyze starch and proteins in the subsequent mash (moromi) fermentation. The high salt concentration selects for the halophilic organism *T. halophilus* as the dominant bacterial representative of the moromi microbiota; *Z. rouxii* and other halophilic yeasts contribute to ethanol and flavor formation. Products in other East Asian countries use cooked soybeans as the sole ingredient and employ salt concentrations of up to 27%. Drawn with information from reference 110.

Tempe is a soybean cake fermented by *Rhizopus stolonifer* or *Rhizopus oligosporus*; the fungal mycelium produces a white mat on the surface of the product; the mycelium penetrates the cake and secretes extracellular proteases and carbohydrate hydrolases (114).

Natto is fermented in Japan by inoculation of cooked soybeans with *Bacillus subtilis* var. natto. *B. subtilis* produces hydrolytic enzymes but also contributes to the slimy or ropy appearance of the natto by synthesis of polyglutamate and fructans (110, 115).

FERMENTED VEGETABLES

Products and Production Processes

Vegetables are preserved by fermentation in most regions of Asia, Europe, and North America. The most common fermented vegetables are cabbage, which is used to produce sauerkraut and kimchi, pickle cucumbers, and olives; carrot juice, mustard or mustard leaves, and radish roots are also subjected to fermentation (Fig. 33.1) (112,116–118). Sauerkraut, kimchi, pickles, and olives are fermented on an industrial scale; most other products are fermented at the artisanal or household level.

Sauerkraut is prepared from finely sliced white cabbage, which is dry salted to a concentration of 1.8 to 2.2% and spontaneously fermented in covered containers at ambient temperature (15 to 20°C) (119). Refrigerated sauerkraut is shelf stable for several weeks, but it is most commonly sold after pasteurization. Kimchi is prepared from coarsely cut Chinese cabbage with addition of radish, onions, garlic, and spices, including black pepper and mustard. The raw material is brined in a 10% salt solution to achieve a final NaCl concentration of 2.5% and fermented in closed containers at temperatures ranging from 5°C to 20°C (112). Kimchi is usually consumed fresh. Depending on the fermentation temperature, sauerkraut and kimchi fermentations are completed in 2 to 4 weeks.

Pickles are fermented by brining in 5 to 8% NaCl solution; the brine is typically acidified with vinegar to a pH of 4.5 to prevent growth of CO_2-producing *Enterobacteriaceae* and *Leuconostoc* species. Spontaneous fermentation is carried out without temperature control at ambient temperature (15 to 30°C). After about 2 to 3 weeks of fermentation, pickles are seasoned, cut as desired, and usually pasteurized after packaging (119). Fermentation of other vegetables after cutting and dry salting or brining is done in a comparable manner, with ambient temperatures ranging from 5°C to 30°C, depending on the region (112, 116).

Green and black olives are preserved by treatment with lye (1.8 to 2.5% NaOH), chemical acidification, and pasteurization, by fermentation with lactic acid bacteria, or by a combination of these processes (118). Fermentation is completed after 30 to 60 days at ambient temperature (119).

Fermentation Microbiotas and Their Impact on Product Quality

Vegetables are generally fermented spontaneously without addition of starter cultures; fermentation microbiotas thus derive from the microbiota of the raw material, and the evolution depends on the substrate availability, the NaCl concentration, the pH, and the presence of plant-derived antimicrobial compounds. Cabbage and carrots contain about 2 to 4% glucose and fructose (31, 119). Vegetables harbor 10^5 to 10^7 CFU of bacteria per g; aerobic bacteria including *Pseudomonas* and *Enterobacteriaceae* dominate. Lactic acid bacteria are present, with a cell count of 10^2 to 10^4 CFU/g; *Lactococcus*, *Leuconostoc*, *Weissella*, *Enterococcus*, and lactobacilli are generally present (116).

On the basis of the consistent microbiota of the raw material, vegetable fermentations are characterized by a consistent succession of fermentation microbiotas (the usual suspects) (Fig. 33.13). Fermentation microbiotas are stratified by oxygen requirement and acid tolerance; growth of plant-associated *Enterobacteriaceae* is followed by that of enterococci, lactococci, *Leuconostoc*, and *Weissella* spp. until, at later stages of the fermentation after the pH drops to 4.5, *L. plantarum* and *L. brevis* dominate and acidify to a pH of ~3.5 (Fig. 33.13) (31, 120). The succession of fermentation microbiota is not specific to the vegetable (31, 119, 120) and closely resembles the succession of microbiota in spontaneous cereal fermentations (Table 33.3). The addition of salt favors growth of lactic acid bacteria over *Enterobacteriaceae* (121). Gas production is undesirable in production of pickles or olives, because CO_2 may disrupt the plant tissue; in these fermentations, acidification with vinegar or lactic acid shortcuts the deployment of the usual suspects by inhibition of *Enterobacteriaceae* and, if the pH is 4.5 or less, of the heterofermentative organisms *Leuconostoc* and *Weissella* (119). The ambient temperature also impacts fermentation microbiota; the psychrotrophic organisms *L. sakei* and *Lactobacillus curvatus* complement the usual suspects in low-temperature batches, while pediococci may occur in high-temperature (30°C) fermentations. Fermentation microbiotas of olives are additionally impacted by the high content (1 g/kg) of phenolic compounds; free phenolic acids exert antimicrobial activity at this

concentration (122). The use of starter cultures for fermentation of vegetables has been described; however, starter cultures do not have a significant influence on the evolution of fermentation microbiotas (116, 120). Decarboxylase-negative starter cultures were reported to decrease formation of biogenic amines during sauerkraut fermentation, particularly tyramine, putrescine, and cadaverine (123).

Early spoilage of pickles and olives occurs by gasproducing *Enterobacteriaceae*; late spoilage by yeasts or acetic acid bacteria occurs if the fermentation batch is not maintained under anaerobic (tightly sealed) conditions. Lactate-consuming bacteria, including clostridia and *Lactobacillus buchneri*, also contribute to spoilage (Fig. 33.13) (36, 117).

Acid production represents the main contribution of fermentation microbiota to product quality; formation of exopolysaccharides and excessive production of acetate are considered spoilage events (116, 117). Product flavor is determined by properties of the raw material and the addition of spices and therefore not dependent on flavor production by fermentation microbes.

Olives are unpalatable unless the main bitter compound, oleuropein, is removed. Oleuropein is a β-glucosylated phenolic compound that can be removed by lye treatment or by fermentation. During fermentation, the β-glucosidase activity of *L. plantarum* hydrolyzes oleuropein to its aglycone, which does not impart a bitter taste (118, 124).

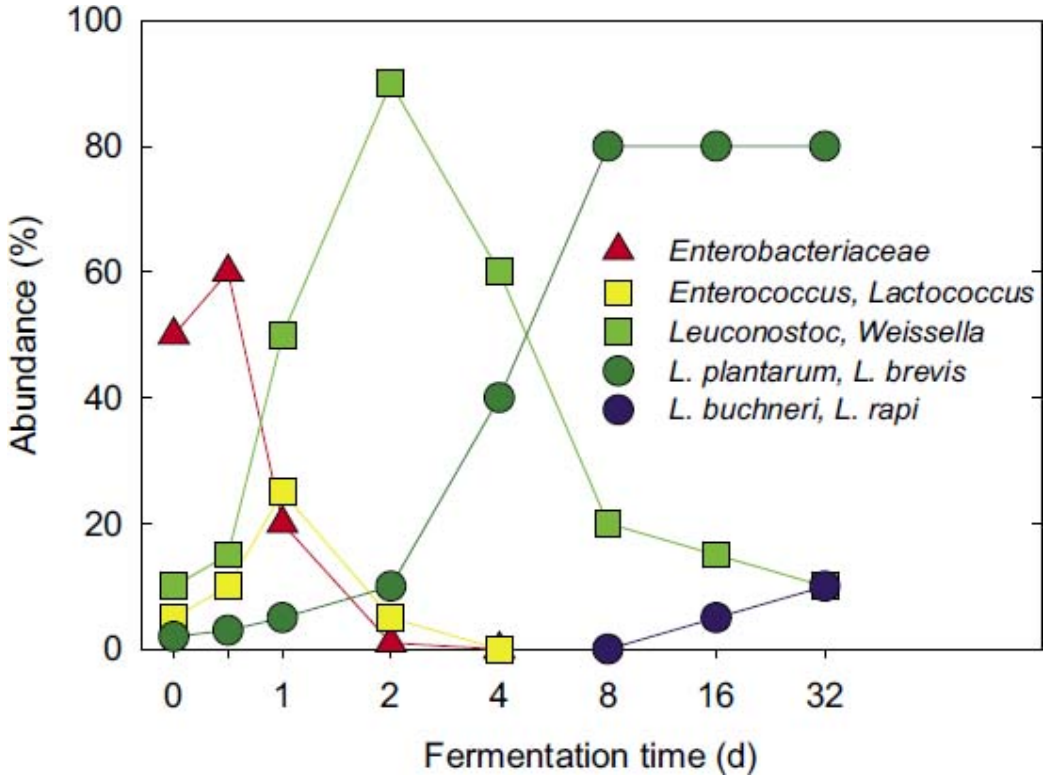

Figure 33.13. Schematic representation of the typical succession of fermentation microbiota in spontaneous plant fermentations, including most cereal fermentations, sauerkraut or kimchi, and olives (the usual suspects). Plant-associated *Enterobacteriaceae* include *Enterobacter*, *Klebsiella*, *Cronobacter*, and *Pantoea*; among lactococci and enterococci, *E. faecium*, *Enterococcus faecalis*, and *Lc. lactis* are most frequently observed. Later fermentation stages include growth of *Weissella cibaria*, *Weissella confusa*, *Weissella kimchi*, and *Lu. mesenteroides*. *L. buchneri* and *Leuconostoc rapi* are lactate-utilizing spoilage organisms. Drawn with information from references 31, 116, and 120.

FERMENTED (CULTURED) DAIRY PRODUCTS

Products and Production Processes

Microbiotas of raw milk acidify the substrate if it is stored at ambient temperature. Acidification coagulates casein to form a weak gel or a highly viscous liquid. Raw milk contains a highly diverse microbiota originating from the animals and their housing, bedding, feed, and water (125). Lactococci, lactobacilli, streptococci, and enterococci are generally

present but are not necessarily major components of the raw milk microbiota; one or more of these organisms become dominant after spontaneous fermentation and inhibit the growth of pathogens or spoilage microbes. Control of fermentation by backslopping supports development of reproducible mesophilic or thermophilic fermentation microbiotas and consistent product quality.

Yogurt originated in the Fertile Crescent and is currently produced from pasteurized milk by fermentation at 40 to 45°C. Yogurt is produced with identical cultures globally, but product properties, particularly the acidity, flavor, and gel structure, can vary widely. Aseptic packaging prior to fermentation in retail containers leads to set-style yogurt with a firm texture; fermentation in bulk prior to aseptic packaging in retail containers for production of stirred yogurt alters the gel structure of the product (126). The fermentation organisms *Sc. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* differ in their acid tolerance and growth temperature; *Sc. thermophilus* grows optimally at 36 to 42°C, while *L. delbrueckii* subsp. *bulgaricus* grows optimally at 44 to 45°C (127). Adjusting the ratio of cocci to rods by appropriate composition of the starter culture, by the use of attenuated, less acid-tolerant strains of *L. delbrueckii*, or by the choice of fermentation time and temperature results in products with low acidity and mild flavor (streptococci dominate) or in more acidic and flavorful “Balkan style” yogurts (lactobacilli dominate). Increasing the solid content by the addition of milk solids prevents syneresis; alternatively, hydrocolloids can be used to prevent expulsion of whey during refrigerated storage (126). Yogurt is often flavored or filled with a fruit preparation as a flavoring agent.

Sour cream, cultured butter, and buttermilk are produced from cream after adjustment of the fat content to 30 to 40% and fermentation with mesophilic starter cultures. Churning of the cultured cream separates the butter, with a fat content of about 80%, from the buttermilk, which contains the aqueous phase and the phospholipids of the milk fat globule membrane. Phospholipids of the milk fat globule membrane and the low pH make traditional buttermilk from cultured sour cream highly prone to oxidation (128, 129). Commercially available buttermilk with a higher oxidative stability is often produced by fermentation of sweet cream buttermilk or skim milk with mesophilic starter cultures.

Kefir is fermented with a mixture of thermophilic and mesophilic lactic acid bacteria, yeasts, and acetic acid bacteria to obtain a sour, carbonated beverage with an alcohol content of < 0.5 to 2% (130). Fermentation microorganisms are not homogenously dispersed in the product but are embedded in the kefir grains, granular structures that resemble cauliflowers and are composed of insoluble exopolysaccharides and microbial biomass (131, 132). Koumiss (or "airag" in Mongolian) is produced from mare's milk in Central Asia. Fermentation with lactic acid bacteria and yeasts yields a beverage with less than 1% ethanol (sweet koumiss) or up to 3% ethanol (strong koumiss) (133).

Fermentation with mesophilic or thermophilic cultures results in soured and set milk products; examples include viili (Finland), leben (or leban or lben; Middle East and North Africa), and diverse products from the milk of cows, goats, sheep, camels, or buffalo; an overview of African fermented milk products has been provided by Jans et al. (134).

Fermentation Microbiotas and Their Role in Product Quality

Yogurt is fermented by *Sc. thermophilus* and *L. delbrueckii* subsp. *bulgaricus* (Table 33.6); the use of both organisms is mandated by the Codex Alimentarius for products called "yogurt." The two fermentation organisms form a symbiotic relationship and grow faster in coculture than in single culture. Initially, *Sc. thermophilus* grows, and the reduction of the pH, the consumption of oxygen, and the formation of CO_2 and formate by pyruvate-formate lyase improve conditions for growth of *L. delbrueckii*. Conversely, the extracellular protease activity of *L. delbrueckii* provides amino acids that stimulate growth of the generally protease-deficient *Sc. thermophilus* (135, 136). Flavor formation is also enhanced by coculture of the two organisms (137). Major flavor volatiles in yogurt include acetaldehyde, diacetyl, acetoin, and acetic acid. Acetaldehyde and acetate are predominantly produced from glucose via pyruvate and acetyl-CoA; threonine aldolase additionally contributes to acetaldehyde production (138). Diacetyl and acetoin production is dependent on the use of citrate as alternative source of pyruvate (Fig. 33.14) (139). In homofermentative lactic acid bacteria, pyruvate formation from glucose necessitates further metabolism by lactate dehydrogenase or pyruvate formate lyase to

regenerate reduced cofactors (Fig. 33.9) (36, 139). Pyruvate formed from citrate is not burdened with reduced cofactors and can thus be partially converted to α-acetolactate; this conversion is also observed during growth of lactococci under aerobic conditions. Cultured butter, sour cream, and traditional buttermilk are fermented with mesophilic DL cultures (see below), including citrate-utilizing *Lc. lactis* and *Leuconostoc mesenteroides* (*Lu. mesenteroides*) (Table 33.6). Diacetyl produced from citrate is the character impact compound of the cultured-butter flavor.

Table 33.6. Examples of cultured dairy products and the corresponding fermentation microbiota

Product (origin)	Major fermentation organisms	Metabolites relevant for product quality
Yogurt (Bulgaria, global)	*Sc. thermophilus*, *L. delbrueckii* subsp. *bulgaricus*	Diacetyl, acetaldehyde, exopolysaccharides
	L. acidophilus, *Bifidobacterium* spp.	Added as probiotic cultures without contribution to sensory quality of yogurt
Viili (Finland)	*Lc. lactis*, *Lu. Mesenteroides*	Diacetyl, exopolysaccharides
Kefir (north Caucasus, global)	*Lactobacillus kefiri*, *Lactobacillus parakefiri*, *L. paracasei*, *Lu. mesenteroides*, *Lc. lactis*, *Bifidobacterium breve*, *Acetobacter orientalis*, *Candida kefyr*, *K. marxianus*, *S. cerevisiae*	Exopolysaccharides, acetic acid, CO_2, ethanol
Cultured butter and buttermilk (global)	*Lc. lactis* subsp. *lactis* biovar diacetylactis, *Lu. Mesenteroides*	Diacetyl, contribution to lipid peroxidation in sour cream and buttermilk
Koumiss (Central Asia, Mongolia)	3–7 species of lactic acid bacteria, including *L. helveticus*, *L. casei*, *L. plantarum*, and *Lc. lactis*; *S. unisporus* and *K. marxianus*	CO_2, ethanol
Suusac (Sudan)	*E. faecium*, *L. helveticus*, *Sc. infantarius*, *W. confusa*, *Candida famata*	

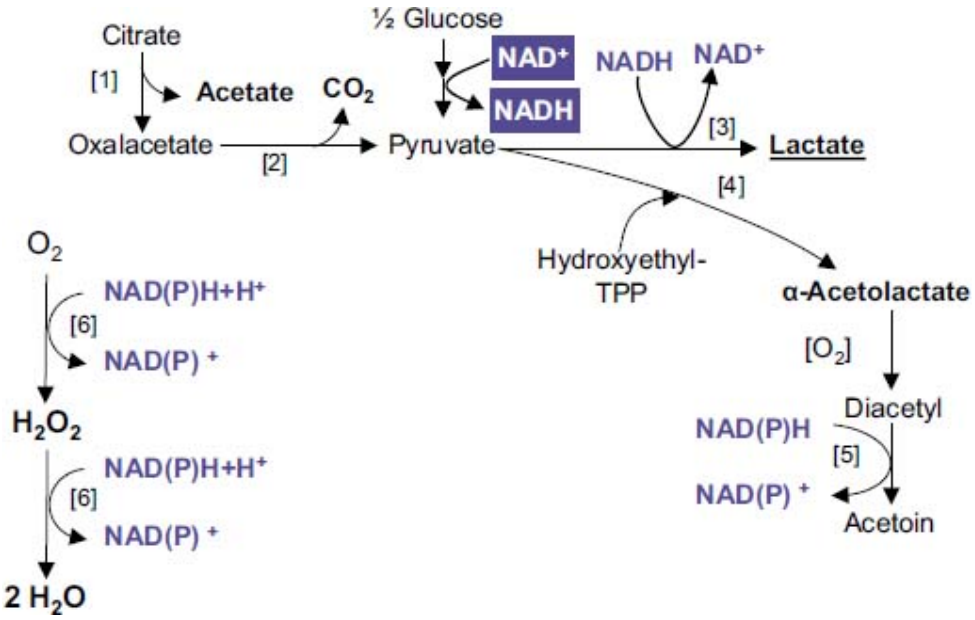

Figure 33.14. Production of diacetyl by lactic starter cultures. Enzymes are indicated by numbers as follows: 1, citrate lyase; 2, oxaloacetate decarboxylase; 3, lactate dehydrogenase; 4, acetolactate synthase; 5, diacetyl/acetoin reductase; 6, NADH oxidase or NADH peroxidase. The formation of reduced and oxidized cofactors (in white on a blue background and in blue, respectively) is indicated if it occurs upstream or downstream of relevant metabolic branching points. Drawn with information from references 36 and 139.

Acid coagulation of milk casein generates only weak gels that are prone to syneresis during refrigerated storage; in yogurt and other cultured dairy products, exopolysaccharide production by the fermentation microbiota is a key determinant of the texture and rheology of the products (140). Lactic acid bacteria produce exopolysaccharides (EPS) through extracellular dextransucrases or fructansucrases or by intracellular glycosyltransferases (141). Extracellular EPS-producing enzymes generate large quantities (1 to 20 g/liter) of EPS but require sucrose as a substrate and are thus relevant in cereal fermentations (108) but not in dairy products unless sucrose is added. Synthesis by intracellular glycosyltransferases generates relatively low concentrations of EPS (less than 1 g/liter). These EPS are typically heteropolysaccharides that are composed of repeating units with one to eight sugar moieties.

EPS from *Sc. thermophilus* and *Lc. lactis* are typically composed of glucose, galactose, and rhamnose as major constituents; ribose, fucose, and *N*-acetylglucosamine are also constituents of some EPS (for reviews, see references 141–143). The constituent monosaccharides are synthesized as nucleotide-activated precursors; the repeating unit of the EPS is assembled intracellularly through successive activity of dedicated glycosyl transferases (Fig. 33.15). During assembly, the repeating unit is linked to the membrane-bound undecaprenyl phosphate, the lipid carrier that also mediates synthesis and export of the peptidoglycan (Fig. 33.15). Export and subsequent polymerization yield polysaccharides with a relative molecular weight ranging from 4.0×10^4 to 6.0×10^6. Strains of *Sc. thermophilus* are typically more copious EPS producers than *L. delbrueckii* strains; the size, charge, and linkage type of EPS produced by *Sc. thermophilus* strongly impact yogurt texture (140). Ropy EPS produced by *Lc. lactis* also account for the viscous texture of viili, a cultured milk produced with *Lc. lactis* and *Lu. mesenteroides* (Table 33.6).

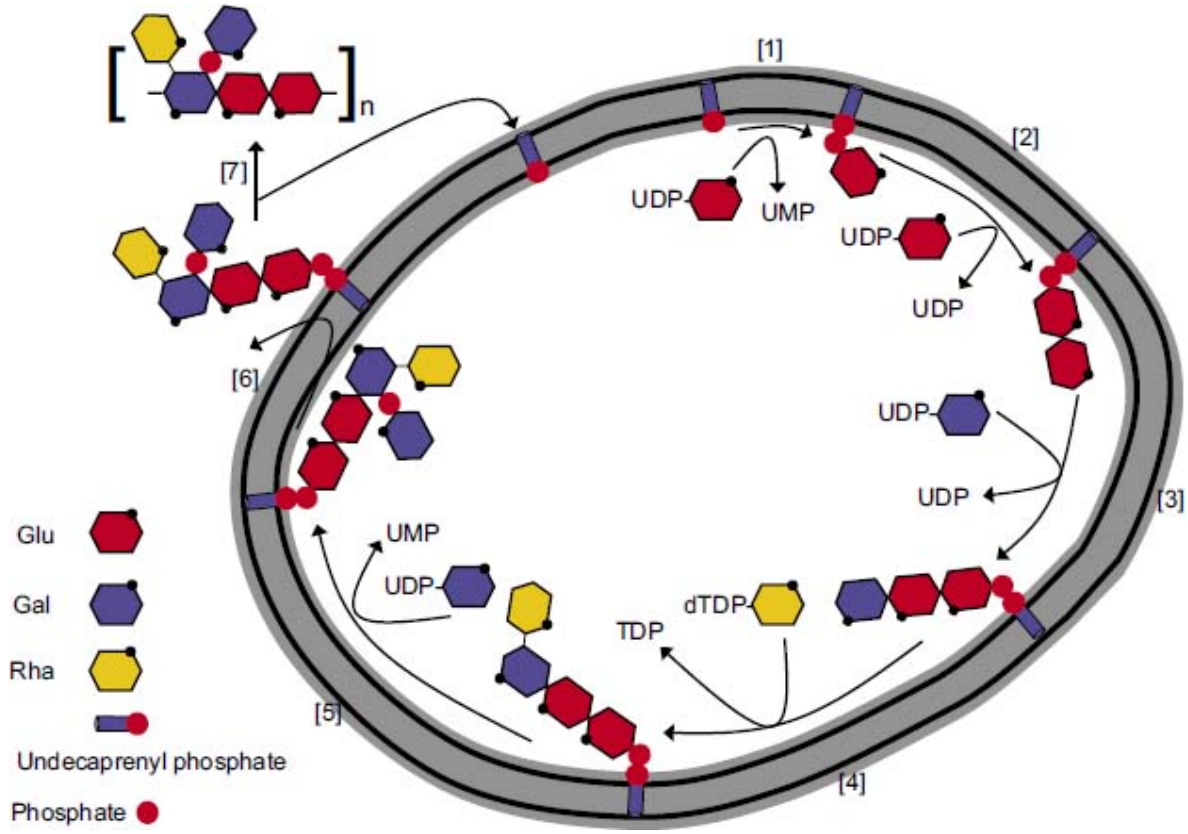

Figure 33.15. Synthesis of exopolysaccharides by intracellular glycosyltransferases. Shown is the example of exopolysaccharide synthesis in *Lc. lactis* B40. (1) The priming glycyltransferase links glucose to the membrane-bound lipid carrier undecaprenyl phosphate using UDPglucose as the substrate. (2 to 5) Successive activity of the glycosyltransferases EpsE, EpsF, EpsG, EpsH, EpsH, and EpsJ assembles the repeating unit of the EPS, with UDP-glucose, UDP-galactose, and dTDP-rhamnose as substrates. (6) EpsK translocates the repeating unit, which is then (7) polymerized by EpsI with EpsA and EpsB, determining the chain length. The lipid carrier is retranslocated and dephosphorylated. Drawn using data from reference 142.

Kefir grains consist of microbial cells embedded in an extracellular polysaccharide matrix. The matrix consists of kefiran, an EPS produced by *Lactobacillus kefiranofaciens* (131, 132). Homofermentative and heterofermentative lactobacilli are the dominant organisms in kefir grains and coexist with *Lc. lactis* and *Lu. mesenteroides* as well as acetic acid bacteria and yeasts. A core microbiome of kefir has not been established, but *L. kefiranofaciens* or related kefiran-producing

lactobacilli appear to be invariably present. Yeasts in kefir include the lactose-utilizing *Kluyveromyces marxianus* but also lactose-negative *Saccharomyces unisporus* and *S. cerevisiae*, indicating metabolic cooperativity between yeasts and lactose-utilizing lactic acid bacteria. The composition of the microbiota of kefir grains differs from that of the microbiota of the bulk liquid (132), demonstrating that some organisms are preferentially associated with the EPS matrix.

The fermentation microbiota of yogurt, sour cream, and cultured butter is controlled by back-slopping or the use of starter cultures and is uniform globally. Fermented milk products in Africa exhibit a much larger diversity of fermentation organisms, which also include *Streptococcus infantarius*, *Enterococcus* spp., pediococci, and *Weissella* spp. (134). It is unclear, however, whether this diversity reflects the use of milk from species other than cows, different production practices, or the use of spontaneous fermentation.

CHEESE

Production Processes

Cheese is produced by precipitation of casein from milk; 90% of the lactose, whey proteins (20% of protein in cow's milk), and 10% of the fat are removed with the whey. Cheese making converts perishable milk to a stable and tradable commodity; moreover, it removes most of the lactose from milk. Cheese has been produced in the Mediterranean for over 7,200 years (144) and thus predates the spread of lactase persistence in Europeans (145). Most cheese is made from the milk of cows, but milk from goats, sheep, and water buffaloes is also used in cheese production (Fig. 33.1 and 33.16). Cheese production involves four basic processing steps: coagulation of casein by acidification and/or the use of rennet, cutting of the curd to drain the whey, salting and shaping of the cheese, and ripening (Fig. 33.16). Ultrafiltration is additionally employed to concentrate cheese milk prior to coagulation. Process variables and the use of diverse fermentation microbiotas result in a large variety of cheeses. Comprehensive descriptions of processes and fermentation microbiotas that are used in cheese making have been provided by Fox et al. (146) and McSweeney (147).

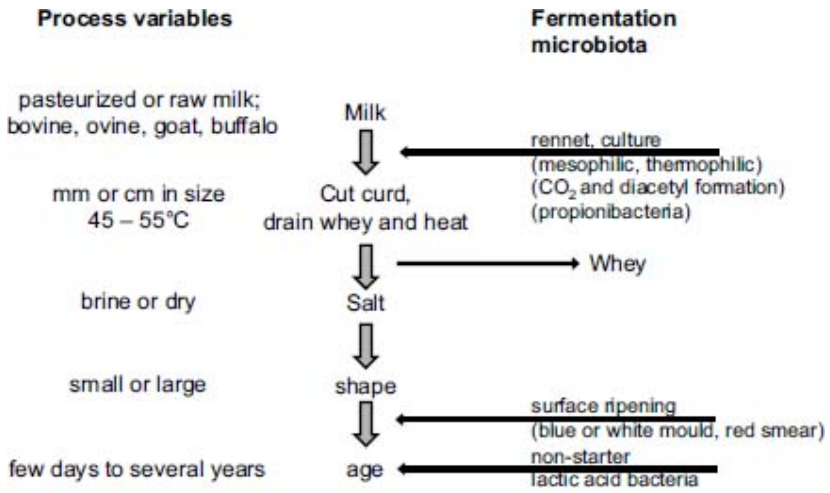

Figure 33.16. Overview of basic processing steps during cheese production. Variables related to processing steps are on the left; variables related to fermentation microbiota are on the right.

The different compositions of bovine, ovine, and caprine milk also relate to different cheese compositions; ovine milk has a higher fat and protein content than bovine milk (146). Milk pasteurization eliminates vegetative cells of pathogens that are present in the milk, particularly *Salmonella*, enterohemorrhagic *Escherichia coli*, and *Staphylococcus aureus*. Pasteurization also eliminates nonpathogenic milk microorganisms that may impact cheese quality as nonstarter adjunct cultures and inactivates enzymes present in raw milk. In addition to proteases and lipases, bovine milk harbors γ-glutamyltransferase activity, which produces taste-active peptides during ripening (148). As an alternative to pasteurization, milk destined for the production of long-ripened cheeses is treated at 60°C for 30 min to reduce contaminants.

Coagulation of casein, which constitutes 80% of the protein in bovine milk, is achieved by acidification, treatment with rennet, or a combination of these. Casein micelles in milk are aggregates of several thousand molecules of α_{s1}-, α_{s2}-, β-, and κ-caseins with an average size of 150 to 200 nm (149). Casein micelles are stabilized by colloidal calcium phosphate nanoclusters and κ-casein, which has a glycosylated and hydrophilic C terminus. κ-Casein is found almost exclusively at the surface of the micelle, and the glycomacropeptide “hairs” on the surface mediate steric stability of the micelles (149). Acidification to the isoelectric point of casein, pH 4.6, solubilizes the calcium phosphate

nanoclusters and collapses the κ-casein layer on the surface, allowing formation of a weak gel. Heating of milk to more than 70°C denatures whey proteins, which associate with κ-casein and destabilize the casein micelles.

Rennet is produced from calf stomach and contains chymosin. Chymosin is an acid protease that specifically cleaves κ-casein between Met_{105} and Phe_{106} and thus removes the glycomacropeptide. Cleavage of κ-casein during cheese making occurs optimally at pH 6 to 6.5 and 45 to 48°C (146). Removal of the glycomacropeptide destabilizes the casein micelles and supports gel formation. Rennet from calf stomach can be replaced by recombinant chymosin, or by microbial and plant proteases. Proteases other than rennet, however, also cleave other milk proteins and may reduce the cheese yield and favor formation of bitter peptides during ripening.

After the cheese curd is set by acid- or rennet-induced gelation, whey removal is initiated by cutting of the curd to cubes with a volume of about 1 ml. Cutting to a smaller size facilitates whey removal for production of hard cheeses. Cooking of the curd to temperatures ranging from 30 to 55°C further improves whey removal; high temperature and low pH are complementary with regard to their effect on draining of the whey. Light pressing of the cheese curd can be applied to further expel whey. Heating of the cheese curd to >65°C plasticizes it; it can be stretched and molded into its shape (pasta filata).

Cheese is salted to provide taste, to enhance syneresis, and to contribute to preservation. Salt is applied directly to the curd, e.g., in the case of Cheddar, by dry salting of the surface after shaping or by placing the cheese in brine. The salt concentration in the water phase of cheese ranges from 1% for fresh, acid-coagulated cheeses to more than 9% for long-ripened cheeses, such as Parmigiano Reggiano.

Aging of cheeses is one of the most variable production steps. Acid-coagulated cheeses are generally not ripened; the ripening time for rennet-coagulated cheeses ranges from a few weeks to a few years (146) (Fig. 33.1). Aging of cheese achieves dehydration, degradation of proteins and lipids to taste-active peptides, amino acids, and fatty acids, and their further conversion to flavor volatiles. Microbial contaminants that may be present in raw milk and grow during initial stages of cheese

production are inactivated during ripening; cell counts of *Salmonella*, *E. coli*, and *St. aureus* are decreased by more than 5 log CFU/g if the ripening time exceeds 60 days (146). During aging of internally bacterially ripened cheese, the primary acidification cultures are replaced or complemented by nonstarter lactic acid bacteria and, in some cheese varieties, propionibacteria. Ripening with surface microbiota accelerates proteolysis and lipolysis; however, the respiratory metabolism of surface microbiota increases the pH and increases hygiene risks.

Products

Cheese is produced traditionally in Central Asia, the Mediterranean, and European countries. European migration to the Americas and Oceania introduced cheese making to those areas. Although cheese is not traditionally produced in Southeast Asia, industrial development and the associated changes in lifestyle have resulted in increased cheese consumption. A few types of cheese, particularly Cheddar and mozzarella, account for a majority of the global cheese production, but the number of cheese varieties is virtually unlimited. The former French president Charles de Gaulle asked in frustration, “How can you govern a country that has two hundred and forty-six varieties of cheese?” As the number of cheese varieties in other countries with a long tradition of cheese making is comparable, hundreds of different cheese varieties have been recognized (150), and Fig. 33.1 provides only a very selective overview. Numerous cheeses are protected by a “protected designation of origin” scheme and are produced only in specific geographic regions (147). Cheeses can be classified based on the method of coagulation (rennet, acid, or acid and heat) and subdivided on the basis of technological parameters and ripening microbiota (146, 147). Acid-coagulated cheeses account for about 25% of cheese production and are typically produced without ripening. Examples include Greek yogurt, quark, cottage cheese, and cream cheese (Fig. 33.1). Ricotta and paneer are examples of fresh cheeses that are produced in Italy and South Asia, respectively, from skim milk or whey by heat and acid coagulation of proteins. Owing to the high pH, these products are highly susceptible to spoilage. Some acid-coagulated cheeses, e.g., queso blanco, are acidified by addition of acetic or citric acid rather than microbial acidification.

Mysost, geitost, and related products in northern Europe are produced by concentration of cheese whey to a solid content of more than 80%, followed by cooling, kneading, and packaging. The taste of these whey products is determined by sweetness imparted by the high lactose content and Maillard products that are formed during whey concentration (146).

Rennet-coagulated cheeses account for a majority of the global cheese production; these products are ripened for weeks or up to several years. Most cheeses, including Cheddar and Gouda, are ripened internally by bacterial activity; in these products, the development of a surface microbiota is inhibited by regular washing or dehydration of the rind. Rennet-coagulated cheeses contain small irregular holes if the cheese curd is imperfectly packed, e.g., in the case of Tilsiter. The use of citrate-utilizing or heterofermentative starter cultures leads to formation of small regular holes in the cheese matrix, e.g., in Gouda and Edam cheeses. Gas formation by propionibacteria in Emmental cheese and, to a lesser extent, in Jarlsberg and Leerdammer leads to formation of large, regular holes.

The development of surface microbiota fundamentally changes the color, texture, and flavor of cheeses. Red smear cheeses are ripened by a surface biofilm consisting of yeasts and bacteria; these produce orange and red pigments and characteristic flavor volatiles. Flavor production is more pronounced in soft cheeses, e.g., Oka (Quebec, Canada), Tilsiter (Tilsit, East Prussia; now produced in Poland, Germany, and Switzerland), Limburger (Limburg, Belgium), and Münster (Alsace, France), than in hard cheeses (e.g., Gruyère and Tête de Moine, Switzerland) and increases during ripening. Camembert and Brie, which originate from Normandy in France, are ripened with surface mycobiota that form white mycelia on the surface of the cheese and soften the cheese curd through production of extracellular proteases and lipases. Roquefort is the archetypical blue cheese; it is a raw-milk cheese produced from ovine milk in Roquefort-sur-Soulzon in France. Roquefort is ripened in caves surrounding Roquefort-sur-Soulzon which are also inhabited by the blue mold *P. roqueforti*. Poking of holes in the cheese curd transfers fungal spores as well as oxygen into the interior. Other traditional blue cheeses include Gorgonzola (Italy) and Stilton (England). Contemporary cheese varieties combine ripening with white

surface mycobiota and internal ripening with *P. roqueforti*, e.g., Cambozola and Danablu.

Fermentation Microbiotas

Table 33.7. provides an overview of cheese microbiotas. Acidification of cheese milk to achieve coagulation of casein or to support rennet-mediated coagulation is mediated by addition of mesophilic or thermophilic starter cultures. Mesophilic cultures grow optimally at around 30°C but can tolerate heating of the cheese curd to a temperature of up to 45°C; thermophilic cultures grow optimally at 37 to 45°C and resist higher temperatures used to treat the cheese curd to expulse whey.

Mesophilic cultures consist primarily of the homofermentative organisms *Lc. lactis* subsp. *cremoris* and/or *Lc. lactis* subsp. *lactis*; cultures containing only these organisms are termed “O cultures.” *Lc. lactis* subsp. *cremoris* is often associated with *Lc. lactis* subsp. *cremoris* biovar diacetylactis (D cultures), which converts citrate to diacetyl and CO_2 (Fig. 33.14), and with the heterofermentative organisms *Lu. mesenteroides* (L cultures) (151). Citrate utilization, the defining criterion for *Lc. lactis* subsp. *cremoris* biovar diacetylactis, is plasmid encoded. *Lc. lactis* subsp. *lactis* is differentiated from *Lc. lactis* subsp. *cremoris* by the presence of the arginine deiminase pathway and glutamate decarboxylase (151). Undefined multistrain starter cultures are maintained by backslopping at the farm level or in dairies; these cultures contain multiple strains with complementary phage resistance patterns and exhibit a remarkable functional stability over years of back-slopping (151). Phage predation on individual strains temporarily reduces individual strains in the mixture without compromising starter functionality. Milk contains lactose as the sole fermentable carbohydrate and is a substrate with a low concentration of peptides and amino acids; microbial growth thus requires extracellular proteinase activity (152). Lactococci and *Leuconostoc* spp. are plant-associated organisms and populate raw-milk microbiota through contamination from feed or straw; in *Lc. lactis*, lactose utilization and proteolytic activity are plasmid-encoded traits. Some but not all strains in the starter mixtures express extracellular proteases to satisfy the demand of other strains for peptides and amino acids (151).

Thermophilic starter cultures consist of *Sc. thermophilus* in combination with *L. helveticus*, *L. delbrueckii* subsp. *lactis*, or *L. delbrueckii* subsp. *bulgaricus*. *L. helveticus* is a commensal member of chicken intestinal microbiota (21, 153); *L. delbrueckii* occurs in the lactose-rich intestines of suckling mammals (26). *Sc. thermophilus* is closely related to oral streptococci but readily distinguished from pathogenic members of the genus (154). Thermophilic starter cultures hydrolyze lactose through intracellular β-galactosidase and preferentially metabolize the glucose moiety and excrete galactose (35, 154). *L. delbrueckii* and *L. helveticus* generally express extracellular proteases, while most strains of *Sc. thermophilus* rely on other components of the starter mixture to supply amino acids and peptides (154).

Undefined, mixed-strain starter cultures have been available since the end of the 19th century; single-strain defined starter cultures were developed in New Zealand in the 1930s (146). Currently, defined strains that are directly added to the cheese vat (referred to as “direct vat set” or “direct vat inoculation”) are routinely used in industrial operations. The use of single strains has the advantage of defined and reproducible metabolic properties; however, single strains rapidly succumb to phage predation unless appropriate measures are taken (155, 156). Phage control relies on hygienic design and sanitation of cheese making operations to prevent dispersal of phages to the cheese milk and the buildup of phage populations in the cheese plant. Because phages of *Lc. lactis* and *Sc. thermophilus* are highly specific for their target strains, culture rotation prevents culture failure due to phage attack. After several consecutive days of using strain (or strain mixture) A, phages that prey on these strains are likely to accumulate; timely switching to strain (or strain mixture) B with a different phage sensitivity prevents starter failure. Defined strains are additionally selected for phage resistance, making use of the mechanisms of phage resistance in lactic starter cultures (Fig. 33.17) (155, 156). Restriction-modification systems and phage resistance by abortive infection are often plasmid encoded and transferable; phage resistance mediated by clustered regularly interspaced short palindromic repeats (CRISPR)-Cas systems is considered the bacterial “immune system” against phage attack and is trained by successive exposure to diverse phages (Fig. 33.17) (155, 156).

CRISPR spacers that direct the Cas endonuclease to hydrolyze incoming phage DNA are added after a phage attack and provide resistance to subsequent attacks by the same phage (156).

Table 33.7. Microbiotas of cheese fermentations[a]

Process	Organism	Characteristics	Products (examples)
Primary acidification Mesophilic	*Lc. lactis* subsp. *Lactis*	Citrate utilizing (biovar diacetylactis D cultures) or not (all other biovars, O cultures)	Gouda, Cheddar, Camembert
	Lu. mesenteroides	Heterofermentative and citrate utilizing (L cultures)	
Thermophilic	*Sc. thermophilus*, *L. delbrueckii*, *L. helveticus*	Homofermentative and thermophilic	Parmesan, Emmental, mozzarella
Secondary/adjunct cultures Propionibacteria	*Pr. freudenreichii*, *Pr. acidipropionici*	Formation of CO_2, acetate, and propionic acid	Emmental (Swiss cheese), other cheeses with eyes
Molds	*P. roqueforti*	Blue mycelium, formation of methylketones	Roquefort, Stilton
	P. camemberti	White mycelium	Camembert and Brie
	G. candidum	White mycelium, formation of *S*-methylthioesters	Camembert, red smear cheese
		All are lactate utilizing, proteolytic, and lipolytic	
Nonstarter lactic	*L. plantarum*, *L.*	Proteolysis and	Long-

acid bacteria	*paracasei*, *L. rhamnosus*, *Enterococcus* spp., others	peptide hydrolysis, conversion of glutamine to glutamate; glutamate dehydrogenase, formation of diacetyl, strain-specific amino acid decarboxylation	ripened cheeses, including aged Gouda, Cheddar, Parmigiano Reggiano, Pecorino
Rind biofilms	*Br. linens*, *Staphylococcus* spp., *Corynebacterium* spp.	Proteolysis, lipolysis, formation of red pigmented biofilm	Limburger, Münster, Oka, Tête du Moine
Spoilage microbiota Early blowing	*Enterobacteriaceae*	Gas production and formation of small, irregularly shaped holes early during cheese ripening	
Late blowing	*Clostridium butyricum*	Gas formation and rupture of the cheese curd late in cheese ripening	Swiss-type cheese
	L. wasatchensis	Gas formation and rupture of the cheese curd late in cheese ripening	Cheddar

[a] Organisms that are used in starter cultures are underlined.

During cheese ripening, the viable cell counts of the primary mesophilic or thermophilic acidification culture decrease, and other lactic acid bacteria—nonstarter lactic acid bacteria (NSLAB)—grow in the cheese curd to high cell counts (157). Growth of NSLAB occurs more rapidly in cheese made from raw milk than in cheese made from pasteurized milk (146). The composition of NSLAB is more heterogeneous than the

composition of starter cultures; nomadic organisms of the *L. plantarum* and *L. casei* groups are frequently encountered in high cell counts, but *L. curvatus*, heterofermentative lactobacilli, including *L. brevis*, and *Enterococcus faecium* also occur (157). Owing to their important role in cheese quality, NSLAB can be included as adjunct cultures in starter culture preparations.

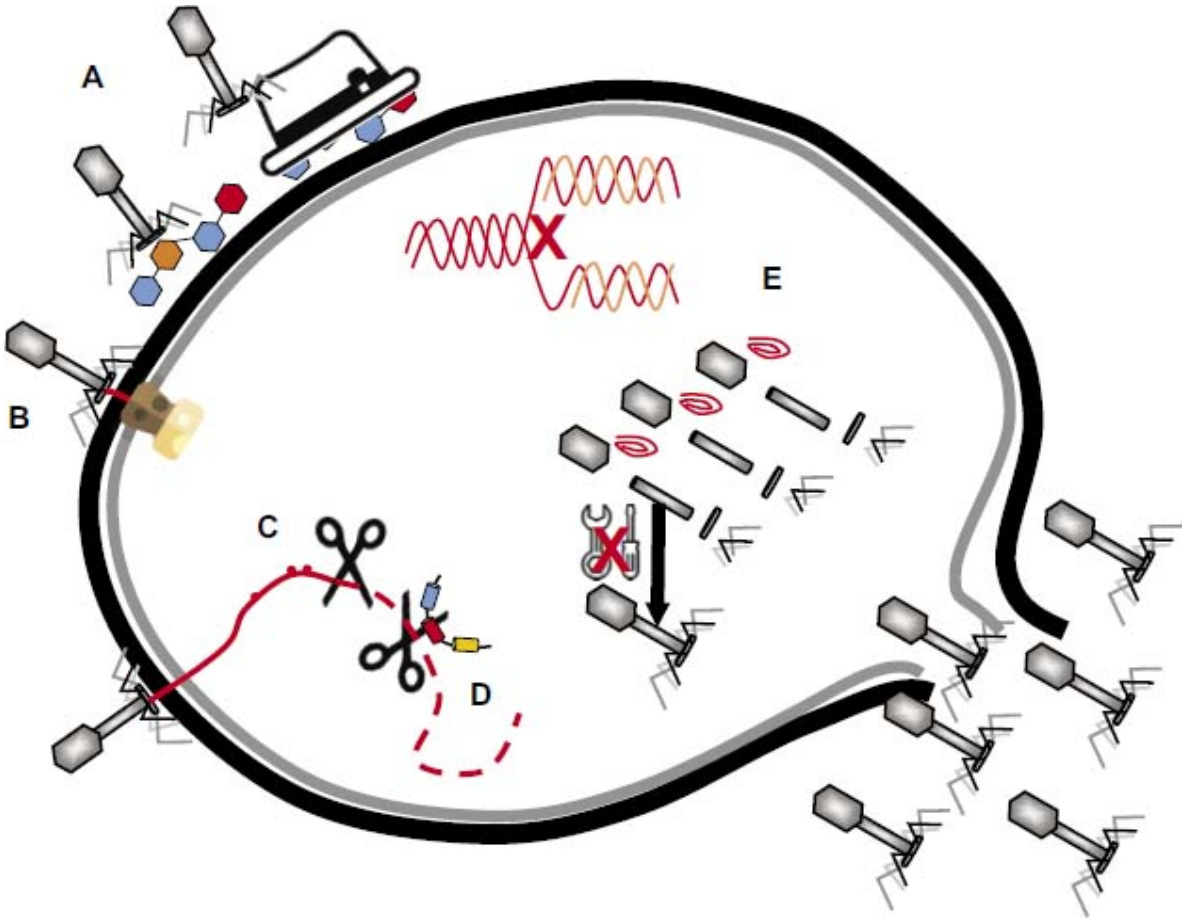

Figure 33.17. Mechanisms of phage resistance in dairy starter cultures. (A) Inhibition of adsorption by masking or modification of the phage receptor, which is usually a surface polysaccharide. (B) Inhibition of transfer of phage DNA into the host cytoplasm by membrane-associated Sie-like proteins (*Lc. lactis* and *Sc. thermophilus*). (C and D) Cutting of phage nucleic acids by restrictionmodification systems, which recognize DNA methylation patterns, or by CRISPR-Cas systems, which recognize proto-spacer sequences of the phage DNA. (E) Inhibition of replication of the phage DNA or of phage assembly by abortive infection (Abi) systems. In *Lc. lactis*, 23 different Abi systems have been described; these are generally plasmid encoded and interfere with DNA replication, RNA transcription, or packaging of the phage DNA. Abi systems also lead to the death of the infected cell. Drawn with information from references 155 and 156 and icons from https://www.flaticon.com.

Gas formation in Swiss-type cheeses, including Emmental, is mediated by *Propionibacterium freudenreichii* (*Pr. freudenreichii*) and/or

Propionibacterium acidipropionici. Propionibacteria are present in low cell counts in raw milk or added as a minor component of the starter culture. These organisms are thermotolerant but not acid or salt resistant; accordingly, heating of the cheese curd to high temperatures and a low acid (pH >5) and salt (NaCl < 1%) content favor their development. *Pr. freudenreichii* lacks protease activity, and its growth is thus dependent on the proteolytic activity of the primary acidification culture (158). During production of Swiss cheese, development of propionibacteria is stimulated by ripening at 20 to 25°C in the first weeks of ripening.

Production of red smear cheeses includes ripening with a red-colored surface biofilm composed of yeasts, including *Debaryomyces* spp. and *Geotrichum candidum*, and bacteria, including staphylococci, members of the *Actinobacteria*, such as *Brevibacterium linens* and *Corynebacterium* spp., and halotolerant members of the *Gammaproteobacteria*, such as *Halomonas*, *Vibrio*, and *Pseudoalteromonas* (159–161). These biofilms develop naturally unless the cheese rind is washed regularly or dried to a low water activity. Red smear cheeses are inoculated by smearing on the surface of the cheeses. Yeasts are the trailblazers of red smear communities, as they consume lactate; the concomitant increase of the pH supports growth of bacterial members of red smear communities (161). Community assembly of red smear microbiotas is not influenced by geography but is dependent on the moisture and, to a lesser extent, the pH of the rind (161). Halophilic Gram-negative bacteria may be introduced into the cheese rind from sea salt (161); many Gram-positive members of biofilm microbiotas, including staphylococci, *Brevibacterium*, and *Corynebacterium*, are commensal or opportunistic pathogenic members of human skin microbiota (162, 163).

Ripening with surface mycobiotas is achieved by inoculation with *P. roqueforti* or *P. camemberti* and incubation at 10 to 15°C and high relative moisture; both fungi may occur in association with *G. candidum*. Spores or the fungi are added directly to the cheese milk or applied to the surface of the cheese.

Growth of *Enterobacteriaceae* in the first 24 to 48 h of ripening of white brined cheese from raw milk leads to gas formation (early blowing defect). Early blowing usually relates to slow acidification by the starter

culture (147). Late blowing is attributed to growth of *Clostridium butyricum* or *Clostridium tyrobutyricum*. Conditions that favor growth of propionibacteria (high temperature, high pH, and low NaCl levels) also favor growth of clostridia; therefore, this defect is most common in Swiss cheese (164). Contamination of cheese milk with clostridial endospores is prevented or reduced by excluding silage from the feed of dairy cows or by centrifugation of cheese milk to remove spores; alternatively, nitrite or lysozyme is added as a preservative to prevent clostridial growth (146, 147). Late blowing in Cheddar cheese is caused by the heterofermentative organism *Lactobacillus wasatchensis*, which uses residual galactose and pentoses to produce CO_2 and acetic acid. Growth of *L. wasatchensis* in cheese is related to contamination of silage and to the use of *Sc. thermophilus* as an adjunct culture in cheese making. Different from *Lc. lactis*, lactose metabolism by *Sc. thermophilus* accumulates galactose, which is later used by *L. wasatchensis* (165).

The low pH and water activity of ripened cheeses inhibit growth of *Listeria monocytogenes* (166); however, respiratory metabolism of surface mycobiota consumes lactate and increases the pH of the cheese surface, providing an opportunity for *L. monocytogenes* to grow if it is present as a contaminant from raw milk or the cheese processing environment (147).

Impact of Fermentation Microbiotas on Product Quality

Unripened cheese curd has a neutral or slightly acidic taste and odor; these are determined by proteolysis and lipolysis during cheese ripening and by microbial formation of odorants (146, 147).

Carbohydrate metabolism early during cheese ripening reduces the lactose concentration to negligible levels; after a few weeks of ripening, cheese is virtually lactose free. Conversion of citrate by DL cultures or by adjunct cultures results in gas formation and production of diacetyl and acetoin, which are major flavor compounds in most long-ripened cheeses. Diacetyl production by adjunct cultures exceeds the production by *Lc. lactis* (167). Acetate accumulates to lower concentrations than lactate; however, because acetate also has a lower taste threshold, its contribution to the sour and salty taste is approximately equivalent to

that of lactate (168). Propionibacteria in Swiss-type cheeses metabolize lactate to propionate, acetate, and CO_2; cometabolism of aspartate and lactate enhances growth and CO_2 production and accumulates succinates (Fig. 33.18) (169). Succinate as well as propionate contributes to the umami taste perception in Swiss-type cheeses.

In contrast to most other food fermentations, cheese milk has a low proteolytic activity. Plasmin is present in milk and cathepsins are present in somatic cells, but milk-derived enzymes are inactivated by pasteurization (147). Accordingly, microbial enzymes play a major role in protein degradation during cheese ripening. The proteolytic system of lactic acid bacteria consists of an extracellular protease; its expression is repressed by high concentrations of peptides in the growth substrate. Peptides are transported by di- or oligopeptide transporters and hydrolyzed by strain-specific intracellular peptidases (Fig. 33.19) (104, 170, 171). Lysis of the primary acidification culture during cheese ripening releases intracellular peptidases and thus increases their activity on casein and casein-derived peptides. Starter lysis and consequently proteolysis are accelerated by a dose of bacteriophages or bacteriocins that lyse the cells without interfering with acidification of the cheese milk. The use of proteolytic surface microbiota also accelerates proteolysis.

Amino acids are the major contributors to the sweet (Met), umami (Glu and Asp), and bitter (Ile) tastes of cheese (109, 168). α-Glutamyl peptides contribute to umami taste; γ-glutamyl dipeptides enhance the activity of sweet, salty, and umami tastants by interaction with the calcium-sensing receptor proteins that mediate signal transduction from the taste receptors to the nerve cells (109, 168, 172). γ-Glutamyl dipeptides are not released by proteolysis but produced by γ-glutamyl-transferases from milk, fungi, or heterofermentative lactobacilli (109, 148). Taken together, taste-active peptides provide a strong umami and salty taste to long-ripened cheeses, such as Parmigiano Reggiano and pecorino. Bitter-tasting peptides accumulate if the peptide accumulation and hydrolysis are unbalanced. The specificity of the protease used for treatment with rennet, the specificity of the extracellular protease of the starter cultures, and the extent of starter lysis during ripening influence the accumulation of bitter peptides (147, 173). The bitter taste defect of cheese is also impacted by the accumulation of umami tastants, which

can mask bitter taste (174). Lipase activity in cheese is derived from surface cultures, i.e., *P. roqueforti* or *P. camemberti*, or from traditional rennet pastes that are used in the manufacture of certain traditional cheese varieties, including Parmigiano Reggiano and Pecorino (147). Free fatty acids do not accumulate to concentrations above their taste threshold (168) but play a role as precursor compounds for flavor volatiles.

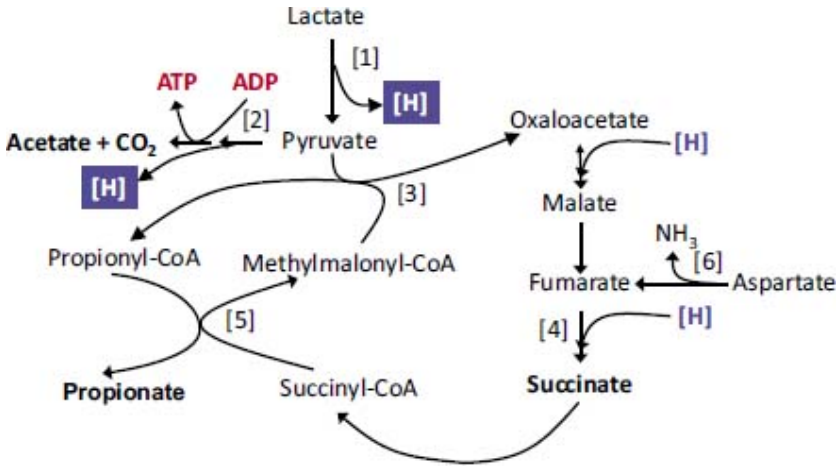

Figure 33.18. Lactate and aspartate metabolism by propionibacteria. The oxidizing branch of the pathway converts lactate to acetate and CO_2 via lactate dehydrogenase (1), pyruvate dehydrogenase (2), and phosphotransacetylase/acetate kinase. This branch generates 2 mol of NADH (indicated as [H]) and ATP. The reducing branch of the pathway (Wood-Werkman cycle) consumes 2 mol of NADH by conversion of pyruvate to propionate via oxaloacetate transcarboxylase (3), fumarate reductase (4), and CoA transferase (5). Fumarate reductase may be linked to an anaerobic electron transfer chain that contributes to ATP synthesis. Cometabolism of aspartate and lactate via aspartate-ammonia lyase (aspartase) (6) provides an alternative route for cofactor regeneration and accumulates succinate as the end product. The formation of reduced and oxidized cofactors (in white on a blue background and in blue, respectively) is indicated if it occurs upstream or downstream of relevant metabolic branching points; synthesis (in red) is shown to indicate the ATP yield of the metabolic pathway. Drawn using data from references 158 and 169.

Glutamate is a key intermediate for the conversion of amino acids to flavor volatiles (Fig. 33.20) (175). Transamination of amino acids with α-

ketoglutarate as the amino acceptor converts hydrophobic amino acids to yield glutamate and the corresponding α-keto-acids. Glutamate is recycled to α-ketoglutarate by glutamate dehydrogenase activity of lactobacilli; α-keto acids are decarboxylated to form organic acids, aldehydes, or alcohols, which contribute to cheese flavor. For example, leucine and isoleucine are converted to 2- or 3-methylbutanal and 2- or 3-methylbutanoic acid, which are major contributors to the flavor of long-ripened cheeses (176–178). In addition, conversion of methionine and cysteine by cystathionine-γ-lyase yields volatile sulfur compounds, including dimethyltrisulfide, with significant contribution to cheese flavor. The strain-specific decarboxylation of amino acids by NSLAB generates biogenic amines, particularly histamine and tyramine (147).

Short-chain (C_4 to C_6) fatty acids that are released from milk fat by lipolysis and their ethyl esters also contribute to cheese flavor. Metabolism of *P. roqueforti* converts fatty acids to methylketones—e.g., 2-heptanone, 2-nonanone, and 2-undecanone—which impart the characteristic flavor of blue cheeses. Surface ripening with red smear microbiota substantially expands the metabolic capacity of fermentation microbiota to convert amino acids to potent odorants, including short-chain fatty acids and *S*-methylthioesters (179, 180). The red to orange color of red smear cheese is imparted by carotenoids produced by *Brevibacterium* spp. (181).

FERMENTED EGGS AND FISH

Products and Production Processes

Fermented fish products are common in coastal regions of East and Southeast Asia and in Scandinavian countries. Fish and eggs have a relatively high pH and a low content of fermentable carbohydrates; additionally, deepsea animals accumulate high concentrations of lowmolecular-weight nitrogen compounds, such as urea and trimethylamine oxide, to protect proteins against cold and pressure denaturation (182). Microbial growth in eggs and fish thus leads to putrefaction and spoilage unless fermentation microbiota are controlled by addition of fermentable carbohydrates or salt or by reduction of the water activity.

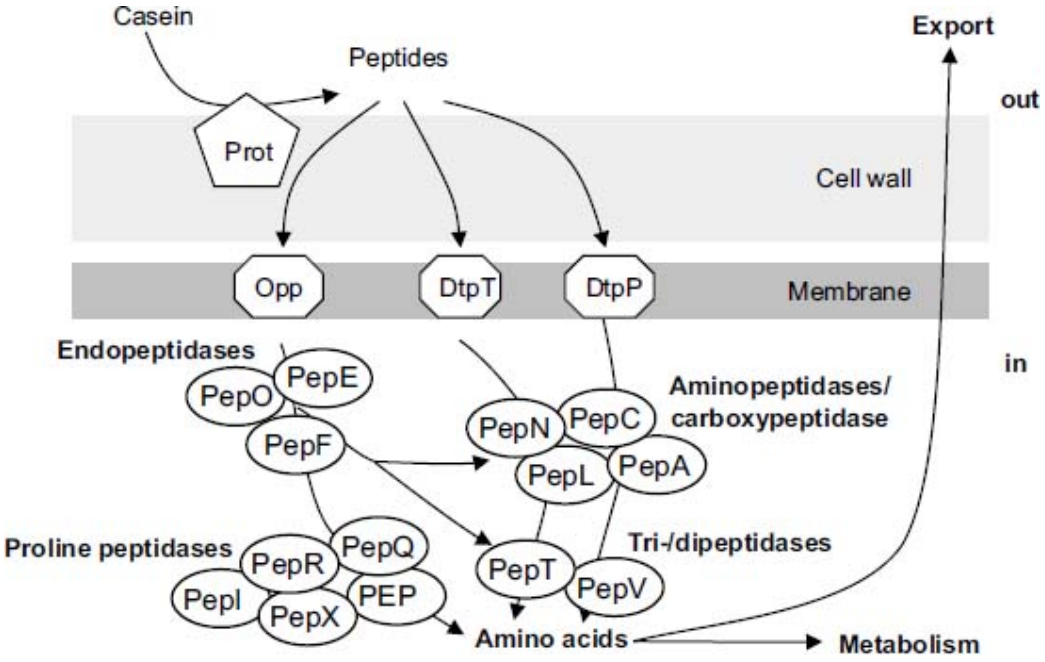

Figure 33.19. Proteolytic system of lactic acid bacteria. Protein degradation is initiated by extracellular and cell wall-bound proteases that are present in some lactic acid bacteria, particularly strains that dominate dairy fermentations, but absent in most species of lactobacilli. Peptides are transported by the dipeptide transporters DtpT and DtpP or the oligopeptide transporter Opp and hydrolyzed by a strain-specific array of intracellular peptidases. Drawn according to information from references 37, 104, and 170.

Fermentation of whole fish or fish pieces is achieved by mixing cleaned and gutted fish, fish pieces, or minced fish with cooked rice or corn and sucrose. Salt is added to a concentration of 3 to 5%; many products additionally include 5 to 8% garlic. Fermentation occurs at ambient temperatures of 20 to 24°C in Japan and China and about 30°C in Thailand, the Philippines, and Indonesia for days or weeks (183–186). Aji-no-susu produced in Japan has a higher salinity, 6 to 7%, and is fermented for several months (187).

In ancient Rome, a sauce called garum was produced from fish, including the intestines and the blood, by addition of salt and fermentation over several months (188). At the time, the price of high-quality garum was equivalent to that of expensive perfume. Its production has gone out of fashion since the fall of the Roman Empire (189), and it is unclear whether contemporary reproductions of garum

match the quality of the antique original (190). Fish sauces in Southeast and East Asia are produced by addition of 15 to more than 20% NaCl to control putrefaction; the production of fish sauce in Japan additionally includes barley koji as a source of carbohydrates and of proteolytic enzymes. Fermentation takes place for several months at ambient temperature; the resulting sauce or paste is used as a condiment (191–193).

Fermented fish products in Iceland, Norway, and Sweden include hákarl, rakfisk, and surströmming, respectively (194). For production of hákarl, washed pieces of shark meat are fermented in gravel pits for 3 to 6 weeks, followed by drying for several weeks or months. Rakfisk is produced from salmonoid freshwater fish, which is gutted, cleaned, brined to a salt concentration of 4 to 6%, and fermented and ripened at 4 to 10°C for several weeks. Surströmming is produced from Baltic herring, which is salted to a concentration of 5 to 10% NaCl and fermented at 15 to 18°C for 3 to 4 weeks before it is transferred to cans without a heating step (194).

Pidan, alkaline-fermented duck eggs produced in China, are produced by coating the eggs with a mud consisting of calcium oxide, water, and sodium carbonate, followed by fermentation for 20 to 30 days at room temperature (195). The alkaline pH (9.0) and the high osmotic pressure lead to gelation of egg white and egg yolk and to formation of FeS, which provides the characteristic green color (195).

Figure 33.20. Glutamine and glutamate metabolism in lactic acid bacteria. "[H]" indicates NAD(P)H-consuming or -generating reactions; individual enzymes are indicated by numbers and discussed below. Amino acids are taken up as peptides and cleaved by an array of intracellular peptidases; glutamate and glutamine are additionally transported by the Gln- or Glu-γ-aminobutyrate (GABA) antiporter GadC. (1) Glutamine is converted to glutamate by glutaminase of glutamine amidotransferases. (2) Strainspecific conversion of glutamate to GABA. (3) Heterofermentative lactobacilli convert glutamate to γ-glutamyl peptides via glutamyl-cysteine ligase. (4) NADH-dependent conversion of glutamate to α-ketoglutarate (αKG) by glutamate dehydrogenase is a strain-specific property of *L. plantarum*, *L. paracasei*, and other LAB. (5) LAB generally exhibit transaminase activity and convert αKG to glutamate in the presence of other amino acids as amino donors. (6) Heterofermentative lactobacilli convert αKG to α-hydroxyglutarate. The formation of reduced and oxidized cofactors (in white on a blue background and in blue, respectively) is indicated if it occurs upstream or downstream of relevant metabolic branching points; proton-consuming decarboxylation of deamidation reactions is on a gray background. Modified from reference 175.

Fermentation Microbiotas and Their Impact on Product Quality

An overview of fermentation microbiota in fermented fish products is provided in Table 33.8. Bacilli and staphylococci have been isolated from pidan, but their cell counts are too low to make a relevant impact on product quality (195). Hákarl is fermented by lactobacilli and organisms of the *Acinetobacter* and *Moraxella* groups. The organisms break down urea and trimethylamine oxide with a concomitant increase in pH; during the drying period, the bacterial counts decrease. The breakdown of urea and trimethylamine oxide is a main contribution of fermentation to improve the palatability of shark meat (194). Rakfisk is fermented with *L. sakei*; the changes in odor and color are attributed to autolytic enzymes (194). Fermentation of surströmming is attributed to strict anaerobic halophiles, including *Halanaerobium* spp., which produce odor volatiles, including propionic acid, hydrogen sulfide, butyric acid, and acetic acid (194).

Fermentation microbiotas of lightly salted fish with addition of starch, sugar, or garlic resemble the fermentation microbiotas of fermented meats (Table 33.8) with *L. plantarum* and *Staphylococcus xylosus* as dominant members of fermentation microbiota. Depending on the ambient temperature, thermophilic (*L. reuteri* and *L. fermentum*) or mesophilic (*L. brevis*) organisms are additionally present. Acid production in conjunction with addition of salt determines the safety of the fish products (185).

Table 33.8. Microbiota of fish fermentations[a]

Raw material	Control of fermentation microbiota	Products (examples)	Major fermentation organisms
Whole gutted fish or fish fillet	Addition of NaCl (3–5%), rice, sugar, and/or garlic	Suan yu (sour fish), narezushi, som fug, plaa-som	*L. plantarum*, *L. fermentum*, *L. alimentarius*, *Pc. pentosaceus*, *L. brevis*, *St. xylosus*, *D. hansenii*
Fish sauce from diverse raw materials	Addition of NaCl (15–26%); addition of koji (Japan)	Naam pla, shottsuru	*T. halophilus*, *Lentibacillus salicampi*, staphylococci, *Z. rouxii*
Trout	Addition of NaCl (3–6%), temperature (0–10°C)	Rakfisk	*L. sakei*
Shark	Low temperature, drying	Hákarl	*Acinetobacter*, lactobacilli

[a] Data are from references 183–187 and 194.

Fermentation microbiotas of fish sauce are controlled mainly by addition of salt; accordingly, the halophilic organism *T. halophilus* and the salt-tolerant organism *Z. rouxii* together are considered dominant members of fermentation microbiota (191–193); aerobic halophilic

bacteria, including *Lentibacillus*, may also be present (196). Protein degradation to generate taste-active peptides and amino acids is predominantly an autolytic process that is catalyzed by enzymes derived from the raw material; the addition of koji accelerates the ripening process (191).

FERMENTED MEATS

Production Processes

Fermented meats are produced from whole-muscle meat, ham, comminuted meat, or dry-cured sausages (Fig. 33.21). Dry-cured ham is produced predominantly from pork. Whole-muscle meat is initially preserved by dry salting with curing salt, brining, or injection of brine. The meat is maintained at refrigeration temperature until the salt concentration is equilibrated through the muscle to prevent growth of toxigenic clostridia. Nitrite or nitrate is used as a curing agent. After a NaCl concentration of about 4.5% has been reached throughout the product, corresponding to a water activity of < 0.96, the products are ripened at a low temperature (12 to 15°C). Depending on the climatic conditions, preservation and drying are supported by cold smoking; this step is usually omitted in Mediterranean countries with a dry climate. After the water activity is reduced to levels below 0.91, further drying and ripening are conducted at ambient temperature. Surface ripening with molds is used for some products, such as Tyrolean bacon. Process innovation in the production of dry-cured hams particularly relates to the salting/brining process. The use of pulsed electrical fields, pulsed pressure brining at 150 to 300 MPa, tumbling, or freezing of meat prior to salting or brining damages tissue integrity and thus accelerates salt diffusion during brining and proteolysis during ripening (197).

Dry-cured sausages are produced with comminuted meat and fat with addition of 2.5 to 3% NaCl, nitrite or nitrate, and spices. Ascorbic acid is added to reduce the formation of toxic nitrosamines from nitrite (198); the addition of glucono-δ-lactone reduces the pH without microbial activity (Fig. 33.21). The content of fermentable carbohydrates in meat is generally low, as glucose and glycogen are consumed in postmortem conversion to lactate by muscle tissue. Therefore, glucose or other

fermentable carbohydrates are added to control acidification during fermentation. The meat is comminuted at a low temperature, often with frozen ingredients, to avoid melting of the fat and coagulation of protein; removal of oxygen during meat cutting prevents lipid oxidation. The sausage batter is then filled into casings. The particle size of meat and fat after cutting and the diameter of the casing influences the water loss during ripening and the texture of the final products. The addition of NaCl and fermentable carbohydrates favors growth of lactic acid bacteria over other organisms that are present in the sausage batter. Lactic metabolism reduces the pH to values ranging from 4.8 to 5.3; acidification reduces the risk of growth of pathogenic bacteria, coagulates meat proteins to generate a solid sausage matrix, and reduces the water binding capacity. After a 2- to 3-day fermentation step at temperatures ranging from 18 to 30°C, products are dried at controlled water activity and temperature over a period of 2 to more than 6 weeks. During drying, the pH of the sausages increases due to amino acid metabolism of the fermentation organisms. If the surface microbiota contributes to ripening, lactate consumption by yeasts and fungi growing on the surface additionally increases the pH. Products are microbiologically stable when the water activity is 0.91 or less, or at a water activity of less than 0.94 and a pH of less than 5.3.

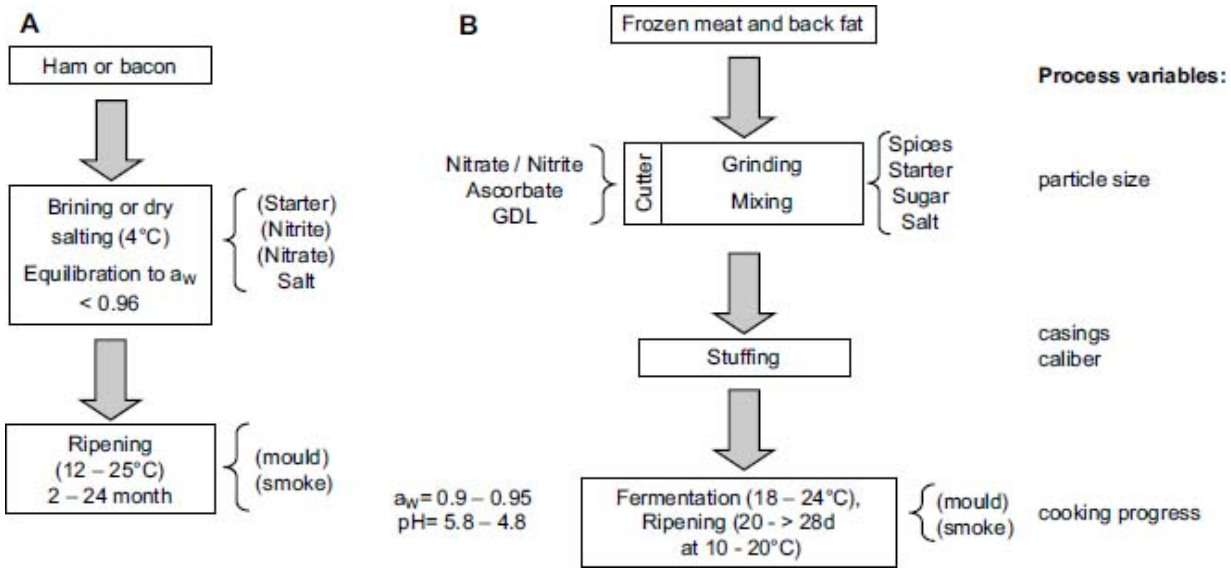

Figure 33.21. Basic processing steps for production of dry-cured ham (A) and dry-cured sausage (B). Ham is produced from whole-muscle pork meat; pork is also a major ingredient in sausage production, but product formulas may additionally include beef and/or horse and donkey meat. Sausages are generally cured with nitrite or nitrate, but not all hams are cured with nitrite or nitrate. Fermentation microbiotas in sausage production are introduced by back-slopping or by use of starter cultures or derived from house microbiota of the production facility.

Dry-cured sausages are generally not heated prior to consumption; therefore, pathogenic microorganisms, including *L. monocytogenes* and pathogenic strains of *E. coli*, *Salmonella*, and *St. aureus*, represent a hygiene risk. Control of pathogenic microorganisms during meat fermentations relies predominantly on the use of NaCl, nitrite, and competitive starter cultures to prevent growth. The risk of *L. monocytogenes* is additionally controlled by bacteriocin-producing starter cultures (199, 200); however, bacteriocins of lactic starter cultures are inactive against Gram-negative organisms (199, 201, 202). Enterohemorrhagic *E. coli* resists the fermentation and initial ripening steps; its safe elimination requires clean raw material, process control to prevent initial growth, and long ripening times (199, 203, 204). If ripening times are not sufficient to eliminate enterohemorrhagic *E. coli* (e.g., in production of summer sausage, which is fermented and ripened

at a relatively high temperature for a short time), a heating step is included after fermentation to control hygiene risks.

Products

Fermented meats are produced throughout Europe, the Middle East, North Africa, Southeast Asia, and North America. An excellent overview of dry-cured hams and bacon has been provided by Bosse et al. (197). The preservation of bacon and ham produced in Central and Northern Europe usually relies on smoking and relatively long ripening times of several weeks to a few months; examples include Tyrolean bacon, Black Forest ham, and jambon d'Ardenne. Reindeer ham is produced in the north of Finland by dry salting and smoking of boneless cuts of reindeer. Mediterranean products are typically ripened for 12 to 18 months and often cured without addition of nitrite or nitrate; typical examples include Parma ham (prosciutto di Parma), San Daniele ham (prosciutto di San Daniele), and Serrano ham (Jamón Serrano). Dry-cured meat products in Islamic countries of North Africa and the Middle East are produced from beef.

Dry-cured sausages produced in Mediterranean countries (Italy, Spain, and France), Hungary, and Turkey are typically dried to a water activity of less than 0.9, corresponding to a water loss of 25 to 40%. A majority of products are ripened with a surface mycobiota composed of yeasts and molds; the pH of these products can increase to 6.0 during ripening (205). Semidry sausages produced in Central and Northern Europe are ripened for a shorter time, 3 to 4 weeks. The water activity in these products ranges from 0.9 to 0.95, corresponding to a water loss of 10 to 20%, and the final pH of the products is typically below 5.2 (205). Surface treatment often includes smoking, and only a few products are mold ripened. Summer sausage in the United States, nham in Thailand, and nem chua in Vietnam are produced with short fermentation times at ambient temperature (25 to 40°C) (205, 206). The final pH of the products is between 4.5 and 5.0. Because the short fermentation times do not provide sufficient pathogen control, hygiene risks are controlled by a heating step after fermentation (summer sausage) or by inclusion of liberal amounts of garlic in the sausage formula (186, 206). Cured sausages with minimal or no fermentation and ripening are available in Germany (Mettwurst), Italy (sopréssa), and Spain (sobrasada); in these

products, the pH remains above 5.3 to prevent coagulation of meat proteins and the moisture loss is less than 10%. Hygiene risks in these products are controlled only by the procurement of clean, uncontaminated meat (205, 206).

Fermentation Microbiotas

Microbial growth on dry-cured ham is restricted to the surface of the product, where bacterial cell counts reach 10^8 CFU/cm2 (197, 207). The microbial diversity is reduced during ripening, and *Micrococcaceae* and *Staphylococcus* spp., including *Staphylococcus equorum*, *St. xylosus*, and *Staphylococcus saprophyticus*, account for a majority of the bacterial microbiota during ripening. The diversity of mycobiota increases during ripening and includes salt-tolerant yeasts such as *Debaryomyces hansenii*, *Candida* spp., *Penicillium chrysogenum*, and *Penicillium nalgiovense* (197, 207).

Dry-cured sausages are fermented with a combination of lactic acid bacteria and staphylococci or *Kocuria varians* (207) (Table 33.9). Rapid growth of lactic acid bacteria to cell counts ranging from 10^8 to 10^9 CFU/g is decisive for product quality and safety. Dominating lactic acid bacteria include, in decreasing order of importance, *L. sakei*, *L. curvatus*, and *L. plantarum;* high fermentation temperatures favor *Pediococcus pentosaceus* and *Pc. acidilactici* (207). *E. faecium*, *Lactobacillus paracasei*, *L. alimentarius*, *L. brevis*, *Leuconostoc* spp., and *Weissella* can also be present as minor components (207–209). The competitiveness of *L. sakei* in meat fermentations relates to its rapid growth at 15 to 25°C in the presence of NaCl (207); in addition, metabolism of pentoses, nucleic acids, and sialic acid and formation of heme-dependent oxidoreductases and bacteriocin have been suggested to contribute to its competitiveness (210–212). Growth of staphylococci in the meat matrix remains restricted to the outer layer, where oxygen remains available throughout ripening; cell counts range from 10^6 to 10^7 CFU/g and decline during ripening (205, 207). *St. xylosus* and, less frequently, *St. equorum* or *St. saprophyticus* are the dominant catalase-positive organisms, but numerous other coagulase-negative staphylococci, including *Staphylococcus carnosus*, *Staphylococcus*

epidermidis, *Staphylococcus sciuri*, and *Staphylococcus warneri*, are also present at lower cell counts (213).

Table 33.9. Major fermentation organisms in meat fermentations[a]

Group	Organism(s)
Lactic acid bacteria	Key organisms: *L. sakei*, *L. curvatus*, *L. plantarum*, *Pc. acidilactici*, *Pc. pentosaceus*
	Other organisms: *Enterococcus* spp., *L. paracasei*, *L. alimentarius*, *L. brevis*, *Leuconostoc* spp., *Weissella* spp.
Actinobacteria	*Kocuria varians*
Staphylococci	Key organisms: *St. xylosus*, *St. equorum*, *St. saprophyticus*
Other organisms: *St. carnosus*, *St. epidermidis*, *Staphylococcus pasteuri*, *St. sciuri*, *St. warneri*	
Yeasts	*D. hansenii*, *C. famata*
Molds	*P. nalgiovense*, *P. chrysogenum*, *P. camemberti*

[a] Organisms that are used in starter cultures are underlined. Modified from reference 207.

In traditional meat fermentations, fermentation organisms are derived from the raw material, ingredients, or "house microbiota" (i.e., organisms that persist in the production environment). Most industrial fermentations and many small-scale, artisanal fermentations are controlled by starter cultures to minimize hygienic risks, to prevent growth of fermentation organisms that decarboxylate amino acids to biogenic amines, and to ensure a uniform product quality (205, 207, 213). Starter cultures are added as freeze-dried preparations directly to the sausage batter. Their use enables control of fermentation microbiota throughout ripening (212, 214); however, the reduced bacterial diversity of sausages produced with starter cultures also relates to a reduced flavor intensity (212–214).

Surface microbiotas consisting of yeasts and mycelial fungi develop during ripening unless fungal growth is controlled by smoking or surface treatment with potassium sorbate. Yeast microbiotas are typically dominated by *D. hansenii*, an acid-tolerant and osmotolerant yeast, but other yeasts, including diverse *Candida* spp., have also been identified (215, 216). Mycobiotas on dry-cured sausages include *Penicillium* spp. and, less frequently, *Aspergillus* spp. (215, 216). Mycobiotas include mycotoxin-producing strains; the use of *D. hansenii* or the mycotoxin-negative *P. nalgiovense* as a starter culture controls growth of mycotoxin-producing fungi during ripening (204, 218).

Impact of Fermentation Microbiotas on Product Quality

Biochemical conversions during ripening of dry-cured ham are mainly attributable to muscle proteases and lipases. Hydrolysis of proteins to peptides is attributable to activity of cathepsins, calpains, and the 20S proteasome; of these enzymes, cathepsin D is the major contributor to proteolysis during ripening (219, 220). Muscle peptidases further convert peptides to amino acids; the umami-tasting glutamate and aspartate as well as alanine and proline (sweet taste) accumulate to concentrations exceeding the taste threshold (109). Peptides also contribute to the taste of ham; in particular, peptides with umami and kokumi taste activity contribute to the taste of the final product (109). Lysosomal lipases and phospholipases remain active throughout ripening and contribute to lipolysis (220). Surface mycobiotas contribute to proteolysis, lipolysis, and flavor formation (197). Bacterial metabolism is relevant mainly during brining. Growth of salt-tolerant and nitrite reductase-positive staphylococci in brine and on the surface of the ham increases nitrite concentration and enhances color formation by formation of nitroso-myoglobin (197, 221). Staphylococci also influence flavor formation through conversion of amino acids to flavor volatiles (197).

Acidification is the key contribution of lactic acid bacteria to the quality and safety of dry fermented sausages (Table 33.10). Rapid acidification coagulates meat proteins; therefore, it confers a firm texture to the sausages, favors nitrite disproportionation to nitrate and NO, and thus improves formation of the characteristic color of cured meats by nitroso-myoglobin and controls hygienic risks by inhibition of the growth of

pathogens and spoilage microbiota (198, 199, 205). Acid formation is controlled by fermentation parameters and the addition of fermentable carbohydrates to the sausage batter. Rapid acidification with pediococci in summer sausage or in Central and Northern European-style semi-dry fermented sausages (Fig. 33.1) also leads to acidity as a dominant part of the taste profile; in contrast, Mediterranean-style, long-ripened products have a less acidic taste (222). The formation of bacteriocins by lactic acid bacteria in meat fermentations contributes to control of *L. monocytogenes* and increases the competitiveness of cultures (199, 200, 212).

Staphylococci also express catalase and thus prevent lipid oxidation by peroxides that are formed by meat enzymes or in metabolism of lactic acid bacteria. Nitrate reductase activity of staphylococci or *Kocuria varians* is essential when nitrate is used as the curing agent but also supports formation of the typical color of cured meats if nitrite is used as the curing agent (Table 33.10). Nitrite reacts to nitrate and NO, which has a high affinity for the oxygen-binding site of myoglobin; the resulting formation of nitroso-myoglobin is responsible for the characteristic color and oxidative stability of cured meats (198, 205). NO also has strong inhibitory activity against clostridia, including *Clostridium botulinum*, while growth of other microorganisms, including lactic acid bacteria and *Listeria*, is not affected by nitrite. The specific inhibitory activity of NO against clostridia also relates to the high affinity of NO for iron proteins (223), which are essential components of the clostridial anaerobic electron transport chain (224).

Table 33.10. Contribution of microbial conversions to the safety and quality of fermented meats

Organisms	Metabolic pathway	Technological role
Lactic acid bacteria	Acid formation	Coagulation of meat proteins; enhanced disproportion of HNO_2 to NO and HNO_3; control of hygienic risks and spoilage microbiota
	Production of bacteriocins	Increased competitiveness; control of *L. monocytogenes* and spoilage microbiota
	Peptidase activity	Release of taste-active amino acids from peptides
	Decarboxylation of amino acids	Undesirable formation of biogenic amines from histidine, tyrosine, and phenylalanine
Staphylococci	Nitrate reductase	Reduction of HNO_3 to HNO_2
	Catalase	Removal of H_2O_2 to control lipid oxidation
	Amino acid metabolism	Conversion of amino acids to flavor volatiles
	Decarboxylation of amino acids	Undesirable formation of biogenic amines from histidine, tyrosine, and phenylalanine
Surface mycobiotas	Release of lipases and proteases	Formation of taste-active peptides and flavor volatiles
	Mycotoxin formation	Undesirable formation of mycotoxins
		Product-specific appearance is improved by formation of even and stable mycelium of desirable color.

Flavor formation during fermentation of dry-cured sausages also relies on muscle proteases and lipases as primary degraders of meat proteins and lipids (219, 220). The accumulation of amino acids in aseptic batches of meat and in lactic acid-fermented sausages is comparable, but strain-specific peptidase activities of lactic starter cultures contribute to the accumulation of amino acids (Fig. 33.19) (225, 226). The taste of dry-cured meats is mediated by organic acids and taste-active amino acids and peptides, particularly amino acids and peptides with umami and kokumi taste activity (109, 219, 220). Lipolysis, lipid oxidation, and the conversion of amino acids to flavor volatiles shape the odor of dry-cured sausages. Conversion of amino acids to flavor volatiles through the transaminase pathway (Fig. 33.20) is primarily attributed to staphylococci; the increased diversity of staphylococcal communities in traditionally fermented sausages thus corresponds to an increased production of flavor volatiles. Lactic acid bacteria produce organic acids, including acetate, and diacetyl (214, 222, 227, 228). Surface mycobiotas consume lactic acid, increase the sausage pH, and contribute to flavor generation by proteolysis and lipolysis; in addition, surface ripening controls lipid oxidation and leads to formation of flavor volatiles (227, 229).

Decarboxylation of amino acids by contaminants of the raw material prior to sausage production or by the fermentation microbiota results in accumulation of biogenic amines (204, 217). The presence of amino acid decarboxylases in lactic acid bacteria is strain specific; tyramine is usually the most abundant biogenic amine in dry-cured sausages. Staphylococci have a lower potential for amino acid decarboxylation (213). Fermentation control by decarboxylase-negative starter cultures reduces the formation of biogenic amines during sausage ripening (207, 217).

CONCLUDING REMARKS

Owing to the diversity of fermented food products, a chapter on fermented foods is invariably incomplete. Moreover, the study of food fermentations and fermenta fermentation microbiotas is closely linked to economic activity; therefore, production processes and fermentation organisms of many products that are produced in developing countries

are not well represented in the scientific literature and in this chapter. Many spots on the periodic table of fermented foods were filled in the last decade. Moreover, newly available sequencing technologies that allow a rapid assessment of the composition and activity of food microbiotas by high-throughput sequencing of bacterial 16S rRNA genes, genomes, and transcriptomes are a very powerful complement to classical culture-based methods. Sequencing technologies can guide the tedious but indispensable culture-dependent experimentation and application trials that provide the link between the presence and metabolic activity of bacteria in food fermentations and the quality and safety of fermented foods. This will not only maintain the diversity of fermented foods as affordable, nutritious, and tasty foods and as part of our cultural heritage but also allow us to exploit processes and fermentation organisms from traditional fermented foods in novel food and nonfood applications.

Current Issues and Advances in Food Microbiology

Hua Wang Yang Zhou
Lu Zhang

34
Antimicrobial Resistance, Gut Microbiota, and Health

Antimicrobials have been broadly used in human medicine, agricultural production, and food processing. They are essential for ensuring human and animal health, as well as the productivity and safety of our food supply. Besides antibiotics, many natural or synthetic compounds, such as salt, alcohol, acids (e.g., lactic acid and acetic acid), bacteriocin, common synthetic preservatives, sanitizers, etc., also exhibit antimicrobial activities. The term "antimicrobial resistance," in a broad sense, describes the decreased susceptibility of a multitude of microbes to a broad spectrum of single or multiple agents, including the temporary or permanent ability of an organism and its progeny to remain viable and/or multiply under conditions that would otherwise destroy or inhibit the susceptible members of such organisms (1). Various antimicrobial mechanisms of resistance, whether to antibiotics, food antimicrobials (e.g., acids and bacteriocin), or disinfectants, due to permanent genetic and structural alterations or to temporary adjustment of metabolic machinery such as stress responses, formation of biofilms and spores, etc., directly contribute to the persistence of the microbes in the environment or, for pathogens, to infection in their host.

The rapid rise of antibiotic-resistant (ART) pathogens negates effective prevention and treatment of infections by antibiotics, causing serious losses in public health and social economy and societal panic on antibiotic resistance (AR). Despite the fact that antibiotics are not used in food processing, their broad applications in food animal, crop, and aquaculture production still impact the

food chain. For decades, it has been a common belief that the use of antibiotics in agriculture and medicine inevitably led to the AR problem seen today. However, scientific breakthroughs in the past decade have illustrated that AR is a more complicated issue, and a comprehensive understanding is essential for targeted strategies with productive outcomes. It thus becomes necessary to equip professionals in food science, microbiology, and public health with a comprehensive scope and updated knowledge, to better combat the major challenges to human society. This chapter summarizes important concepts and knowledge breakthroughs regarding AR and microbiota. This is an update of the chapter "Antibiotic Resistance" in the previous edition of this book (2) and thus includes content adopted directly without further citation.

SCIENTIFIC SCOPE

Pathogens, Commensals, and Microbiota

The immediate threat to medical therapy and the ultimate concern, with the public perception of an upcoming postantibiotic era, is the failure of ART pathogens to respond to normal antibiotic treatment. However, limiting the scope of research on AR to ART pathogens in past decades turned out to be a big mistake, as it missed a big part of the picture. Actually, pathogens represent only a very small percentage of the microbial population (microbiota), as commensal bacteria dominate in the host, food, and environmental microbiotas. It is now recognized that commensal bacteria have key roles in AR ecology, including emergence, enrichment, dissemination, and persistence (3–6). Due to their dominance in populations, it is more likely that AR-encoding genes emerged in commensals first and then spread to pathogens. Even though it was the general belief that after removal of the antibiotic selective pressure, the corresponding AR trait(s) would gradually be lost, scientific data obtained in the past couple of decades from studies of humans, animals, food, and the environment illustrated that this was not the case. Various

molecular stabilization mechanisms and niche fitness advantages have led to the persistence and even dominance of certain ART commensals and pathogens in the ecosystem. Thus, once ART pathogens have emerged and been detected, it is already too late to get rid of them. Therefore, shifting the role of the current government AR surveillance system, i.e., the National Antimicrobial Resistance Monitoring System (NARMS), by the Food and Drug Administration (FDA), Centers for Disease Control and Prevention, and U.S. Department of Agriculture (USDA) from ARTpathogen-oriented disaster reporting to a commensal microbiota-associated AR risk forecast system has become a pressing need (6, 7).

Foodborne Microbes, Gut Microbiota, and Health

Besides nutrients from digested foods, the human gastrointestinal (GI) tract is also home to as many as 10^{14} microbes, almost equivalent to the total number of cells in a human body. Conventional food intake, through foodborne microbes and food ingredients, serves as the most important avenue bridging the host and environment, constantly shaping the host gut microbiota. It is now recognized that in addition to helping digest foods, the gut microbiota has more important roles in host health. For instance, the gut bacteria modulate the maturation and maintain the normal function of the host immune system (8–11) and produce small molecules affecting brain function (12, 13). The profiles of gut microbiota further impact potentially serious infections by opportunistic pathogens such as *Clostridioides* (formerly *Clostridium*) *difficile* and vancomycin-resistant enterococci (14, 15), as well as energy metabolism of the hosts, contributing to growth promotion in food animal production and obesity in human beings (16–19).

Foodborne Antibiotic Residues, AR, and Gut Microbiota Dysbiosis

It is important to recognize that antibiotic residues and AR are two different concepts. The presence of trace amounts of antibiotics and other chemical residues in food animal, seafood, vegetable, fruit, and grain products is sometimes inevitable due to the environment to which products are exposed (e.g., water, soil, and air) and production practices. To ensure the safety of the U.S. food supply, government agencies have established practices to limit hazardous compounds in edible food products. The FDA has established tolerance levels for chemical residues including antibiotics (20), and the USDA's Food Safety Inspection Service and Agriculture Research Service have established standard practices and procedures for sampling and assessing the products.

The primary concern about the presence of chemicals, including antibiotic residues, in food products is the potential public health hazard posed by the compound or its derivative(s). For instance, the antibiotic chloramphenicol may increase the risk of childhood leukemia (21), and it has been detected in certain foreign seafood products stopped by the FDA from entering the food chain in the United States (22).

Although in theory, foodborne antibiotic residues might inhibit or kill susceptible bacteria and accordingly select for ART bacteria and disrupt the integrity of the gut microbiota, in reality, the levels of antibiotic residues in USDA-certified meat and poultry are very low. For instance, the FDA's established tolerance level for penicillin is 0.05 ppm (or 0.05 mg/kg) in uncooked, edible tissue of cattle, 0.01 ppm (or 0.01 mg/kg) in uncooked, edible tissue of turkey, and 0 ppm in all other meat, egg, and dairy products; the value is 0.01 ppm for negligible residues of ampicillin, a derivative of penicillin, in uncooked edible tissues of swine and cattle and in milk (20). Meanwhile, the MIC_{50}s of ampicillin are around 0.12 to 8 μg/ml for susceptible and 16 μg/ml for resistant strains of *Enterococcus* and 0.35 to 8 μg/ml for susceptible and 32 μg/ml for resistant Gram-negative bacteria, respectively (23). The antibiotic exposure that occurs through a normal, single-meal intake with 1 lb of meat is no more than 0.023 mg. For an adult with 5 liters of blood in the

circulation system, the resulting maximum plasma concentration is 0.0046 μg/ml, far below the effective concentration to inhibit sensitive bacteria and select for resistant populations.

In the GI tract, once the antibiotic residue is mixed with other foods as well as fluid in the stomach and intestine, its concentration in the food matrices also decreases to significantly below the MICs for susceptible bacteria. In addition, many antibiotics are heat sensitive; thus, their activities would be reduced by cooking. On the other hand, the therapeutic dosages of ampicillin, for instance, are 250 to 3,500 mg by the oral route or 250 to 500 mg by intramuscular or intravenous injection every 6 h, depending on the nature of the infection(s) (24). If fully absorbed, the therapeutic drug concentrations (50 to 700 μg/ml of plasma) are up to thousands of times of the MICs of susceptible *Enterococcus* and Gram-negative bacteria and 3 to 43 and 2 to 22 times of the MICs of ART *Enterococcus* and Gram-negative bacteria, respectively. While sufficient to inhibit and kill pathogens, the therapeutic drugs, especially when given by oral administration, also massively kill susceptible bacteria and further wipe out even the resistant subpopulation of bacterial groups with lower MICs, causing irreparable gut microbiota dysbiosis. The exposure through medical treatment by oral antibiotics is 4 to 5 log (10,000 to 100,000 times) greater than the exposure from conventional food intake. The data suggest that therapeutic antibiotic intake, especially oral administration, which directly exposes the gut microbiota to unnecessarily high concentrations of drugs, is the dominant, key driver for massive AR and gut microbiota dysbiosis, while the impact of the foodborne antibiotic residues is minimal. This conclusion is further supported by a ground breaking study by Zhang et al. (25), detailed below.

Drug Administration and Excretion Routes and Fecal Microbiota

Through a carefully designed experiment in a well-controlled mouse system, the Wang team discovered that mainstream oral antibiotic intake and drugs excreted through the gut are key drivers for the rapid surge of AR in feces as well as the disruption of gut microbiota integrity (gut microbiota dysbiosis). In mice that had been inoculated with a bacterial cocktail with three *Escherichia coli* strains carrying the ampicillin resistance-encoding gene bla_{CMY2} and then given the therapeutic dosage of ampicillin by mouth, the targeted marker bla_{CMY2} gene pool in feces increased very quickly and remained high throughout the treatment period. However, when the same drug dosage and 5-day treatment duration were used but the ampicillin administration was changed from oral to injection, the bla_{CMY2} gene pool remained same as those in mice in the placebo group throughout the treatment period, which was only 1/100,000 of the AR gene pool seen in mice receiving oral ampicillin. The data revealed that oral antibiotic administration, instead of the application of antibiotics itself, was the direct driver for massive AR in feces. Since the ART-bacteriumrich feces from billions of human beings and animals released to the environment represent the most impactful contributor to the environmental AR gene pool, the finding in fact suggested that the mainstream oral antibiotic intake is a key driver for the rapid surge of AR in the ecosystem. Consistently, the profile of the gut microbiota was disrupted by oral ampicillin but spared by intravenously injected ampicillin throughout the 5-day treatment period. Furthermore, certain changes in the gut microbiota (dysbiosis) due to oral ampicillin remained even 10 days after the antibiotic treatment was halted (25).

Drugs also differ in pharmacological properties. Thus the Wang team further tested tetracycline, a drug with significant excretion through the bile/gut and feces, versus ampicillin, which is mostly excreted through the kidney and urine. As expected, changing tetracycline administration from oral to injection reduced the side effects of AR and gut microbiota dysbiosis in mice, but the

mitigation was less than that in the case of ampicillin, since part of the injected tetracycline still ended up in the gut.

The knowledge breakthrough regarding key drivers was further supported by historical data. Penicillin has been broadly used worldwide since World War II, but massive resistance was not a problem until after the 1970s in industrialized countries and the 1990s in China, correlating well with the switch of mainstream penicillin administration from muscle injection to oral (derivatives) in the corresponding countries. Although this time point also overlapped with the broad applications of antibiotics in food animal production, the antibiotics have been given to animals predominantly by mouth through feed or water. The historical trends of many modern diseases associated with gut microbiota dysbiosis are further quite similar to that of AR.

The Wang team further illustrated the main contributions of the food chain to AR using the same mouse model. For mice without prior inoculation of the bla_{CMY_2}+ *E. coli*, the marker gene pool was not detected in feces through out the 5-day ampicillin treatment period, regardless of whether it was given orally or by injection (25). The result illustrated that without the foodborne ART bacteria as the seed, the 5-day antibiotic treatment was not sufficient for the development of the AR gene.

Therefore, the food chain primarily impacts AR ecology through (i) the emergence, enrichment, and spread of ART bacteria in the food production environment and (ii) the role of conventional food or feed intake as a critical avenue for spreading ART bacteria and AR genes to the human and animal hosts. Once ingested, the foodborne ART bacteria serve as the seed in the host GI tract, facilitating additional evolution, enrichment, dissemination, and persistence of AR genes and ART bacteria, independent of clinical antibiotic exposure. The AR-rich feces further affect the AR gene pool in water, soil, air, etc., and accordingly contaminate food and feed, swelling the AR gene pool through continued circulation among the

food (feed), hosts, and the environment, as different components of the ecosystem are closely connected (Fig. 34.1).

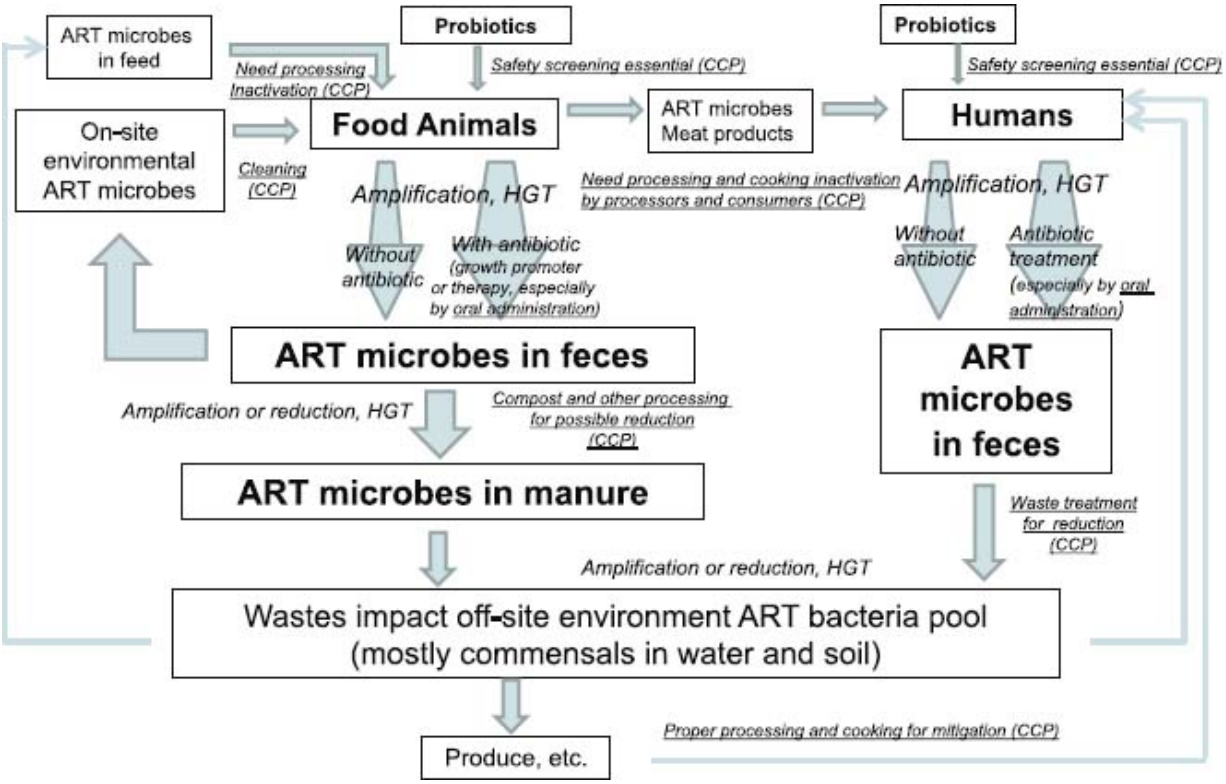

Figure 34.1. Flow of ART microorganisms from farm to fork. CCP, critical control point for mitigation.

Antibiotic Resistance, Health Care-Related Infections, and Biofilms

Difficult-to-treat hospital-acquired infections caused by ART pathogens and opportunistic pathogens, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci, have captured public attention. In 2003, over one-quarter of nosocomial (health care-related) enterococcal infections were resistant to vancomycin, and almost 60% of health care-related *S. aureus* infections were caused by MRSA. These represent 12% and 11% increases, respectively, in resistance compared to the previous 5-year averages (26).

However, it is essential to recognize that the failure of health care-related infections to respond to antibiotic treatment in the clinical environment is not necessarily due to the direct application of antibiotics during the treatment. In fact, data from Massachusetts General Hospital suggested that improving sanitation significantly reduced health care-related infections, including those caused by ART pathogens. Thus, health care-related infection is more of an issue of cross-contamination followed by selective enrichment, and simply limiting the uses of antibiotics in disease prevention and treatment is not the right solution. Knowing the difference is essential for targeted controls.

It is further important to recognize and differentiate multiple mechanisms which contribute to the lack of response of bacteria to various antimicrobial treatments, including antibiotics. For instance, when microorganisms attach to surfaces and tissues, they can form complex and protective structures called biofilms. While planktonic (floating) cells are easy to suppress or kill with antimicrobial agents, biofilms are resistant to adverse environmental factors, including antibiotic treatment. The formation of biofilms is a leading cause of many persistent and even deadly diseases, regardless of whether AR genes are present. Therefore, it is much more productive to use antibiotics promptly for disease prevention and treatment, instead of waiting until minor infections turn into serious diseases involving biofilms that are naturally resistant to any treatment, including antibiotics.

RELATED BACKGROUND AND IMPORTANT CONCEPTS

Types of Antibiotics

Depending on the mode of action, antibiotics can be categorized into bactericidal and bacteriostatic agents. Bactericidal antibiotics normally target key cell structures and activities, such as the biosynthesis of cell wall (β-lactam antibiotics) and DNA

(fluoroquinolones), whereas bacteriostatic antibiotics commonly interfere with protein synthesis, inhibiting the proliferation of bacterial cells (27, 28). The three types of commonly used bactericidal antibiotics include the members of the β-lactam antibiotics family, the aminoglycosides, and the quinolones, whereas macrolides (including telithromycin), sulfonamides, and tetracycline are normally bacteriostatic antibiotics (29).

Bactericidal Antibiotics

β-Lactams

β-Lactam antibiotics are most commonly used in clinical therapy for infections. β-Lactam antibiotics are antibiotic agents containing a β-lactam in the molecular structure and are sometimes β-lactamase inhibitors (although β-lactamase inhibitors are not true antibiotics). β-Lactam antibiotics are bactericidal, interfering with the biosynthesis of the peptidoglycan layer in bacterial cell walls by irreversibly blocking penicillin-binding proteins, including carboxypeptidases, endopeptidases, and transpeptidases. Penicillin-binding proteins are a group of proteins that facilitate cross-linking of newly synthesized peptidoglycan to the existing cell wall structure (30, 31). Once treated with β-lactam antibiotics, susceptible bacterial cells develop a weak cell wall and are eventually subject to cell lysis. Four major classes of antibiotics and their derivatives belong to the β-lactam antibiotic category, including penicillin, cephalosporins, carbapenems, and monobactams. Based on their antimicrobial activities and antibacterial spectra, they can be further divided into different groups.

β-Lactamase inhibitors

Apart from the four families mentioned above, β-lactamase inhibitors are also recognized as β-lactam antibiotics. One of the most common mechanisms of resistance to β-lactam antibiotics in bacteria is furnished by genes encoding β-lactamase, which

hydrolyzes intracellular β-lactam molecules. To be most effective, β-lactamase inhibitors are administered together with β-lactam antibiotics to minimize the effects of bacterial resistance. β-Lactamase inhibitors are not true antibiotics but rather antibiotic enhancers (32, 33).

Aminoglycosides

Aminoglycosides are another type of bactericidal antibiotic. Their key structure includes an aminocyclitol ring, with different glycosidic linkages and side chains distinguishing the members of this family (34). Aminoglycosides affect bacterial cells by displacing cations such as Mg^{2+} and Ca^{2+} on the outer bacterial membrane, thereby disrupting membrane permeability. Moreover, aminoglycosides can also be bacteriostatic, as they impair growth of bacterial cells by binding to the 30S subunit of the bacterial ribosome, thereby inhibiting protein synthesis. Susceptible bacteria are primarily aerobic Gram-negative bacteria, such as *Klebsiella* spp. and *Pseudomonas aeruginosa*, whereas most Gram-positive bacteria and anaerobes are not susceptible to this antibiotic class (35). Representative members of the aminoglycoside group include gentamicin, kanamycin, neomycin, and streptomycin. This group of antibiotics is primarily used for treating infections on the skin surface and in the respiratory system and is normally combined with other types of antibiotics for clinical therapy.

Quinolones

Quinolones are also bactericidal, as they inhibit DNA synthesis in bacterial cells by binding to DNA gyrase and DNA topoisomerase, both of which are involved in DNA replication, transcription, and repair systems (36–38). Quinolones are effective against many types of Gramnegative bacteria, including *Klebsiella* spp., *E. coli*, *Salmonella* spp., and *Shigella* spp. (39). Ciprofloxacin, gemifloxacin, moxifloxacin, and trovafloxacin are examples of quinolone antibiotics.

Bacteriostatic Antibiotics

Bacteriostatic antibiotics inhibit the growth of bacteria rather than killing them. Intracellular nucleotide or protein synthesis is most commonly targeted by this type of antibiotic, and a broad spectrum of bacterial species are affected. For example, sulfonamides are competitive inhibitors of dihydropteroate synthase (40–42), an enzyme that plays a key role in folic acid synthesis. The lack of folic acid eventually leads to the breakdown of nucleotide synthesis and interruption of cell proliferation. Four groups of sulfonamides have been defined based on their modes of absorption and excretion. These include shortto medium-acting sulfonamides, long-acting sulfonamides, GI tract sulfonamides, and topical sulfonamides. Commonly used sulfonamides include sulfamethoxazole, sulfadoxine, sulfasalazine, and silver sulfadiazine Tetracyclines are different from sulfonamides in that they inhibit bacterial growth by impairing protein synthesis. This type of antibiotic blocks aminoacyl-tRNA by binding to the 30S subunit of bacterial ribosomes (43, 44).

Spectrum of inhibition

Tetracyclines can inhibit a broad spectrum of bacteria, including most Gram-positive bacteria and Gram-negative bacteria, aerobes, and anaerobes. Tetracyclines are divided into three groups depending on their pharmacokinetic characteristics. These include short-acting tetracyclines (oxytetracycline and tetracycline), intermediate-acting tetracyclines (demeclocycline), and long-acting tetracyclines (doxycycline and minocycline).

The macrolides and ketolides are another type of bacteriostatic antibiotic and are capable of binding to subunits of the 50S ribosome, thereby inhibiting transpeptidation and translocation during protein synthesis. Macrolides have a relatively broad antibacterial spectrum, especially against Gram-positive bacteria. Members of the macrolide family include erythromycin,

clarithromycin, dirithromycin, and telithromycin, and they are often used to treat infections of the respiratory tract.

Mechanisms of AR in Bacteria

Besides biofilms, bacteria can become resistant to specific types or groups of antibiotics in many different ways, which can be summarized as (i) innate resistance; (ii) reduction of the intracellular concentration of corresponding antibiotics; (iii) inactivation of corresponding antibiotics; (iv) mutations at binding sites of corresponding antibiotics; and (v) formation of additional metabolic pathways that compensate for the loss of key enzymes or substrates (caused by corresponding antibiotics) (45, 46).

Bacterial cells with innate resistance to a particular antibiotic naturally lack the molecule or pathway targeted by the drug; therefore, the drug has no effect on the survival of the microbes. Bacteria can also become resistant to antibiotics by reducing the intracellular concentration of the antibiotic, which can be achieved with a reduction of membrane permeability (decreased import) and adoption of efflux pumps (increased export). Gram-negative bacteria generally have better control over importing molecules, because their outer membranes have a smaller size exclusion limit than the peptidoglycan layer surrounding Gram-positive bacteria. Hydrophilic solutes diffuse into Gram-negative bacteria primarily through porins on the outer membrane. Bacterial mutants that lack porins may present a broad spectrum of resistance. Decreased permeability to chloramphenicol is regarded as a cause of resistance in *Haemophilus influenzae* and *Pseudomonas cepacia* (47, 48). In Gram-positive *Staphylococcus epidermidis*, glycopeptide resistance may result from overproduction of glycopeptide binding sites within the cell wall peptidoglycan (49). *Bacillus subtilis* mutants resistant to the protonophore carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) have altered membranes with reduced amounts of C_{16} fatty acids and increased ratios of iso- to anteiso-branches. The CCCP-

resistant mutants are crossresistant to other inhibitors, including 2,4-dinitrophenol, tributyltin, and neomycin (50).

Energy-dependent efflux pumps are another mechanism for reducing intracellular antibiotics in ART bacteria. The efflux pumps can be specific to single antibiotics, or they can export multiple antibiotics. For example, both multidrug-resistant pumps and tetracycline-specific pumps were discovered in tetracycline-resistant bacteria. The coordination of reduced membrane permeability and the presence of efflux pumps likely can contribute to high-level resistance to antibiotics. For example, it was determined that active efflux pumps, as well as a reduction in the amount of major porins, contributed to increased resistance to chloramphenicol in some *Enterobacter* strains (51). Antibiotic inactivation can be achieved by degradation or modification. An example of antibiotic inactivation is that brought about by β-lactamase, which is carried by many bacterial species. β-Lactamase inactivates the antimicrobial activity of β-lactam antibiotics by hydrolyzing the β-lactam ring in these antibiotics. Currently four types (classes A, B, C, and D) of β-lactamases are recognized, and each type possesses its own characteristic nucleotide and amino acid sequences. Some lactamases confer resistance to various β-lactam antibiotics, whereas others are responsible for resistance to a single type of β-lactam antibiotic. Many types of β-lactamases are also resistant to a variety of β-lactamase inhibitors. In some situations, antibiotics are not degraded but are modified by resistant bacteria. For example, aminoglycosides can be modified by bacterial phosphotransferase and acetyltransferase, thereby losing their capability to bind the ribosome subunit (52, 53). Chloramphenicol is inactivated by acetylation, which is catalyzed by the chloramphenicol acetyltransferase of resistant bacteria (54).

Resistant bacteria can modify aminoglycosides by a variety of enzymes, including acetyltransferases, nucleotidyltransferases, and phosphotransferases (53). Another strategy for gaining resistance is to modify (mutate) antibiotic recognition sites on the intracellular structure or enzymes of bacterial cells, so that the corresponding

antibiotics cannot recognize them. This mechanism is involved in the development of resistance to many types of antibiotics, such as quinolones (mutations on target sites in DNA gyrase), tetracycline, and macrolides (mutations on corresponding ribosome subunits) (46, 54). The formation of alternative metabolic pathways is responsible for resistance to some antibiotics that target critical metabolic activities of bacterial cells. For example, sulfonamides are effective against bacteria by competing with *para*-aminobenzoic acid, a substrate involved in folic acid synthesis, which is critical for nucleotide production. Bacteria can inhibit sulfonamide activity by producing additional *para*-aminobenzoic acid, which has been observed in many sulfonamide-resistant bacteria (55).

In summary, various mechanisms have been adopted by bacteria to provide resistance to different types of antibiotics. Depending on the mechanism, resistance to antibiotics can be low, medium, or high level. Bacteria can be resistant to a single antibiotic or become multidrug resistant via one or multiple AR mechanisms. Liu and Pop (56) created the Antibiotic Resistance Genes Database by compiling publicly available information. The database includes annotation of each AR gene and resistance type, with information on AR profile, mechanism of action, ontology, and external links to sequence and protein databases. The database also supports sequence similarity searches and has a tool for characterizing common mutations conferring AR. The site provides useful information for AR prevalence studies and for identification and characterization of resistance mechanisms.

Resistance Due to Point Mutation and AR Genes

Spontaneous mutations occur at different rates in different organisms, regardless of the presence of antibiotics. The reported frequency of mutation ranges from 10^{-6} to 10^{-10} per bacterial generation (57). Usually, it takes a long time to accumulate enough mutations for new AR genes to evolve. Once genes or gene clusters encoding specific AR mechanism(s) emerge, however, they can be

spread quickly through horizontal gene transfer (HGT). However, single mutations in certain genes can lead to resistance to certain antibiotics. For instance, certain point mutations in the *gyrA* gene can lead to fluoroquinolone resistance (58).

Generally, without the selective pressure from antibiotic usage, the mutants would account for only a very small portion of the total bacterial population and generally would not be detected. However, antibiotic usage selects for ART populations. Some data also indicate that certain ART bacteria have a survival advantage, which may become dominant even without the corresponding selective pressure, such as the fluoroquinolone-resistant isolates of *Campylobacter* with a point mutation in the *gyrA* gene (58). Data also suggest that constant exposure to inhibitory levels of antibiotics may increase the mutation rate in bacteria and lead to multidrug-resistant offspring (59).

Assessing AR Determinants and the Antibiotic Resistome

The molecular mechanisms of AR involve many different facets of bacterial cell function. Identification and assessment of AR determinants in bacteria exhibiting phenotypic resistance to a specific antibiotic(s) are important for fundamental and clinical research. The rapid development of PCR and sequencing techniques facilitates high-throughput analysis of AR due to genetic changes. Identification and quantification of a limited number of known AR genes can be conducted via conventional PCR and real-time quantitative PCR. However, several different AR genes may cause the same AR phenotype, and it is not uncommon for an ART bacterial strain to exhibit several AR phenotypes. The comprehensive information concerning all the AR genes and their precursors is called the antibiotic resistome.

The analysis of the antibiotic resistome in the ART bacterial genome or in environmental or host samples requires high-throughput sequencing, data processing, and AR gene database-dependent

analysis. The Antibiotic Resistance Genes Database and the Comprehensive Antibiotic Resistance Database are among the earliest AR gene databases (56, 60). Newly developed databases such as Structured Antibiotic Resistance Genes and DeepARG-DB are usually based on the former database but with improved accuracy and/or comprehensiveness (61, 62). AR genes located in gene cassettes are expected to be highly mobile. One advantage of the RAC database is that it provides information on integron-related AR genes (63). It is important to note that the detection of AR genes by molecular methods does not translate directly to an antibioticresistant phenotype, which can be validated only by using live cultures. Some AR determinants may share significant homology with structure genes, while other AR-encoding genes may be silent or may have lost activity during evolution. Therefore, false positivity by molecular detection is not unusual. On the other hand, the databases include only genes with confirmed AR function. They may not include newly evolved genes conferring an AR phenotype, so false-negative results are not unusual either. Functional genomics has been adopted to tackle both challenges of false positives and false negatives (64).

Transmission of AR in Bacteria

Resistance to antimicrobials can be due to genetic and structural changes or temporary adjustment of metabolic machinery. AR due to genetic changes can be transmitted to progeny by vertical transmission and to other susceptible bacteria by HGT. Resistance due to a particular mode of living or stress response is transient and is not transferable.

Vertical Gene Transmission

Both mutated genes (resulting from mutations in genes encoding the antibiotic recognition site, alternative metabolic pathways, membrane porin/efflux pump, or antibiotic degradation systems, etc.) and acquired AR genes can be transferred by vertical transmission to offspring during bacterial growth.

HGT

HGT mediates the spread of resistance determinants (AR genes) to susceptible bacterial cells, most likely by mobile gene elements, such as plasmids, transposons, and integrons (65). The transfer can occur via conjugation, transformation (uptake of free DNA), and transduction. In contrast to the time-consuming mutation accumulation process, resistant units can be disseminated rapidly among microorganisms, within or across species and genera, via HGT events; therefore, HGT mechanisms play a key role in the rapid emergence of AR in microbial ecosystems. It is worth noting that the immunity gene(s) in antibiotic-producing microbes that protects the organisms from the antimicrobial compound (if applicable) can potentially serve as an AR determinant(s) if acquired by others.

Three important mobile gene elements (plasmids, transposons, and integrons) are involved in HGT more commonly than others. A plasmid is a type of circular DNA that self-replicates independently of chromosomal DNA. Plasmids may carry beneficial genetic traits, such as additional genes for metabolic activities, and can be readily transferred to another host bacterial cell via conjugation (66, 67). Various AR gene-carrying, evolutionarily related plasmids have been isolated from clinical, environmental, food, and human microfloras, indicating that plasmids are an important shuttle for disseminating AR in nature. A transposon is a type of mobile DNA element that can “cut/copy and paste” itself using a transposase enzyme. Once separated from its original position, a transposon can integrate into a specific or random site on genomic or plasmid DNA (68). Transposons often contain an AR gene, thus contributing to AR dissemination. An integron is a mobile DNA element with a site-specific DNA recombination system that is capable of recognizing and capturing mobile gene cassettes (69, 70). Depending on the content of the gene cassettes, integrons can be divided into AR integrons, which carry mainly AR genes and can reside on plasmid and genome DNA, and superintegrons (large genomic DNA

elements containing an array of genes that encode a variety of adaptive functions, such as virulence and metabolic activities). Resistance integrons are an important contributor to the dissemination of AR throughout the food chain. More than 70 AR genes have been detected in AR integrons, and a single integron may contain multiple AR genes. Compared with integrons, insertion sequences are small and compact DNA elements that primarily code for mobility (71). Once an insertion sequence contains an AR gene, it becomes a mobile vessel capable of disseminating the resistance genes within and between bacterial populations.

Common Natural HGT Mechanisms

Conjugation is the transfer of genetic material from donors to recipients through direct contact between the cells. Susceptible recipient cells may become resistant to corresponding antibiotics by acquiring an AR-encoding genetic element (plasmid or transposon) from the donor cell. The frequency of conjugal transfer of functional genetic elements is affected by both the genetic compatibility of the donor-and-recipient pair and the cell concentration.

Apart from conjugation, it is also possible to transform susceptible bacterial cells with cell-free DNA segments containing AR genes, leading to acquired resistance in these cells to the corresponding antibiotics. A bacterial cell able to absorb naked DNA and integrate it into the genome is called a competent cell, and the process is called transformation. The frequency of transformation is commonly low. However, given the high concentration of free DNA in certain natural and host environments, the intake of DNA by bacteria via transformation may be a critical route in modifying the microbial ecosystem in such cases.

Transduction is another form of HGT mediated by bacterial phages, during which DNA from the donor cell can be packaged into the phage by mistake and then transmitted to the recipient cells in the subsequent round of infection and eventually integrated into the host (recipient) genome or plasmid. Besides facilitating AR

dissemination, transduction also plays an important role in bacterial evolution. For example, DNA sequence data suggest that a bacterial phage likely was involved in the evolution of *E. coli* O157:H7, during which Shiga toxin-encoding genes were initially transmitted from another toxin-producing bacterium to an *E. coli* strain via bacterial phage infection (72). Due to the extensive involvement of transduction in the evolution of microbes, including pathogens, it is important to reevaluate the long-term safety impacts of phage-based intervention strategies intended to control foodborne pathogens.

AR IN THE FOOD CHAIN

Antibiotic Usage in Food Animal and Agriculture Production

The usage of antibiotics extends beyond human medicinal purposes. Antibiotics are used in food and aquaculture production to treat infected animals, prevent infection of animals potentially exposed to pathogens, and promote growth. To a lesser extent, antibiotics are also used in plant agriculture production to prevent diseases and improve productivity. Estimates of the combined total use of antibiotics, including human and animal use, vary widely. According to a recent report from the FDA, the total domestic sales and distribution amount of antimicrobial drugs approved for use in food animal production in 2015 was close to 35 million pounds (73). Thus, on a mass basis, agricultural practices, including therapeutic treatment, contribute a significant portion of the antibiotics introduced into the biosphere. The growth-promoting function of antibiotics is only partly understood and is the subject of heated debate (74–76). It is generally believed that the increasing prevalence of AR is directly related to increased antibiotic uses, both prudent and frivolous, in clinical and agricultural settings. Many argue that the widespread use of antibiotics at sub-therapeutic levels exacerbates the selective pressure that enriches microbial

populations for ART bacteria and suggest that growth promotion and disease prevention could be achieved through nonantibiotic alternatives and novel management practices (77, 78).

As a result of the debate, many European countries have discontinued the administration of antibiotics for growth promotion. Denmark essentially banned the use of antibiotics for growth promotion in food animal production in an effort to decrease the prevalence of antibiotic-resistant human pathogens. While the total use of antibiotics in animals in Denmark decreased by >30% from 1996 (before the ban) to 2001, there has been a 96% increase in the use of antibiotics for therapeutic purposes during the same period (79, 80). This makes it difficult to assess the impact of this mitigation strategy. A 2002 meeting of the World Health Organization assessing the impact of the Danish ban on growth-promoting antibiotics revealed that ART enterococci decreased. For example, resistance of *Enterococcus faecium* to virginiamycin declined from approximately 60% to 10% among isolates found on broiler meat from 1997 (the peak of virginiamycin use) to 1999 (when there was no virginiamycin use). However, the incidences of *Salmonella*, *Campylobacter*, and *Yersinia* infections in humans were not affected (79).

In the United States, organic farming is increasing in response to consumer demand. A small three-state study compared the rates of pathogen isolation in conventional swine production (indoor rearing) versus antimicrobialfree farms (outdoor rearing) (81). The prevalence of both *Salmonella* and *Toxoplasma* was statistically higher in the antimicrobial-free production systems, although it is not clear how long the antimicrobial-free farms were in operation or if they had always been antimicrobial free. In 2007, Cox et al. proposed a model that estimated the increased load of *Campylobacter* on chickens when animals were reared without antibiotics (82). Hence, the risks and benefits of antibiotic use in animal agriculture need to be carefully weighed. Regardless, FDA released a new rule in January 2017 to phase out the use of antibiotics to promote growth in food animal production.

Agricultural antibiotic usage extends beyond animal use but presumably occurs in other settings to a much lesser extent. In the United States, fruit plants may be sprayed with oxytetracycline and streptomycin. Since there are no surveillance systems for ART bacteria on crops, it is difficult to estimate the number of ART bacteria on plant products. Although evidence for the direct transfer of AR determinants between plant pathogens and human pathogens under natural conditions is lacking, an impact of plant antibiotic usage on the environmental commensal flora and, consequently, pathogens is anticipated.

There is very limited use of antibiotics in U.S. aquaculture. Only sulfadimethoxine, ormetoprim, sulfamerazine, and oxytetracycline are approved for use, although sulfamerazine is no longer commercially available. The extent of antibiotic use in other countries that export seafood and produce is unknown and presumed to be much higher. The presence of antibiotic residues is a common reason for seizure of imported seafood. As indicated by Cabello (83), the use of prophylactic antibiotics in aquaculture compensates for unsanitary or otherwise poor fish production practices. Antibiotics administered through fish feed can be deposited in the aquaculture animals and the environment and may select for AR in environmental flora. These microbes, in turn, can be further involved in AR gene dissemination. Cabello's review suggested that the AR determinants in *Salmonella* DT104 originated from fish pathogens and resulted from HGT. Heuer et al. (84) also described the human health consequences of antimicrobial use in aquaculture, noting the likelihood of transmission of drug-resistant pathogenic bacteria to humans from the aquaculture reservoir and the evidence for exchange of AR genes between fish pathogens and human bacteria. Briefly addressing risk management options, the authors mentioned that the use of effective vaccine strategies by the Norwegian salmon industry reduced by 99% the use of antimicrobials in aquaculture between 1987 and 2007, despite an increase in production.

However, a study conducted in a U.S. aquaculture farm without a history of antibiotic usage identified a broad spectrum of ART bacteria with various AR genes across the farm environment, the fish feed, and the fish products (85). A new tetracycline resistance gene isolated from fish intestine was further characterized (86). Similar results were also reported from other food animal production systems and products and even human infants with no direct exposure to antibiotics (6, 87). The data indicated that direct exposure to antibiotics is no longer the sole risk factor for AR. AR ecology is complicated by multiple risk factors, and ART bacteria have been circulating among the sectors within the connected ecosystem.

Foodborne ART Bacteria

In the past few decades, a variety of ART foodborne pathogens have been isolated and characterized. While it is important to realize the significance of the contribution of foodborne pathogens to foodborne illness, as mentioned previously, pathogens account for only a small percentage of the microbes associated with foods, with the number of foodborne ART pathogens being even smaller. Furthermore, raw meat and poultry are subjected to cooking before consumption, which effectively kills bacteria. Thus, the prevalence of ART pathogens in retail meat and poultry did not justify treating foodborne AR, nor its impact on AR ecology, as a significant food safety challenge. Since 2004, a series of studies revealed not only the prevalence but also the abundance of a broad spectrum of ART commensal bacteria in retail ready- to eat foods. A very large AR gene pool was identified in ready-to-eat products consumed without further processing, and the foodborne AR genes led to acquired resistance in human pathogens via HGT events (4, 88). These data clearly demonstrated that conventional food intake serves as a critical avenue for spreading AR to the public.

ART Foodborne Pathogens

Extensive research has led to an in-depth understanding of microbe-specific mechanisms in AR emergence, dissemination, and persistence, although only for a small number of zoonotic pathogens. An enhanced understanding of the differences in AR prevalence among pathogen species and serovars within the same genus is still beneficial. Such information may enable a better assessment of the relative contribution of different animal hosts and environmental factors, including selective pressure, to AR development and persistence for a given pathogen population. Furthermore, a comprehensive understanding of the relative contribution of pathogens in AR development in complex microbial ecosystems along the food chain, from the natural environment to acquisition by animal hosts, is needed for conducting a proper risk assessment and developing a well-targeted mitigation strategy. Several important foodborne pathogens as well as nonpathogenic *E. coli* strains and their resistance to antibiotics have been well documented.

Salmonella

Considering the large number of *Salmonella* serotypes (more than 2,500) and the differences in AR among different *Salmonella* serotypes, it is difficult to make generalizations regarding AR in *Salmonella*. This is compounded by differences that occur among *Salmonella* serotypes in the incidence of the human illnesses they cause. For example, the incidence of foodborne illness caused by *Salmonella enterica* serovar Typhimurium decreased by 40% between 1996–1998 and 2004, whereas *Salmonella* serovar Newport-related foodborne illnesses increased by 40% during the same period (89). Changes in serotype prevalence should be considered when trends in AR are examined, so that the potential impact of AR on human health can be evaluated in the context of pathogen prevalence. Despite the variation that occurs in AR, pathogenicity, and incidence of human illness associated with different serotypes of *Salmonella*, there are some general relationships that occur among *Salmonella* species and AR. AR rates

vary depending on the product (e.g., chicken versus turkey or layers versus broilers), country, year, and the type of antimicrobial. Gyles (90) proposed that differences in AR profiles observed among *Salmonella* serotypes in different countries or regions could be the result of dissemination of dominant *Salmonella* clones specific to these locations. However, in general, resistance to tetracycline and streptomycin in *Salmonella* is high, whereas ciprofloxacin resistance is usually low, if it exists at all. Resistance to extended-spectrum cephalosporins in *Salmonella* is of particular concern, because this class of antibiotics is commonly used to treat salmonellosis. Extended-spectrum-cephalosporin resistance is mediated by genes encoding β-lactamases. One gene, bla_{CMY2}, has been found in plasmids carried by *Salmonella* isolates worldwide. β-Lactamase-mediated resistance in *Salmonella* is encoded mainly by transposons and transmissible plasmids (91). Over the past several years, *Salmonella* serovar Newport MDR-AmpC, which is resistant to at least four additional antibiotics, has received much attention due to its epidemic spread. The bla_{CMY2} gene was identified in resistant isolates examined and was successfully transferred from a representative *Salmonella* isolate to *E. coli* by conjugation (92–94).

Campylobacter

In 2015, FoodNet identified 6,289 laboratory-confirmed infections by *Campylobacter*, corresponding to a rate of 12.82 per 100,000 persons in the United States (95). While sporadic cases are typically associated with poultry, outbreaks are most often associated with consumption of raw milk, unchlorinated water, and produce (96). Occasionally, a *Campylobacter* infection must be treated with antibiotics; erythromycin or a fluoroquinolone is most commonly prescribed, followed to a lesser extent by tetracycline and gentamicin. Fluoroquinolones are also used in animal agriculture in different countries. In the United States, fluoroquinolones had been used to control disease in poultry. However, the FDA withdrew in 2005 the approval of the fluoroquinolone enrofloxacin, marketed as Baytril, for use in poultry because the agency judged that

fluoroquinolone use in poultry increased the prevalence of fluoroquinolone-resistant *Campylobacter*, which potentially compromised the treatment of human campylobacteriosis (97). Resistance to fluoroquinolones in *Campylobacter* is due to a single chromosomal mutation in *gyrA* (98), unlike most other pathogens, which require multiple mutations for clinically relevant resistance. There appears to be no fitness cost associated with fluoroquinolone resistance in *Campylobacter*, and in fact, the mutation in GyrA confers a fitness advantage, increasing colonization of the pathogen in chickens (58). Resistance to fluoroquinolones can be detected shortly after exposure to the antibiotic. This is in contrast to resistance to macrolides, which requires repeated exposure to the antibiotic (98).

The macrolide erythromycin is also used to treat human campylobacteriosis. In a study using chickens colonized with the macrolide-sensitive species *Campylobacter coli* and *Campylobacter jejuni*, the effect of erythromycin dose on developing resistance was examined (99). One group of chickens was given a subtherapeutic dose of tylosin (a macrolide), and the other was given a therapeutic dose. Approximately 63% of the *Campylobacter* isolates were resistant to erythromycin after the subtherapeutic dose was administered, whereas only 11.4% were resistant among the isolates from the group treated with the therapeutic dose (99). This finding was consistent with the results of a laboratory study in which longterm use of subtherapeutic doses of tylosin, but not therapeutic treatments, selected for macrolide-resistant *Campylobacter* (100). It appears that *C. coli* has higher frequencies of macrolide resistance than *C. jejuni*; however, the reasons for this difference are unknown (98). Macrolide resistance in *Campylobacter* most commonly results from point mutations in 23S rRNA, which results in modifications to the antibiotic. Active efflux mediated by CmeABC is another mechanism that works synergistically with antibiotic modification in conferring macrolide resistance (98). Compared to other antibiotics, tetracycline resistance in *Campylobacter* is relatively high and is mediated by the *tet*(O) gene. The *tet*(O) gene

in *Campylobacter* is most often carried on a plasmid but occasionally is chromosomal. The protein product of this gene binds to the ribosome, protecting it from the inhibitory action of tetracycline (98, 101).

Shigella

When considering antibiotic-resistant *Shigella*, it is important to understand that humans, not food animals, are the host for this pathogen. Hence, human cases of shigellosis are not due to carriage of the pathogen in food-producing animals or to contamination of crops with manure from food animals. Human fecal contamination of food, either on the farm or during food preparation, is the root source of shigellosis. The infection is classified as a foodborne illness because food is often the vehicle (not the source) for transmitting *Shigella*. The NARMS has maintained a database of antimicrobialresistant enteric bacterial isolates from humans, food, animals, and fowl, including human *Shigella* isolates, since 1996. In 2010, most (81.8% of 407 isolates) of the *Shigella* species reported were *Shigella sonnei* (102), and most (91.2%) of the NARMS *Shigella* isolates were resistant to streptomycin; 40.8% were resistant to ampicillin; 48.2% were resistant to trimethoprim-sulfamethoxazole; 30.2% were resistant to sulfamethoxazole/sulfisoxazole; 31.7% were resistant to tetracycline; 10.1% were resistant to chloramphenicol; 4.4% were resistant to nalidixic acid; 1.7% were resistant to ciprofloxacin; less than 1% were resistant to gentamicin, ceftiofur, ceftriaxone, and ceftriaxone; and 0% were resistant to amoxicillin-clavulanic acid and kanamycin.

The emergence of cefotaximase-producing *Shigella* isolates in the United States has become a concern, because cefotaximase-type β-lactamases are among the extended-spectrum β-lactamases that confer resistance to extended-spectrum cephalosporins and significantly compromise shigellosis treatment options (102). A study by Wong et al. (103) on antimicrobial resistance trends among *Shigella* isolates from patients with shigellosis in New York City

between June 2006 and February 2009 revealed that 70% of 477 patients received an antibiotic for shigellosis, and 11% of these were treated with an antibiotic to which their *Shigella* infection was resistant. High levels of resistance against amoxicillin-clavulanate, ampicillin, and trimethoprim-sulfamethoxazole were found among these isolates, and resistance at a lower level to ciprofloxacin was also reported.

Listeria monocytogenes

Infection with *L. monocytogenes* is typically treated with a combination of ampicillin and aminoglycoside. Rates of AR in this pathogen have not been studied to the same extent as in other pathogens, such as *Salmonella* and *Campylobacter*. Because *L. monocytogenes* is considered widely distributed in the environment, it is not strictly a zoonotic organism and has not been considered problematic in terms of AR. Hence, it is not included in any of the NARMS surveys. Prazak et al. (104) reported that 95% of the *Listeria* isolates from cabbage and environmental or water samples in Texas were resistant to two or more antibiotics, with 85% of those being resistant to penicillin. More recent studies (105–109) have revealed that *L. monocytogenes* isolates from raw meat and a variety of retail foods in several countries outside the United States are ART. A study of food products in China reported multidrug resistance (i.e., resistance to ≥2 antibiotics) in 63.9% of 72 *Listeria* isolates and resistance to only one antibiotic in 19% of isolates (106). A study by Pesavento et al. (108) revealed that eight *Listeria* isolates were resistant to ampicillin and nine were resistant to methicillin. This finding is of note because ampicillin is used for treatment of listeriosis and *Listeria* can potentially transfer the methicillin resistance gene to *Enterococcus* spp., thereby compromising the treatment for *Enterococcus* infections. However, more likely the dominant commensal bacteria have played key roles in disseminating the AR genes. Yücel et al. (105) also reported *Listeria* resistance to ampicillin (five isolates), nalidixic acid (nine isolates), cephalothin (nine isolates), trimethoprim-

sulfamethoxazole (six isolates), and kanamycin (one isolate) among isolates from meat products in Turkey. Lyon et al. (110) examined the antimicrobial resistance profiles of 14 *L. monocytogenes actA* types (n = 157) isolated from a poultry processing plant and found that the prevalence of antimicrobial resistance among all *actA* types and the diversity within resistotypes were both low. All isolates were sensitive to the antibiotics used to treat listeriosis, and except for tetracycline, resistance was not related to type or lineage. In the same study (110), it was also observed that persistence of *L. monocytogenes* in a poultry processing plant was not related to antimicrobial resistance and that there was little difference in antimicrobial resistance variability between clinical and environmental isolates.

Escherichia coli

Pathogenic strains of *E. coli* may be among the more publicly recognizable foodborne pathogens, although only certain pathogens, such as enterohemorrhagic *E. coli* (e.g., *E. coli* O157:H7), cause illness. Human infections caused by enterohemorrhagic *E. coli* are not typically treated with antibiotics. This makes AR in these strains less practically relevant from a public health standpoint. However, when animal and human clinical isolates of *E. coli* O157:H7 have been tested for antibiotic susceptibility, resistance against tetracycline, streptomycin, and sulfamethoxazole is most commonly found. While the subject of innate stress resistance is outside the scope of this chapter, it is a noteworthy characteristic of *E. coli* O157:H7. A major outbreak of *E. coli* O157:H7 illness was associated with unpasteurized apple juice, an acidic product in which conventional knowledge regarding *E. coli* deemed that this pathogen would not survive. However, the enhanced ability of *E. coli* O157:H7 to survive acidic conditions by acid stress response mechanisms is an innate quality and has been confirmed in multiple studies (111–114). The vast majority of *E. coli* strains are nonpathogenic and are part of the natural microbiota of many animals, including humans.

E. coli organisms make up about 1% of the colonic microflora (115–117).

A European Food Safety Authority (EFSA) Community Summary Report (2010) on antimicrobial resistance in zoonotic and indicator bacteria from animals and food in the European Union from 2004 to 2007 indicated that resistance to antimicrobials was common among indicator (commensal) *E. coli* organisms, with resistance being greater among isolates from fowl and pigs than cattle and varying among fowl and pig isolates from the 20 member states providing information (118). In North America, Alexander et al. (119) investigated the effect of subtherapeutic use of chlortetracycline plus sulfamethazine, chlortetracycline, virginiamycin, monensin, and tylosin on the development of AR in *E. coli* in fecal samples from feedlot steers (n = 300) in Canada. They found that cattle not receiving antimicrobials prior to arrival at feedlots were carrying *E. coli* strains that were resistant to tetracycline and ampicillin and that clonal dissemination of ampicillin-resistant *E. coli* appeared to readily occur between animals within the same pen. They also found that administering subtherapeutic levels of chlortetracycline in combination with sulfamethazine increased the prevalence and cell numbers of tetracycline- and ampicillin-resistant *E. coli*, and tetracycline-resistant *E. coli* populations were higher in animals fed a grain-based diet than in those fed a silage-based diet. The investigators concluded that the GI and environmental factors influencing the development and dissemination of antimicrobial-resistant *E. coli* in feedlot cattle are complex and that other factors in addition to the use of antimicrobials need to be considered when assessing the acquisition of AR by bacteria, such as relationships between environmental stressors and AR genes.

Morley et al. (120) compared differences in AR between non-type-specific *E. coli* (NTSEC) isolates and *S. enterica* isolates recovered from pen floors of feedlot cattle in Colorado raised without exposure to antimicrobial drugs (40 pens and 4,557 animals) and those reared using conventional practices (44 pens and 4,913

animals). They determined that overall, the prevalence of resistance among all NTSEC isolates was very low (<1% for 9 of 15 drugs, 1 to 5% for more than 2 drugs, 6 to 15% for 2 drugs, and >15% for only 1 drug, including antibiotics of interest in zoonotic transmission to humans, e.g., potentiated penicillins, cephalosporins, quinolones, and aminoglycosides) and that conventional feedlot production methods predictably or uniformly increased the prevalence of antimicrobial resistance among fecal NTSEC isolates compared with rearing methods that restrict exposure to antimicrobial drugs. The investigators suggested that it is possible that the impacts of different antimicrobial drug exposures were overwhelmed by environmental exposures. Marshall et al. (115) concluded that although there is strong evidence for direct transfer of AR traits from animal- to human-associated microorganisms, there is still little direct evidence of transfer of resistance genes from animal-associated *E. coli*, *Bacteroides*, or *Enterococcus* spp. into comparable human microflora members, which subsequently resulted in ART infections.

The EFSA Community Summary Report indicated that *E. coli* is thought to be a reservoir of resistance genes that may be transferred to pathogens and that resistance in *E. coli* over time may serve as an "early warning system" for resistance in potentially pathogenic bacteria (118). However, recent studies have revealed that although nonpathogenic *E. coli* strains are commensals of the GI tracts of animals and humans, they are not the major and earliest carriers of AR genes in various ecosystems from foods to the human gut microflora (4, 87, 121). Hence, proper selection of an AR indicator should be based on a comprehensive understanding of the AR ecology, which is described below.

Staphylococcus aureus

Toxin production by large cell numbers of *S. aureus* causes foodborne illness; ingestion of the bacterium itself does not. There has been much publicity in the medical community and among the general public regarding MRSA. MRSA usually causes health care-

related infection rather than foodborne illness, although recent reports suggest potential zoonotic (or foodborne) transmission due to the finding of common genotypes in both animal and human MRSA isolates (122). However, since there are no reports of increased toxin production by MRSA, while this pathogen is of great clinical significance, its AR has no effect on staphylococcal food poisoning.

Foodborne Commensal Bacteria and AR

Although the idea that commensal members of the microflora might play an important role in the development of resistance in bacterial pathogens was raised at least 40 years ago, this concept did not receive serious attention and there was lack of strong scientific evidence supporting this hypothesis. From a regulatory agency's perspective, the immediate threat of AR to human health is due to pathogens, not commensals; therefore, studies on ART commensal bacteria have received minimal attention compared to AR of pathogens. In addition, AR was not considered a major health problem when new antibiotics were developed on a regular basis. Moreover, a technical challenge for microbiologists is the lack of methods to culture all the bacterial species in complex samples and determine gene transmission by such members of the microbiota to enable the measurement of the overall impact of unidentified commensal bacteria on AR dissemination. It has been much more direct to study mechanisms of AR in designated bacterial species, such as particular pathogens or opportunistic pathogens, including *Salmonella*, *Campylobacter*, *E. coli*, enterococci, etc., than in commensal bacteria. Therefore, for a long time, the influence of commensal bacterial populations on AR dissemination, and particularly the size and breadth of the resistant population and the spectrum of bacteria involved, has remained unknown.

Roles of Commensal Bacteria in AR Dissemination

Andremont (3) reported that horizontal transmission of AR genes between commensal and pathogenic microorganisms in ecosystems

is a much more likely event than direct gene dissemination from one pathogen to another. AR gene reservoirs in commensal microbes in various environmental and host ecosystems have been identified (123–128). Nandi et al. (124) determined that Grampositive bacteria, not Gram-negative members of the *Enterobacteriaceae* such as *E. coli*, served as a major reservoir of class 1 AR integrons in poultry litter. More specifically, Luo et al. (129) determined that an inherited, clumpingassociated high-frequency conjugation system, previously considered beneficial for disseminating fermentation-related traits in *Lactococcus lactis* (a beneficial bacterium known for its application in dairy fermentation), can enhance the transmission of a broad-host-range drug-resistant plasmid, pAM β1, more than 10,000 times in laboratory settings. Since similar clumping-associated high-frequency conjugation systems were previously detected in *Enterococcus*, *Bacillus*, and *Lactobacillus*, this finding likely has broad biological implications. This study revealed for the first time that commensal bacteria could serve as not only a reservoir of AR genes but also a facilitator of their dissemination. Furthermore, it indicates that beneficial bacteria, including fermentation starter cultures and probiotic microbes, are not exempt from AR gene dissemination.

Magnitude and Spectrum of the Commensal ART Bacteria

Data from the past decade have revealed that ART bacteria are prevalent in commercial cheese and other retail food products, including seafood, meat, poultry, produce, and delicatessen and restaurant foods (4, 88, 121). A survey conducted during 2004 to 2005 with samples from grocery chain stores in Columbus, OH, involving multiple types and brands of commercial cheese products revealed that most of the cheeses contained large numbers of ART bacterial cells, with *tet* and *erm* genes being detected in about 10% of the isolates assayed (4). As many as 10^7 copies of AR genes/g of food were detected in retail cheeses before 2007, and AR gene

carriers included a broad spectrum of commensal bacteria, including *Streptococcus thermophilus*, *L. lactis*, *Enterococcus* spp., and *Pseudomonas* spp., with some being used as fermentation starter cultures (4, 121, 130). Due to limitations of the cultivation conditions that were used, the reported data were likely an underestimate of the actual AR status of the commensal bacteria in the samples. Kastner et al. (131) also reported that starter culture and probiotic strains used in fermented dairy and meat products contained AR-encoding genes. A study by Durán and Marshall (132) revealed the existence of a broad spectrum of ART commensals and pathogenic bacteria in ready-to-eat shrimp products. Because many of these products were directly consumed without further processing, the data suggest that members of the public who consumed these products were often exposed to high levels of ART bacteria, including AR genes, even without being exposed to clinical antibiotic treatments. The use of new methods in lieu of the standard selective enrichment-based approach played a key role in more accurately assessing the extent of AR in the commensal bacterial population. For instance, instead of testing for antibiotic susceptibility of individual isolates, Durán and Marshall (132) applied an antibiotic disk diffusion method directly to food samples and successfully isolated a large number of ART bacteria associated with shrimp products. The resistant bacteria were further identified by gas chromatography fatty acid methyl ester and API tests, revealing a broad spectrum of ART commensal and pathogenic bacteria. Using a direct-plating method supplemented with DNA profiling techniques, such as 16S rRNA gene sequence analysis and denaturing gel gradient gel electrophoresis coupled with 16S rRNA gene fragment sequence analysis, the Wang research group isolated a wide variety of ART commensal bacteria from dairy, seafood, meat, produce, and delicatessen and restaurant foods (4, 88, 121). These new methods are also applicable to detecting ART bacteria in a variety of hosts and environmental ecosystems.

AR Amplification, Dissemination, Evolution, and Persistence in Microbial Ecosystems

Animal and human fecal wastes are by far the most significant sources of ART bacteria (124, 133, 134). However, contrary to common belief, the initial and rapid development of the ART bacterial populations in the host GI tract, at least in the case of Tet^r bacteria, likely no longer results from exposure to antibiotic treatment as well as food intake (135). Zhang et al. (87) reported that Tetr bacteria and a *tetM* gene pool developed rapidly within days following natural birth in the GI tracts of infants without their being exposed to antibiotic treatment. Bacteria resistant to additional antibiotics have also been found to be prevalent in infant fecal samples. The investigators concluded that the oral-nasal exposure to mother's vaginal and skin microbiota through natural birth and breastfeeding may be routes for seeding resistant bacteria in the GI tract. Furthermore, since the inoculated resistant bacteria were much less numerous than those excreted through feces, the resistant bacteria must have been significantly enriched in the gut, even without exposure to antibiotics (87). Stanton et al. (136) reported the abundance of chlortetracycline-resistant anaerobic bacteria in fecal samples from organically raised swine, but the number was significantly lower in fecal samples from feral swine.

ART bacteria were also found in poultry without the corresponding antibiotic treatment (137). These data illustrated the prevalence and abundance of ART bacteria in the gastrointestinal tracts of animals lacking direct exposure to antibiotics, as well as the potential impact of human activities, environmental factors, and also possibly host specificity on AR development. In an early study involving home-bred hamsters, not only were Tet^r bacteria isolated from both parents and their offspring, none of which had been treated with antibiotics, but the Tet^r gene patterns from Tet^r isolates from the baby hamsters were similar to those of the mother but different from those of the father (138). These data suggest that the ART bacteria initially found in the infant GI tract were acquired from the

mother, through either the birth canal or other contact that eventually resulted in oral exposure of the infants, independent of therapeutic antibiotic exposure and regular food intake. This conclusion is in agreement with recent data on the development of the microbiota in animal and human GI tracts, suggesting that transmission of both specific pathogens such as *Salmonella* spp. and the general microbial population is largely from mother to infant (139–141). This is also in agreement with findings from a study of a remote Bolivian community in which ART bacteria were isolated from 73% of the population's fecal samples (142), although antibiotics were not used in agriculture and were rarely used by humans in the community. ART bacteria colonizing the host digestive system can further serve as an "immobilized" source of AR genes for potential HGT events, regardless of the presence of antibiotics. A constant supply of large populations of AR gene-containing bacteria acquired through daily food consumption, coupled with occasional colonization and HGT events, will inevitably have an impact on the AR status of the host gut microflora (4).

Jacobsen et al. observed that, after inoculating a tetracycline-resistant *Lactobacillus plantarum* strain and a nonresistant *Enterococcus faecalis* strain into the digestive tracts of germ-free rats, HGT occurred even in the absence of selective pressure and that the administration of tetracycline caused only a slight increase in transmission of AR (143). Evidence also suggested AR gene transmission among *Bacteroides* spp. and bacteria of other genera in the human colon, indicating that the colon likely provides a suitable environment for HGT events to occur (144). Based on quantitative analysis, the cell populations of ART bacteria in fecal samples were much greater than those in foods consumed during daily food intake, suggesting that ART bacteria were enriched in the host GI tract, even in the absence of antibiotic exposure (5, 87, 145). Once released into the environment, these ART bacteria can then spread to other human and animal hosts through contact with water, food, and the environment (146–149). Hence, proper waste

treatment is a critical control point for targeted mitigation of ART bacteria (5, 145).

Many human pathogens and their ART derivatives do not cause disease in animal hosts, such as *L. monocytogenes*, *Salmonella*, and *E. coli* O157:H7, but can cause disease in humans when consumed via raw, smoked, fermented, or undercooked foods. Marshall et al. (117) reported that there was strong evidence for direct transmission of AR traits from animal- to human-associated microorganisms, such as *Salmonella*, *Vibrio*, *Campylobacter*, *Yersinia*, and *Listeria*. Kieke et al. (150) observed that exposure to poultry was associated with acquisition of a quinupristin-dalfopristin resistance gene and inducible quinupristin-dalfopristin resistance in human fecal *E. faecium*. Johnson et al. (151) determined that many human-source drug-resistant fecal *E. coli* isolates in the U.S. population were more likely to have originated from poultry than from humans, whereas drugresistant poultry isolates likely were derived from drug-susceptible poultry isolates. Stanton and Humphrey (152) isolated Tet^r *Megasphaera elsdenii* strains having a novel mosaic gene containing hybrids of *tetO* and *tetW* from swine fed with or without chlortetracycline. Their results revealed a likely role of commensal bacteria not only in the preservation and dissemination of AR in the intestinal tract but also in the evolution of resistance.

A significant portion of AR genes from resistant bacteria are quite stable in the absence of antibiotic selective pressure (88). Some AR genes have been integrated into the host genome, and others may reside on plasmids with special stabilization mechanisms (5). For example, a pRE25-like plasmid with the toxin-antitoxin (TA) stabilization system has been found to be widely distributed among *Enterococcus* spp. and other bacteria (153–157). The TA system was also found to be responsible for persistence of the *vanA*-bearing plasmid in vancomycinresistant enterococci isolated from the clinical and farm environments (153, 157). In addition, a TA-independent plasmid stabilization mechanism is likely responsible

for the persistence of plasmid pM7M2, although the plasmid is closely related to pRE25 (158).

ANTIMICROBIAL USES IN THE FOOD CHAIN AND RESISTANCE

Besides antibiotics, microorganisms often encounter many antimicrobial hurdles during the journey from farm to fork. Sanitizers and disinfectants such as quaternary ammonia compounds (QACs), chlorine-containing agents, and peroxyacids are often used in the food system, from production to processing, and in household environments. During food processing, raw meats may be decontaminated with a variety of physical processes or acidic rinses. Fruits and vegetables may be washed in chlorine rinses and/or packed in modified-atmosphere environments. While antibiotics are not permitted in food products, whether as residues from production or as a means to inhibit the growth of pathogens and spoilage organisms in the final products, various food antimicrobials are added to food to control the growth of both pathogens and spoilage microbes. Many natural food antimicrobials, such as nisin, lysozyme, lactoferrin, essential oils, and organic acids, not classified as antibiotics, have been used in food products (159). Triclosans are used in food processing plants and are now being introduced into many consumer products. Some of these antimicrobial compounds may be removed by washing or inactivated by consumers before consumption; others may be consumed along with the foods.

Microbial Resistance to Food Antimicrobials, Sanitizers, and Disinfectants

Overall, microbial resistance to food antimicrobials, sanitizers, and disinfectants is less well understood and more difficult to characterize and quantify than resistance to antibiotics, and standardized methods have not been developed, nor are surveillance

systems in place. Active export mechanisms contribute in part to bacterial resistance to many agents, including antibiotics, but their potential involvement in bacteriocin resistance has not been reported. However, strains of nisin-producing *L. lactis* contain immunity mechanisms encoded by *nisI* and *nisFEG*, which are located on a transposon (160, 161). Acquisition of the immunity gene(s) can lead to acquired nisin resistance in recipient cells (162). The intracellular accumulation of protons from organic acids acidifies the cytoplasm, inhibiting many metabolic processes. The cell tries to maintain pH homeostasis by pumping these protons out of the cytoplasm using ATP as an energy source. The resultant energy depletion is a major factor in the inhibition caused by organic acids (163). Cells have numerous mechanisms, some of which are inducible, to survive in acidic environments, including proton pumping, changes in the cell envelope, and the production of acid shock proteins and chaperones, as well as the generation of alkali in the immediate external environment (164, 165). In addition, degradation of preservatives by enzymes, either specialized or general, but different from the enzymes that inactivate antibiotics, may also contribute to resistance to antimicrobials. For example, some bacteria metabolize citric acid, rendering it ineffective in their presence. Many proteases inactivate bacteriocins in a nonspecific fashion.

Heir et al. (166) investigated the molecular epidemiology and disinfectant susceptibility of *L. monocytogenes* isolates from food processing plants and human infections. The prevalence of QAC-resistant *L. monocytogenes* was much higher in isolates from food processing facilities than in clinical isolates. While QAC resistance could increase the prevalence of *L. monocytogenes* in the processing plant, these strains or serotypes may not be the dominant causes of human listeriosis. No correlation between resistance and pulsed-field gel elec Heir et al. (166) investigated the molecular epidemiology and disinfectant susceptibility of *L. monocytogenes* isolates from food processing plants and human infections. The prevalence of QAC-resistant *L. monocytogenes* was much higher in

isolates from food processing facilities than in clinical isolates. While QAC resistance could increase the prevalence of *L. monocytogenes* in the processing plant, these strains or serotypes may not be the dominant causes of human listeriosis. No correlation between resistance and pulsed-field gel electrophoresis profile or between resistance and persistence was observed. Isolates of *L. monocytogenes* resistant to the bacteriocin nisin have been reported and characterized. While the genetic determinant of the resistance is currently unknown, these strains typically have a more rigid cell membrane, which may physically impair attachment or insertion of nisin molecules (167, 168). Nisin is approved for use in some foods to prevent clostridial outgrowth but not to control *L. monocytogenes*. It is not known if nisin resistance results in increased survival of *L. monocytogenes* in foods treated with nisin and potentially increased foodborne illness. Some strains of *S. aureus* are resistant to QACs, due to either plasmid acquisition or chromosomal alteration that results in efflux of the sanitizer (169–171). While this may help the pathogen persist in the food processing environment, most cases of foodborne illness related to *S. aureus* are related to postprocessing contamination, making the industrial significance of QAC resistance questionable. While some *L. monocytogenes* and *S. aureus* strains were described as "resistant" to QACs, the levels of QACs at which "resistance" was observed are severalfold lower than what is used industrially (172). While these organisms may be classified as resistant in a laboratory, they are likely still susceptible to QACs at the levels normally used in food processing plants.

Adaptation to Stressors at Sublethal Levels

Microbes may be innately resistant to certain food antimicrobials, but sensitive organisms do not typically mutate or acquire resistance to food antimicrobials. However, exposure to subinhibitory levels of antimicrobials may cause temporary adaptation, so that subsequent exposure to levels that are normally lethal is less effective. "Bacterial adaptation" is the term used to

describe temporary phenotypic changes in response to stress. Adaptation is more common in response to food antimicrobial agents than antibiotics. New genetic material is not required for bacteria to adapt; instead, the stressor quickly activates certain existing pathways and mechanisms to produce a physiological response that helps the organism withstand the stressor. In contrast to the antibiotic selecting for resistance, in the case of adaptation, the antimicrobial causes the observed resistance.

Some mechanisms of adaptation are known. The synthesis of stress response proteins, including heat shock proteins, is triggered by low levels of the stressor, and alternative sigma factors are involved in the process. These stress response proteins protect the cells from subsequent related or unrelated stressors. In many cases, these proteins have a general protective function. In addition, the alternative sigma factors are involved in regulating additional metabolic pathways, likely with universal impact. For example, exposure to low levels of acid may activate the stress response system, protecting cells from subsequent heat exposure as well as acid exposure (173). Quorum sensing allows cells to communicate with each other and exchange information in a nongenetic fashion. Signal compounds secreted by stressed cells may also be sensed by surrounding cells, including the nonstressed progenies, and impact the corresponding gene expression, until the signal becomes sufficiently diluted.

Cross-Resistance and Coselection

The ability of a bacterial strain to display resistance to more than one antimicrobial can also be due to cross-resistance or coselection. In cross-resistance, the multidrug resistance may be due to a single resistance mechanism that is effective against multiple antibiotics. For example, an alteration in a cellular target may make a cell resistant to allantibiotics that act on that target; acquiring a general drug efflux may increase the resistance to several antibiotics. In cases of coselection, the microbe may be resistant to a number of different antibiotics, each with a distinct mechanism of action. The

different resistance determinants are generally genetically linked. This also applies to resistance against antibiotics, heavy metals, and other biocides (174–177). Further, as mentioned previously, exposure to subtherapeutic drug levels may increase the mutation rate and lead to multidrug resistance (59). In a farm study, Alexander et al. (119) evaluated the effect of subtherapeutic administration of antibiotics on the prevalence of antibiotic-resistant *E. coli* in feedlot cattle, finding that subtherapeutic administration of tetracycline in combination with sulfamethazine increased the prevalence of tetracycline- and ampicillin-resistant *E. coli*. However, because this resistance may also be related to additional factors, such as diet and additional oral exposure through environmental contacts, it is important to characterize the corresponding molecular mechanism(s) and confirm the correlation by means of well-controlled laboratory studies. The multiple-AR (*mar*) operon, which controls the expression of chromosomal genes involved in intrinsic multidrug susceptibility and resistance in *Enterobacteriaceae*, is of special interest in food microbiology. This global regulator (*marRAB*) can be expressed by a number of pathogens, including *E. coli* O157:H7 and *Salmonella* serovar Enteritidis. Activation of the operon in *Salmonella* serovar Enteritidis by chlorine, sodium nitrite, sodium benzoate, or acetic acid, all of which are used by the food industry, causes increased resistance to antibiotics such as tetracycline and ciprofloxacin (178). Some sanitation agents and disinfectants may also cause coresistance to other antimicrobial compounds, such as antibiotics.

A review by Hegstad et al. (179) cites several studies that examine the relationship between bacterial resistance to QACs and clinically important antibiotics. The cross-resistance can be attributed to nonspecific resistance mechanisms, such as altered membrane composition and efflux pumps. An EFSA panel on biological hazards considered the possible effects of chlorine dioxide, acidified sodium chlorite, trisodium phosphate, and peroxyacids as used for poultry carcass decontamination. The EFSA scientific opinion is that there are currently no published data supporting the conclusion that

application of these antimicrobials under the proposed conditions of use will lead to acquired reduced susceptibility to these substances or lead to resistance to therapeutic antimicrobials (180).

A few studies have examined the response of ART bacteria to food processing treatments, such as heat. ART *Salmonella* and *L. monocytogenes* are as sensitive to heat as their drug-susceptible counterparts (173, 181). However, there is a relationship between AR and heat resistance: activation of the AR confers increased protection against heat (173). This can be explained by the AR mechanism.

The induction of stress response proteins (due to exposure to acid) results in increased heat resistance, in which stress response proteins also play a role. This exemplifies the need to examine situations of cross-resistance on a case-by-case basis; broad assumptions about cross-resistance cannot be made without an understanding of the mechanism(s).

One study has linked nisin resistance with AR (182). *S. aureus* nisin-resistant isolates were resistant to antibiotics. The MICs of the antibiotics increased 4-fold in the nisin-resistant strains (183). However, similar studies with *L. monocytogenes* revealed no significant increase in resistance to antibiotics (184, 185). Nisin-resistant *L. monocytogenes* and *Clostridium botulinum* isolates are more sensitive to food preservatives, such as low pH, salt, sodium nitrite, and potassium sorbate, than nisin-susceptible isolates (168). Their increased acid sensitivity is caused by increased ATPase activity, which decreases intracellular energy stores (163, 186, 187). Alonso-Hernando et al. (188) also examined cross-resistance between decontaminants and antibiotics in strains of *L. monocytogenes* and *Salmonella* serovars Enteritidis and Typhimurium. Although standard deviations were not provided, the data appear to reveal little or no increase in the MICs of the pathogens to peroxyacetic acid or trisodium phosphate. However, for acidified sodium chlorite (ASC), the MIC increased between 1.88- and 2.71-fold. Exposure to sublethal concentrations of ASC

was related to cephalothin resistance in one strain of *L. monocytogenes* and one strain of *Salmonella*. For both strains of *Listeria* but neither of the *Salmonella* strains, ASC exposure was associated with increased resistance to chloramphenicol. For both *Salmonella* serovars, ASC exposure was associated with increased streptomycin resistance. The authors cited previously identified mechanistic relationships but did not speculate on mechanisms that may cause the cross-resistance observed in this study.

COMPREHENSIVE AND TARGETED MITIGATION OF FOODBORNE AR AND GUT MICROBIOTA DYSBIOSIS

After decades of problematic practices, AR has become a broad and complicated ecological issue impacting many segments of human society. The applications of antibiotics in food animal, crop, and aquaculture production, especially oral drug administration in animals, contribute to AR evolution as well as its enrichment, dissemination, and persistence in the ecosystem; conventional food intake serves as a key avenue connecting the host and environmental microbiota, and AR-rich feces have prominent impact on the environmental AR gene pool. Thus, targeted control of foodborne AR becomes critically important for effective mitigation of AR in the ecosystem. However, simply stopping the growth-promoting uses of antibiotics is not sufficient to get rid of the AR genes and ART bacteria that have already emerged and continue to persist in animals, plants, and the environment. Antibiotic applications in agriculture essential for infection prevention and treatment, particularly administered through feed and water in food animal production, still contribute to the increasing AR gene pool in feces and the ecosystem.

As illustrated in Fig. 34.1, the identification of critical control points throughout the food chain is essential for targeted AR mitigation. In food animal production, it is important to (i) enhance food

processing treatment at the manufacturer and consumer levels to inactivate ART bacteria and pathogens, minimizing the direct introduction of ART bacteria into the host GI tract; (ii) reduce the need for antibiotic applications, such as by prompt infection detection and improving facility, sanitation, and production management to reduce infections and the spread of diseases; (iii) change the antibiotic administration route and select drugs with proper excretion routes to avoid unnecessary exposure of the gut microbiota to antibiotics; (iv) establish effective waste management and processing practices to inactivate ART bacteria and pathogens; and (v) regulate the safety of biocontrol approaches. A significant percentage of the probiotics marketed for food animal applications still contain AR genes. The application of these probiotics as growth promoters facilitates the dissemination of AR genes in the agricultural and aquaculture production system, rather than reducing it.

The new approaches have already led to impressive outcomes. Following the knowledge breakthrough on the potential involvement of lactic acid bacteria and even probiotics in AR ecology (4, 129), an effective collaboration between academia and industry led to the rapid identification of the risk factors in cheese fermentation and removal of the problematic cultures from the market. Data from a follow-up study illustrated that effective mitigation of the largest AR gene pool in the food chain was achieved in just 4 years (2006 to 2010) (121). The European Union has already established safety screening standards for bacterial strains intended for beneficial applications, and China is in the process of adopting such standards. The same strategy needs to be adopted by the United States and should cover probiotics for agricultural and aquaculture production as well. The use of bacterial phages is another proposed strategy to eliminate pathogens in the food chain. However, bacterial phages have been extensively implicated in bacterial (including pathogen) evolution through HGT. Therefore, extreme caution should be used regarding their

application, to avoid another round of unforeseen detrimental consequences, as happened with antibiotics.

Although eliminating ART bacteria from the food production environment is impractical, it is possible to interrupt the transmission of foodborne ART bacteria through conventional food intake by proper food processing. The reduced prevalence of ART bacteria in both retail meat and poultry as well as fresh produce in recent years is in fact an encouragement for improving microbial inactivation at the food processing level in processing plants. Proper education to further minimize foodborne ART bacteria ingestion through proper cooking and other processing by consumers is another essential strategy.

In summary, the misuses of antibiotics in human medicine and food animal production have a paramount impact on AR ecology. Systematic investigation for a comprehensive understanding of risk factors of AR and the development of targeted controls are essential for effective AR mitigation in the food chain as well as in medicine. Proper detection approaches and a predictive surveillance system for early warning are critical components for accurate risk forecast, assessment, and reporting. Innovative strategies are further needed to mitigate persistent AR in the hosts and the environment, as well as gut microbiota dysbiosis and modern diseases. Food microbiologists are well positioned for the mission to improve food safety and public health.

We thank Jennifer Cleveland McEntire and Rosetta Newsome for their contribution to the original chapter "Antibiotic Resistance" in the 4th edition of this book.

Genomics of Foodborne Microorganisms

The genomics and postgenomics era has transformed microbiological and molecular biology research, and genomic analysis is emerging as an important tool in food microbiology and safety. Microbiologists investigating foodborne pathogens, probiotics, starter cultures, and recently the intricate microbiota of a food system are relying more and more on DNA sequencing technologies, genomic analysis, and metagenomic techniques. Foodborne illness represents an important economic and public health burden worldwide, and food contamination can occur at any step along the food supply chain. It is critical to be able to detect microbes with high sensitivity and reliability for surveillance monitoring and to prevent further outbreaks. Traditional methods based on culturing or biochemical tests are often laborious and time-consuming and have limited sensitivity. Testing procedures based on DNA sequencing methods have accelerated pathogen detection, improved consistency, and allowed accurate species identification during outbreaks. Indeed, as outlined in this chapter, genomics-based methods are currently being implemented for foodborne-organism surveillance and tracing. In the early days of DNA sequencing, efforts primarily focused on pathogen detection and on the content of pathogen genomes. More recently, however, analyzing the genomes of probiotic microbes for their potential functional food development has also gained increasing interest. Additionally, advances in high-throughput DNA sequencing technologies, and particularly bioinformatics capabilities, have impacted the available resources for the investigation of the

microbiota in food processing environments or within a complex food matrix.

In an earlier edition of this book, the genomic and proteomic advances in the area of food microbiology were described. Since then, there have been significant developments in high-throughput technologies, metagenomics, and computational capabilities. These are reflected in this updated chapter. We also outline the large-scale use of sequencing technologies for outbreak surveillance, and we look specifically at documented examples of how genomics has expanded our knowledge of foodborne microorganisms and its impact on the food industry and food microbiological research in recent years.

ADVANCES IN DNA SEQUENCING

There have been many changes in DNA sequencing technologies over the last 20 years, the most dramatic being a movement from the sequencing of single stretches of DNA at a time to the in-parallel sequencing of millions of reads, with a large reduction in sequencing costs. These have impacted all areas of microbial genomics, including whole-genome sequencing (WGS), 16S rRNA compositional and metagenomics analysis, and gene expression studies, with the development of direct sequencing of RNA (RNA-Seq) and transcriptomic technologies, all discussed below. Over the years, improvements in sequencing output, accuracy, and speed have generally been defined as first-, second-, and third-generation technologies, the basics of which are briefly outlined below. More extensive overviews of DNA sequencing technology platforms can be found elsewhere (1, 2).

First-Generation (Sanger) Sequencing

First-generation sequencing was based primarily on the Sanger approach, which relies on the incorporation of chain-terminating dideoxynucleotides during the DNA replication process (3).

Automated Sanger sequencing was later introduced by Applied Biosystems through fluorescent base labeling. The first completed bacterial genome sequenced using this method was the 1.83-Mb genome of *Haemophilus influenzae* in 1995 (4). This was a time-consuming and labor-intensive approach, as the genomic DNA of the bacterium was isolated, sheared, and subsequently cloned into a plasmid vector for sequencing. Despite this, however, hundreds more bacterial genomes were sequenced by this method in the following years, including those of *Mycobacterium tuberculosis*, *Escherichia coli*, *Bacillus subtilis*, and the first foodborne pathogen, *Campylobacter jejuni*, in 1999 (5).

Second-Generation Sequencing

Second- or next-generation sequencing (NGS) technologies are capable of massively parallel sequencing, producing millions of reads in one run, in contrast to Sanger sequencing, which can produce just 96 reads per run. NGS technologies differ from conventional (first-generation) sequencing in the basic chemistry. Additionally, they generate a much larger base output and have a reduced DNA concentration requirement. The first NGS sequencer was launched by 454 Life Sciences in 2005 and was based on a pyrosequencing "sequencing by synthesis" technology. This technology is based on a series of enzymes to detect the nucleic acid bases incorporated during strand synthesis. Following the initial launch of the 454 GS20 pyrosequencing platform in 2005, there were many technology advancements over the years, including machine upgrades (GS FLX and GS Junior). This approach was used for many applications, including WGS (*de novo* sequencing and resequencing), metagenomic sequencing, and transcriptomics. Indeed, 454 pyrosequencing was central to the completion of the human microbiome project (6). Despite this, however, the 454 technology could not compete with other NGS technologies that subsequently emerged on the market over the last 10 years and that could produce greater outputs at a reduced cost.

Currently, the market-leading NGS technologies include those offered by Illumina Technologies. Since their launch of their first sequencer in 2008, Illumina sequencing output has grown over 1,000-fold, from less than 1 Gb to 6 Tb per run, while the number of reads has increased from millions to billions. Initial read lengths were typically between 35 and 70 nucleotides, but these have been extended in recent years, with 2 □□300 bp paired-end sequencing available with the MiSeq V3 sequencing kit (https://www.illumina.com/systems/sequencing-platforms/miseq.html). Illumina's sequencing platform utilizes ligation of adapters to fragmented single-stranded DNA, but the fragments are then attached in isolated spots on a solid surface that contains primers complementary to the adapters. After PCR, the solid surface contains millions of isolated colonies of amplified single-stranded DNA (7). Illumina currently offers a range of machines within their benchtop MiniSeq, MiSeq, and NextSeq series and the large-scale HiSeq and NovaSeq series (www.illumina.com). The repertoire of machines provides a range of potential applications, including small-scale WGS on the MiniSeq and MiSeq machines, exome sequencing on the NextSeq instruments, and metagenomics studies on the MiSeq and NextSeq series, while the HiSeq and NovaSeq machines are generally used for large (nonmicrobial) genomic projects, as well as RNA-Seq and other projects (8).

There are also a number of sequencers offered by Thermo Fisher Scientific based on ion semiconductor sequencing (9) (www.thermofisher.com/ie/en/home/brands/ion-torrent.html). Ion torrent technology is based on the principle of detection of released hydrogen ions during the incorporation of new nucleotides into a growing DNA template. Depending on the chip used, the Ion PGM system can run up to 5.5 million reads, with an output of 2 Gb and a read length of 400 bases. The PGM platform is therefore suited for sequencing small genomes or gene sets. The available benchtop machine, the Ion Proton, produces 15 Gb of sequence data with read lengths of 200 bases, which makes the machine suitable for

transcriptomics and exome sequencing. The new Ion GeneStudio platform combines many of the attributes of both of these systems.

Third-Generation (Single-Molecule) Sequencing

Recently, methods that do not require an amplification step have emerged, enabling sequencing of a single molecule and eliminating issues caused by amplification or variability within a strain. These so-called third-generation technologies involve direct sequencing of single DNA molecules and have resulted in much longer sequencing reads than was previously possible. The first singlemolecule sequencer, the HeliScope, developed by Helicos Biosciences, utilized deoxynucleoside triphosphates attached to very bright fluorophores and incorporated a sequencing-by-synthesis method similar to that of the Illumina platform without amplification. Pacific Biosciences delivers its single-molecule real-time technology based on a nanophotonic structure known as a zeromode waveguide. This company developed a method to sequence fragments in zeptoliter wells with fluorophoreassociated deoxynucleoside triphosphates, resulting in sequence reads up to several kilobase pairs in length (10). Oxford Nanopore Technologies, launched in 2014, also has a number of sequencers (MinION, GridION, and PromethION) currently on the market and the promised SmidgION, the smallest device based on nanopore-sensing technology. These third-generation sequencers deliver much longer reads than previously achievable, and although they still have a sizable documented error rate, these technologies are being used in more and more sequencing projects.

GENOMIC ADVANCES IN FOOD MICROBIOLOGY

Pathogen Genomes

With the number of completely sequenced and draft bacterial genomes increasing daily, one powerful approach to defining unique

or conserved gene content and understanding how these microorganisms evolved is comparative genomics, via *in silico* analysis. This was demonstrated in the early years of bacterial genomics, when sequencing of the food pathogen *Listeria monocytogenes* and the nonpathogenic species *Listeria innocua* revealed extensive collinearity (11). It was found that 270 genes (9.5%) were specific to the *L. monocytogenes* genome, whereas only 149 (5%) were specific to the *L. innocua* genome. Many of the *L. monocytogenes*-specific genes were key to survival in the mammalian gut, including those coding for bile salt hydrolases, acid tolerance via glutamic acid decarboxylases, and a virulence locus responsible for infection and motility during pathogenesis. Genomics also revealed that pathogenic *L. monocytogenes* and nonpathogenic *L. innocua* were likely derived from a common ancestor, with the latter subsequently losing most of the genes directing pathogenesis. Therefore, *in silico* comparative analysis of complete genomes can reveal important clues regarding an organism's genetic content, capabilities, and relationships to other microorganisms.

Additionally, other genomic approaches have been used in the identification and characterization of genes of foodborne organisms that confer resistance to environmental stresses. These genes are of interest because they are pivotal to understanding how both foodborne pathogens, such as *E. coli* O157:H7, and potentially beneficial microbes, such as *Lactobacillus* spp. and *Bifidobacterium* spp., survive the dynamic environment of the intestinal tract. Bacteria can adapt and survive in these environments through different mechanisms, including the induction of an acid tolerance response. The best-characterized acid resistance mechanism is the Gad system of *E. coli* (12), first described before the sequence of *E. coli* was published in 1997 (13). The ability to withstand the effects of bile in the intestinal tract is also central to a microbe's capacity to cause and maintain an infection, as bile acts as a detergent that can dissolve the phospholipid cytoplasmic membranes of bacteria, leading to their death (14). *L. monocytogenes* is able to withstand

the presence of high concentrations of bile. Bile salts exist primarily as steroid rings attached through an amide bond to an amino acid group, either glycine or taurine. While the mechanisms of bile tolerance are not fully understood, gene loci such as those for bile salt hydrolases are the most studied, and indeed, disruption of the *bsh* gene in *L. monocytogenes* leads to greater sensitivity to bile (15, 16).

Genomic analysis of *L. monocytogenes* also illustrated the genetic regulation controlling stress resistance in the pathogen. Bioinformatics analysis of the *bsh* promoter region revealed that it is under the control of the transcriptional regulator PrfA, which controls expression of other known virulence genes in *L. monocytogenes* (17). Further analysis revealed that PrfA is regulated by the alternative sigma factor, sigma B, an analogue of RpoS, which is found in Gram-negative bacteria such as *E. coli*. Sigma B is the general stress response sigma factor in Gram-positive bacteria and has a pivotal role in stress resistance and adaptation to the intestinal tract (18, 19). Transcriptomic studies deciphered the sigma B regulon among *L. monocytogenes* isolates (18, 20), identifying many of the genetic determinants responsible for acid, bile, and salt tolerance. Additional transcriptomic analysis by Toledo-Arana et al. elucidated further regulatory complexity within *L. monocytogenes* stress resistance strategies by identifying a diversity of RNAs, including 50 small RNAs and antisense RNAs involved in global transcriptional regulation of virulence (19). RNA-Seq analysis (described below) also was used to identify the genome-wide transcriptome of *L. monocytogenes* following internalization by murine macrophages, also indicating the importance of antisense RNAs to the intracellular growth of this pathogen (21).

Starter Cultures

In recent years, there has also been a surge in the analysis of the genomes of starter cultures of *Lactobacillus* and *Lactococcus* spp. to identify the adaptation of the isolates to a food environment and to

allow the determination of the metabolic capabilities of starters (reviewed in reference 22). Additionally, genome sequence information has provided key insights into the evolution of microorganisms and their adaptation to specific foods (23). *Streptococcus thermophilus* is a lactic acid bacterium used worldwide for the manufacture of yogurt and some hard cheeses. Sequencing the genome of two yogurt strains of *S. thermophilus* and comparison with other streptococci revealed that the organism had undergone extensive rounds of genome decay, with over 10% of the genes being characterized as nonfunctional genes, or "pseudogenes." Notably, with the exception of lactose metabolism, many of the other gene regions associated with carbohydrate transport and metabolism were also degraded. Genes commonly associated with pathogenic streptococci (e.g., *Streptococcus agalactiae* and *Streptococcus pneumoniae*) were either lost or inactivated due to mutations or transposon insertions. Bolotin et al. concluded that *S. thermophilus* has evolved specifically to grow in milk and that, during the adaptation process, much of its genomic complement that is not required for growth in this environment was eliminated or degraded (24).

Probiotic Genomes

Although we have been consuming probiotics for many years, it is only since the advent of DNA sequencing technologies that we have begun to more comprehensively understand the potential mechanisms that confer their benefit to human health. One of the earliest probiotic genome sequences available was that of *Lactobacillus johnsonii* NCC533 (25). Genomic analysis of this organism showed a number of loci important to survival in the gastrointestinal tract, including three for bile salt hydrolases and two for bile acid transporters. Additionally, the genome sequence shows that this commensal lacks loci for the biosynthesis of amino acids but compensates via a plethora of transporters, peptidases, and proteases, suggesting that it relies heavily on its surrounding host for nutrients and metabolism (25). Further genome

sequencing of porcine isolates of *L. johnsonii* indicated large genomic rearrangements and evidence of horizontal gene transfer, suggesting host-specific genetic divergence (26).

In the years following this analysis, numerous complete and draft genomes of strains belonging to species of *Lactobacillus* and *Bifidobacterium* were made available on GenBank to advance the field of probiogenomics (27), and more recently, a "newer generation" of potential probiotics, including strains of *Akkermansia muciniphila* and *Faecalibacterium prausnitzii*, have become widely available for genomic analysis. Indeed, genome-scale metabolic reconstructions have allowed the evaluation of metabolic cross-talk between the gut inhabitants *Bifidobacterium adolescentis* L2-32 and *F. prausnitzii* A2-165 and provided insight into the demand and supply of acetate and butyrate in the gut, which have an important role in cancer prevention and the microbial balance in the intestinal tract (28). Results also suggest a beneficial role for *A. muciniphila* in maintaining the integrity of the mucus layer in the intestine, contributing to the control of glucose homeostasis and insulin resistance (29). Recent whole-genome comparative analysis of 40 genomes of *A. muciniphila* traced the identity of three species-level phylogroups and examined their correlation to body mass index and antidiabetes-drug usage (30).

Overall, the accumulating genomic data that are becoming available for a multitude of potential probiotic species enables analysis of how the strain has adapted to the intestinal tract, its metabolic profile, its technological robustness, and its potential safety for use in foods. In fact, in Europe, any probiotic with potential commercial application is now required by the European Food Safety Authority to undergo full genomic safety assessments before use. A probiotic strain has to be genome sequenced so that it can be analyzed for overall genome stability, the presence of transferable antibiotic resistance loci, potential virulence genes, or genes for adverse metabolites that may compromise the safe use of the strain in food (reviewed in reference 1).

USE OF WGS IN FOODBORNE SURVEILLANCE

The advancements in NGS technologies and the rapid reduction in per-base cost of sequencing have led to the genome sequencing of microbes becoming routine and have allowed even the smallest lab groups to obtain the genome sequence of their organism of interest. WGS is being used more and more in public health laboratories for foodborne-pathogen surveillance and tracing the source of foodborne-illness outbreaks. Potentially, WGS allows the replacement of multiple “wet-lab” procedures with a full genetic blueprint of an organism for full genomic analysis. A number of government-run programs and participating public health laboratories are implementing WGS in surveillance and source tracking for foodborne microorganisms. Some of these initiatives are outlined below.

PulseNet

PulseNet International is an initiative based on the dedicated global laboratory surveillance of foodborne microbes (reviewed in reference 31). At present, it is dedicated to disease surveillance in 86 countries in total, including those in Africa, Asia, Europe, and the Americas. This project is complementary to the Food and Drug Administration (FDA)-driven GenomeTrakr food safety initiative described below. The overall mission is to establish standard genotyping methods to identify and track outbreak strains, and PulseNet currently prevents ~270,000 cases of annual foodborne illnesses due to organisms such as *E. coli* and *L. monocytogenes* in addition to easing the associated financial burden of foodborne illness. Since its conception more than 20 years ago, the main methods of strain detection and identification used by PulseNet have been traditional molecular biology-based methods, primarily pulsed-field gel electrophoresis and multilocus variable tandem repeat analysis on chosen strains where required (32). Although the traditional methods used have indeed been effective in organism

surveillance, sequencing has become a focus of the PulseNet initiative due to lowering DNA sequencing costs in addition to the high level of detail and specificity that can be achieved with WGS. Standardized typing in the form of large-scale WGS and more specifically whole-genome multilocus sequence typing (WG-MLST) is now the vision of the PulseNet program (31).

WG-MLST is a gene-by-gene typing approach allowing MLST on a genomewide scale. Traditional MLST has generally been based on approximately seven housekeeping genes within a genome for which each unique sequence is given an allele number assignment. The drawback of this is that because of the high conservation among housekeeping genes, the technique is suitable only for very closely related organisms and is not useful among species with very low diversity. Additionally, with just seven alleles, it gives only a glimpse of the genetics of a genome and does not take into account the extent of genetic transfer. A genome-wide approach allows analysis of all the loci within an isolate, which can then be compared to the equivalent loci in other isolates; therefore, this method has very large discriminatory power. To achieve this successfully and allow implementation across PulseNet International laboratories, many factors are taken into consideration, including the sequence read set, the storage of data, the deposition of data in public repositories, read assembly, the bioinformatics capabilities required, and the standard strain and allelic nomenclature to be used (31). Overall, the intent of PulseNet International is to standardize a typing method using the discriminatory power of WGS of foodborne organisms to allow dedicated surveillance of foodborne-illness outbreaks globally.

GenomeTrakr

GenomeTrakr is an FDA food safety and traceability initiative consisting of a distributed network of laboratories (university and public health) that collect and share whole-genome sequences for food pathogen identification (https://www.fda.gov/Food/FoodScienceResearch/WholeGenomeS

equencingProgramWGS/ucm363134.htm). Originally a U.S.-focused sequencing initiative dedicated to food microorganisms, GenomeTrakr has expanded internationally in recent years. All sequenced genomes are deposited in public databases at the NCBI (https://www.ncbi.nlm.nih.gov/genbank/) and are fully accessible for analysis of outbreak investigations, with the aim to reduce foodborne illnesses and deaths. The first GenomeTrakr genome was uploaded in February 2013, and currently, almost 5,000 genomes are being added monthly (http://www.fda.gov/Food/FoodScienceResearch/WholeGenomeSequencingProgramWGS/default.htm). At the time of writing, the Genome Trakr network has over 183,000 isolates sequenced, with over 175 closed genomes. Initial efforts by GenomeTrakr member labs focused primarily on pathogenic *Salmonella* and *Listeria* isolates; however, other pathogens are now being added to the network, including strains of *E. coli, Campylobacter, Vibrio*, and *Cronobacter*, as well as parasites and viruses. As the number of genomes increases, the ability to gain insight into outbreak etiology will strengthen. WGS has been specifically applied to the surveillance of *Salmonella enterica* serovar Enteritidis, and it was shown by den Bakker et al. that whole-genome cluster analysis of *Salmonella* isolates largely improved the detection and resolution of outbreak strains compared to the more traditional pulsed-field gel electrophoresis method (33).

The *Listeria* Initiative

In recent years, *Listeria* sequencing has focused on outbreak strains, typing, and traceability. Due to the importance of *Listeria* as a foodborne pathogen, the Centers for Disease Control and Prevention (CDC) launched the *Listeria* Initiative (https://www.cdc.gov/listeria/surveillance/listeria-initiative.html), which is a network dedicated to identifying isolates responsible for outbreaks of listeriosis in the United States. Traditionally, data collected were based on clinical, laboratory, and epidemiologic data, with more recent analyses focusing on genomic data. More

specifically, the focus was initially on a questionnaire for patients and on DNA "fingerprinting" in the form of pulsed-field gel electrophoresis, but since 2013, WGS has been used to type strains (https://www.cdc.gov/listeria/surveillance/listeria-initiative.html). A recent review (34) described how WGS has now been used to trace listeriosis in foods not generally associated with *L. monocytogenes* outbreaks (celery, stone fruits, etc.). As WGS provides the genetic information for the entire genome and as the cost has decreased and the speed of sequencing has increased, it can potentially be used in routine epidemiological investigations.

FOOD METAGENOMICS

Metagenomics, also known as environmental genomics, is the study of genetic material recovered directly from a given environment. This approach allows the gene content of the entire microbial load of an environment or sample to be analyzed without the need for culturing, removing the need for lengthy incubation periods and eliminating the bias towards the small proportion of microorganisms that have been successfully cultured under lab conditions.

While genomic sequencing aims to completely catalog the genetic information within a single food isolate, the aim of metagenomics is to evaluate the composition or function of the entire community of microorganisms and is often used to compare the communities present in different environments or in the same environment under different conditions (Table 35.1). This is achieved by extracting microbial DNA from a sample before sequencing using one of the sequencing technologies described above. The method used to extract, prepare, and sequence this DNA will depend on the goal of the study and the sequencing technologies available. The main factor to consider is whether the composition or the potential function of the microbial community is being examined. The different metagenomics techniques available are outlined in Fig. 35.1.

Compositional Metagenomics

Compositional metagenomics uses a specific marker gene to allow the identification of the individual members of a community and infer their relative abundance within the population. The chosen marker must be present in all microorganisms under consideration, variable enough to provide maximal phylogenetic information, and stable enough to be reliably identified across a broad taxonomic range. The markers most commonly used are the 16S rRNA gene for bacteria and archaea and either the 18S rRNA gene or the internal transcribed spacer sequence for eukaryotes. These marker genes have become the gold standard for their respective domains as, in the years since the development of compositional metagenomics, large databases of marker gene sequences have been assembled against which the sequences generated can be compared. Once the microbial DNA has been extracted, PCR amplicons are generated for the chosen marker before sequencing. The generated reads are then clustered into groups of closely related sequences known as operational taxonomic units and assigned taxonomy based on similarity to sequences in a curated database of marker genes. There are many bioinformatics tools available for analyzing compositional metagenomic data, but two of the most commonly used are mothur (35) and QIIME (36); both are open-source pipelines which connect a large number of bioinformatics programs by transforming their inputs and outputs so that they can be used together. The QIIME pipeline also contains programs for visualizing and interpreting compositional data using methods adapted from classical community ecology, such as diversity indices and multidimensional scaling.

Table 35.1. Summary of the strengths and limitations of genomic technologies

Technology	Description	Strengths	Limitations
Compositional metagenomics	Uses well-characterized marker genes to identify the microorganisms present in a community	Low cost Well-characterized databases	Limited accuracy below genus rank Amplification bias towards specific taxa Marker gene copy number variation between species Compositional information only
Shotgun metagenomics	Uses all DNA present in a sample to identify the microorganisms present and their functional capacity	Resolution to species (and sometimes strain) level Characterizes functional capability Not limited to a single domain	High cost Contamination by host DNA Difficult to identify unknown or poorly characterized species Complex interpretation of results High requirement for data storage and analysis

Metatranscriptomics	Uses all RNA present in a sample to identify metabolically active microorganisms and their functional activity at a specific moment	Functional snapshot (gene expression)	High cost Contamination by host DNA Complex interpretation of results High requirement for data storage and analysis

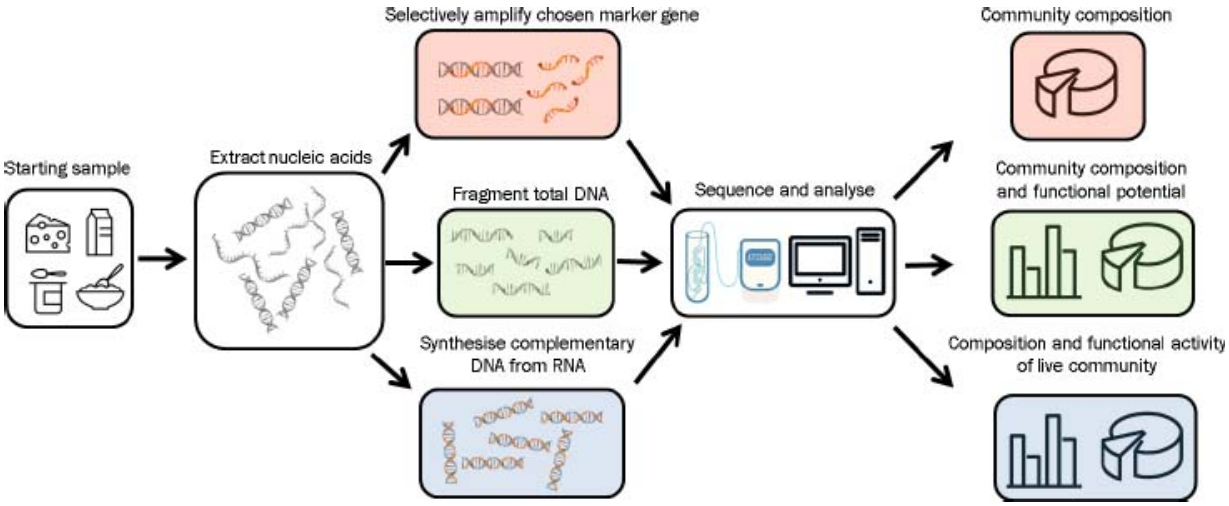

Figure 35.1. Sequencing pipeline for metagenomic and metatranscriptomic analysis from a complex food matrix.

Functional Metagenomics

Functional metagenomics does not rely on marker genes; instead, the total DNA from a sample is randomly fragmented before sequencing, resulting in thousands of short reads. This untargeted method of library preparation led to the approach becoming known as shotgun sequencing. These reads are compared against a database of genes with known functions to gain insight into the functional capacity of the community. The unrestricted approach of

shotgun sequencing means that all microorganisms in a sample are considered, not just those possessing the chosen biomarker gene. Shotgun reads can also be used for compositional profiling of the community and, as they are more heterogeneous than the marker genes typically used, contain greater potential phylogenetic information, enabling classification to lower taxonomic ranks. The HUMAnN pipeline (37) is perhaps the most widely used tool for shotgun data, as it performs both functional and taxonomic profiling. SUPER-FOCUS is another well-known program for functional profiling (38), while KEGG (39), MetaCyc (40), EggNOG (41), and Pfam (42) are all databases that can be used to functionally annotate metagenomic reads. For taxonomic classification, software such as MetaPhlAn (43), Kaiju (44), and Kraken (45) is commonly used.

Use of Metagenomics in Food Microbiology

An example of both comparative and functional metagenomics being utilized in a food setting was in the identification of *Thermus thermophilus* as an agent responsible for the pink discoloration defect in cheese (46). Compositional metagenomics, utilizing both 16S rRNA and shotgun approaches, revealed high proportions of the genus *Thermus* in cheeses with a pink defect but no *Thermus* organisms in unaffected cheeses. A subsequent functional metagenomics approach then noted that genes responsible for the production of carotenoids were identified in defective cheeses only. This led to the isolation of *T. thermophilus* from defective cheeses and the dairy processing environment as well as re-creation of the pinking effect by inoculation of the species (46).

Shotgun sequencing, combined with recently developed bioinformatics tools, shows potential in the future of food safety assessments. For example, an examination of nunu, a traditional Ghanaian drink produced by the spontaneous fermentation of raw cow's milk, highlighted frequent contamination by bacteria associated with the bovine gut and potentially pathogenic strains of *E. coli* and *Klebsiella pneumoniae* (47). Shotgun metagenomics has

also been used to detect foodborne pathogens such as *S. enterica*, *L. monocytogenes*, and *Campylobacter* spp. in the microbiome of the beef production chain (48).

Shotgun metagenomics can also play a preventive role in food safety if employed appropriately. Viral sources of foodborne disease are notoriously difficult to detect and pose a considerable public health risk, particularly relating to seafood and imported fresh food products. Shotgun sequencing has been proven to be an effective method to detect viral DNA from field-grown lettuce (49), and the bioinformatics tool PanPhlAn has proven capable of detecting and characterizing the strain responsible for the German 2011 *E. coli* outbreak from metagenomic data (50).

RNA SEQUENCING

Historically, investigation of the bacterial transcriptome was performed using microarrays, a collection of DNA spots attached to a solid surface which fluoresce upon hybridization to a cDNA strand. This cDNA is reverse transcribed from bacterial RNA, and the level of fluorescence is indicative of RNA abundance and, therefore, expression of the corresponding gene. Microarrays greatly increased the amount of information known about bacterial transcriptomes but are limited to use with known sequences and present technical challenges arising from cross-hybridization and background levels, requiring complex normalization procedures.

RNA-Seq provides many advantages over microarrays, such as removing the need for prior sequence knowledge, eliminating cross-hybridization effects, and allowing better quantification of genes expressed at low and high levels. Similar to shotgun sequencing, these RNA transcripts can be used to identify the community composition in addition to function. The sequences provided by RNA-Seq enable additional information to be obtained in experiments directed at gene expression profiling. For example, while microarrays may be used to discover single nucleotide

polymorphisms (SNPs) through specialized arrays in experiments directed at discovering SNPs, RNA-Seq provides SNP information in all experiments by providing the sequence of each transcript (51). Knowledge of SNPs has been useful for molecular subtyping of *L. monocytogenes*, which may be applied in foodborne-disease investigations (52).

It is important to note that the mRNA transcripts that are most often of interest during transcriptional profiling account for only about 5% of the total RNA. Most of the RNA pool consists of rRNAs and tRNAs, which need to be depleted before sequencing; otherwise, most reads obtained will be housekeeping RNAs rather than the mRNAs or small noncoding RNAs that are of interest. In eukaryotes, mRNA enrichment is easily accomplished by selection for the 3′-polyadenylated tail that is present only on mRNAs. The absence of this tail on prokaryotic mRNA complicates the process required to obtain useful information from RNA-Seq experiments, but several rRNA and tRNA depletion strategies have emerged for prokaryotic RNA-Seq (53).

The aim of many RNA-Seq studies is detection of differentially expressed (DE) genes under different environmental conditions. One of the most widely used tools for detecting these DE genes is DESeq2 (54), a package for the R statistical environment as part of the Bioconductor project (55). This approach uses count data, derived from mRNA transcript numbers, to detect DE genes and quantify the change in expression while compensating for outliers and other problematic features of transcriptomic data. This is just one approach to modeling RNA-Seq data, however; other widely used alternatives are EdgeR (56), BBSeq (57), DSS (58), baySeq (59), and ShrinkBayes (60).

Comparison of the transcriptomes of persistent and nonpersistent *L. monocytogenes* strains from a food processing environment highlighted the role of increased peptidoglycan biosynthesis in benzethonium chlorideresistant strains (61). A subsequent study by the same group also reported that the peptidoglycan biosynthesis

gene was, among other genes, differentially expressed when *L. monocytogenes* was exposed to sublethal concentrations of benzethonium chloride (62). As mentioned above, transcriptomics and RNA-Seq have been used extensively to identify the global transcriptome of *L. monocytogenes*. Additionally, RNA-Seq has also been used to characterize the transcriptome of important food fermentation microbes such as *Aspergillus oryzae*, a mould involved in many oriental food fermentations (63), and investigate the regulatory response of the brewer/baker's yeast *Saccharomyces cerevisiae* to acetic acid (64).

In metatranscriptomic studies, RNA-Seq is applied to microbial communities to measure differences in gene expression between samples under different environmental conditions or over time. For example, a longitudinal RNA-Seq analysis of the lactic acid bacteria present during kimchi fermentation revealed that the microbiome was dominated by six species whose relative abundance changed throughout the fermentation (65). Many genes related to carbohydrate transport and hydrolysis and lactate fermentation were active over the time course. Of particular note to the authors was a high level of *Leuconostoc mesenteroides*-associated mannitol dehydrogenase genes at the early stages of the fermentation, highlighting the species' role in flavor development.

RNA-Seq analysis revealed strong correlations between the abundance of nonstarter lactic acid bacteria and the levels of expression of genes involved in amino acid and fatty acid catabolism in a traditional Italian Caciocavallo Silano cheese, suggesting a role for these bacteria in maturation (66). Similarly, RNA-Seq revealed that genes associated with proteolysis and lipolysis in *Geotrichum candidum* were highly expressed in a surfaceripened cheese, indicating that the fungus is important for flavor development (67). The authors also identified a subset of differentially expressed genes across ripening stages, which suggests that the ripeness of the cheese could be assessed by measuring the expression level of those genes.

CONCLUSIONS

The rise of genomic technologies has led to an explosion of knowledge on both the composition and the functionality of the microorganisms associated with our foods. With this information, it is now possible to understand the complete genetic complement of pathogenic, spoilage, and bioprocessing organisms and determine how environmental conditions affect their survival and the expression of key genetic traits. As outlined in this chapter, genomic sequences are being used to track foodborne pathogens in food and have led to international initiatives that enable outbreak surveillance. Additionally, the availability of the whole-genome sequences of pathogens, starter bacteria, and probiotic strains means that they can be compared for their genetic content and that their pathogenic or potentially beneficial capabilities can be reliably predicted. The advent of metagenomics and transcriptomics has also allowed further understanding of the role of microorganisms in our foods and how they interact in a complex food matrix. There is little doubt that the future of food microbiology will rely heavily on genomics and other "-omics" technologies in the efforts to trace, understand, and control microorganisms associated with our foods.

This chapter contains information presented by G. L. Douglas, E. Pfeiler, T. Duong, and T. R. Klaenhammer in the 4th edition of this book.

Metagenomics of Meat and Poultry

Meat and poultry products, the animals that produce them, and the environments they are processed in are biologically diverse and contain many (thousands) species of bacteria, viruses, and fungi arranged in complex living environments. These organisms work together and share resources (such as metabolites), much like a community. Within this community, each organism has its own genome, yet some genes are ubiquitous across the community, while others are more specialized, present in only a few or one single species in the community. Together, the genomes and genes within this community are known as the pangenome (1) (Fig. 36.1). By looking at samples through the context of community-wide interactions, instead of a few selected organisms, we can obtain a more holistic model of what is occurring in a given microbial community. This ecological way of thinking can be incorporated into any biological research, including that related to meat and poultry production.

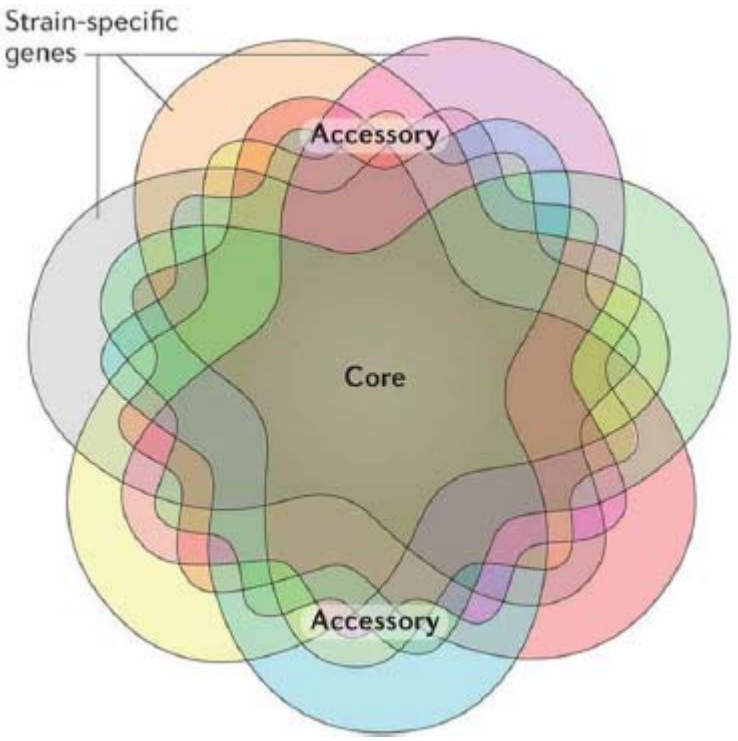
However, even with advancements in microbiological culture techniques, many organisms within and around meat and livestock products will likely never be cultured in a laboratory. This issue is known as the plate count anomaly, which leads to estimates that from 76% (2) to upward of 99.9% (3) of cells within samples cannot be found with culture plating or enumeration procedures alone. While the vast majority of cells will never be cultured in a laboratory setting, these unculturable bacteria still interact within biological communities, contribute to meat safety and quality, and

affect the dissemination of genes of concern to public health, such as virulence factors. To overcome culture-dependent methods, researchers have started integrating culture-free approaches into traditional studies with techniques such as metagenomics, transcriptomics, proteomics, metabolomics, and whole-genome sequencing (WGS).

This chapter specifically addresses the science of metagenomics and how it is used in meat and poultry production to advance food safety and quality.

OVERVIEW OF METAGENOMICS

Metagenomics is defined as the direct genetic analysis of genomes contained within an environment (such as a processing facility, animal model, clinical samples, etc.) (4); such studies can be sequence or function based. The term “metagenomics” was first coined in 1998 by Handelsman et al. (5) in reference to the functional analysis of all of the genomes within a soil sample. Sequence-based studies deal with the direct genetic analysis of genomes contained within environmental samples without a culture step (4). Function-based studies, on the other hand, are conducted by cloning large portions of screened DNA into a host (6). Here, we focus on sequence-based metagenomics.



Strain-specific genes
Accessory
Core
Accessory

Figure 36.1. The pangenome and core genome, based on the Edwards-Venn cogwheel and designed by O. Zhaxybayeva, Dartmouth College. The pangenome of a group refers to the sum of all the genes that are present in members of the group. Pangenomes comprise the core genome, which comprises the genes found in all members of a group of interest, and the accessory genome, genes that are present in only one or a few members of the group. The concept of a pangenome has led to the idea that steps in metabolic pathways may be distributed over several individuals within a community. The Black Queen hypothesis suggests that the combination of leaky functions—genes that produce a product that is shared with others in the community—with a selection for small genomes will lead to a situation in which leaky functions are encoded in the genomes of only a fraction of community members that produce this function as a common good. The pangenomes of many taxa seem to be open (that is, of an unlimited size), although the combination of limited population size and limited time of divergence from a common ancestor certainly limits the numbers of genes actually present in a given taxon. Estimated pangenome sizes taking population size and divergence time into consideration can be large; for example, the *Prochlorococcus* pangenome has been estimated to contain approximately 58,000 genes, whereas the individual genomes of the members of this genus contain only about 2,000 genes each. Reprinted from reference 1.

History and Process

Modern whole-community DNA analysis using sequencing was preceded by cloning environmental DNA into recipient cells (7). This method was eventually replaced by methods that directly isolate nucleic acids from the environment and sequence them; the first such method was Sanger sequencing, published in 1977 (8). Then, in the mid-2000s, next-generation sequencing (NGS) was introduced, with the adoption of pyrosequencing technologies. NGS uses a variety of methods for sequencing, including a popular method called sequencing by synthesis, which allows parallel

sequencing reactions to occur simultaneously, increasing sequencing ability from 96 reactions at a time to several hundred thousand (9). The introduction of NGS brought sequencing costs down by a factor of 10,000 and greatly reduced the labor requirements, which were intensive for Sanger-based sequencing (Fig. 36.2). This technology was first commercialized by 454 Life Science and improved upon by a method known as bridge sequencing, first marketed by Solexa, which was then acquired by Illumina (10). As a result, DNA sequencing became a tool that could be implemented in many laboratories to address more applied topics, including those associated with agricultural production and processing (11). While NGS was initially used for sequencing of single genomes, it eventually became feasible to sequence entire communities of microbial DNA without any need for culture- or PCR-based isolation.

Sequencing a nonenriched sample from an environment of interest (whether that be a processed meat product, feces from a food-producing animal, a sample from a production facility that packages ready-to-eat products, human clinical samples from a foodborne outbreak, or a sample from any other environment of interest to a food microbiologist) provides insights into the structure, composition, and function of the microbial community, which, together, can be referred to as the microbial ecology of the sample. The microbiome is defined as the entire population, and the makeup of the community, of organisms in a given sample or animal. In order to investigate the microbial ecology (the interactions of the microbiome with the environment and host) of a given environment, many steps need to be performed, from study design to molecular biology to bioinformatics to statistical analysis. Metagenomic workflows (i.e., the set of steps conducted to complete a study from study design to publication) are somewhat similar to single-genome workflows; an example of such workflows is presented in Fig. 36.3.

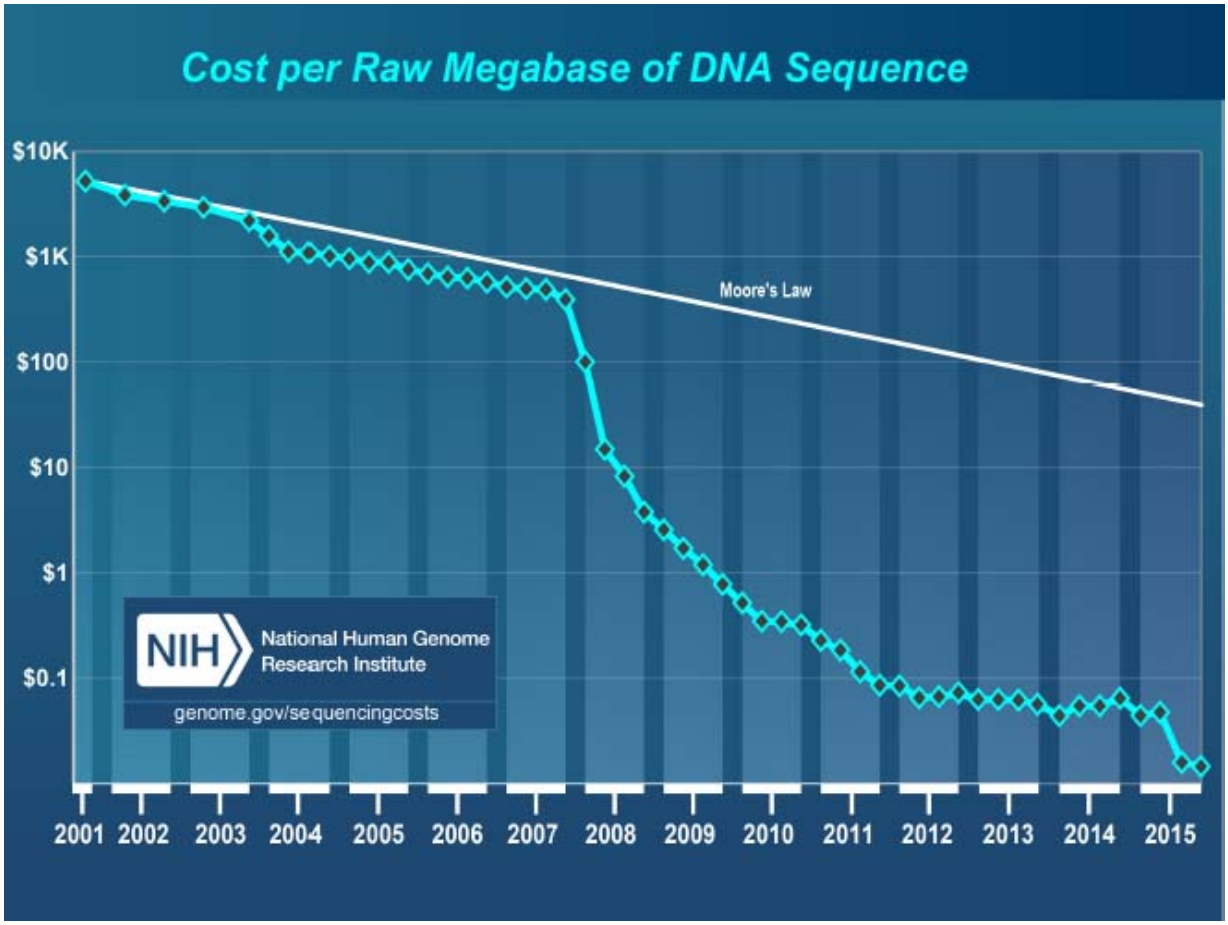


Figure 36.2. The cost of sequencing per megabase pair from 2001 to 2015. Reprinted from reference 87.

Before sampling is conducted, an experimental design is constructed to meet research objectives. While many metagenomics studies currently conducted in meat and poultry science are more explanatory in nature (i.e., determination of what organisms or genes are present in an environment and in what quantities), a shift to hypothesis-driven research is beginning to occur. After the experiment is structured, sampling occurs as aseptically as possible, with special attention paid to not introducing foreign DNA into the sample. From there, DNA is extracted and prepared for sequencing through PCR amplification, “cleanup” steps, and ligation of adapters onto the DNA so that the sequencers can recognize the reads (known as library preparation). Fragmentation, breaking DNA into smaller pieces, is also conducted during library preparation, and

input fragment length is a key difference between short-read sequencing, where this occurs, and long-read sequencing, where it does not.

The manner in which samples are handled (including the specific kits and protocols used to extract DNA and conduct library preparation) can introduce bias into both sequencing and downstream analysis and must be considered carefully in the study design and planning stages (12). A major breakthrough in the preparation of libraries for sequencing was the ability to multiplex samples through the use of bar coding. Bar coding involves the addition of a known, sample-specific nucleotide sequence onto each fragment of DNA, followed by pooling of DNA from multiple samples. This technique greatly reduces sequencing costs by enabling simultaneous sequencing of multiple samples, while maintaining the ability to match DNA sequences back to their originating sample during postsequencing analysis.

It is important to note that one of the main differences between a whole-genome and a metagenomic pipeline is the absence of an enrichment step in the metagenomic pipeline. While single-genome workflows enrich for specific bacteria (through selective culturing and broths), a main objective of metagenomics is to look at a nonenriched view of the entire community. Thus, no steps are taken to differentially increase abundance of specific species, which would not allow accurate relative-abundance estimates. Sample-processing steps must be as unbiased as possible so as not to artificially perturb the composition of the microbial community (12).

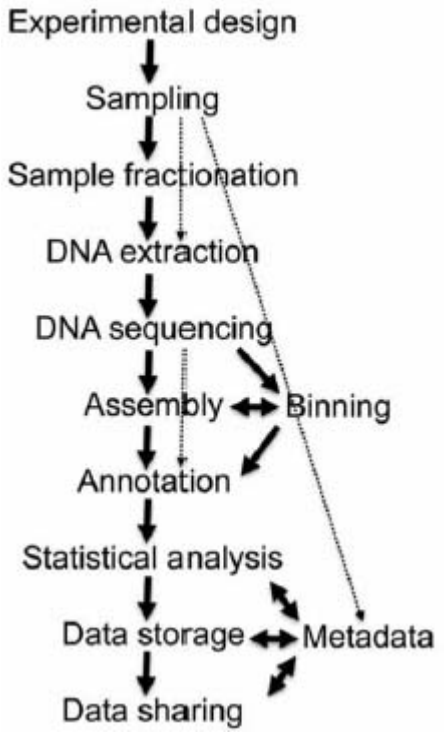

Figure 36.3. Flow diagram of a typical metagenome project. Dashed arrows indicate steps that can be omitted. Reprinted from reference 4.

Once DNA has been extracted, fragmented, and made into a library, DNA is sequenced either through shortread (e.g., Illumina platform) or long-read (e.g., Pacific Biosciences [PacBio]) sequencing. To date, metagenomic studies have mostly utilized short-read sequencing due to lower costs, greater general accuracy, and higher output compared to long-read sequencing technologies. The primary disadvantage of short-read technology is the inability to assign what genes or features of interest belong to what organism due to the shearing of DNA for library preparation.

The process of sequencing DNA produces FASTQ files that contain the DNA sequence of each fragment of DNA, as well as the sequencing quality score for each nucleotide. These short fragments are referred to as “reads,” and each read within the FASTQ files has a unique identifier. With these raw sequence reads as a starting point, bioinformatic analyses can begin. The first step of the bioinformatics pipeline is typically quality control of the sequence

data, which involves removal of library adapter sequences, removal of low-quality nucleotides on the ends of reads, and removal of reads that have overall low quality or are too short. For analyses in which bacterial community is of main interest (such as a study on the shelf life of meat), reads that belong to the host (e.g., *Bos taurus* or *Gallus gallus* DNA) can be removed as part of the quality control process. After quality control is complete, assembly and/or alignment of the sequence reads can begin. Assembly involves stringing the short reads back together into longer sequences called "contigs," typically using de Bruijn graph-based or overlap-layout-consensus algorithms (13). Due to the nature of metagenomic DNA, assemblies tend to be highly fragmented; i.e., they have numerous short contigs, especially compared to assembly of single-genome DNA sequence data. Once contigs are assembled, they typically are compared to existing databases using matching algorithms such as BLAST (14) in order to identify sequences of interest.

Alignment, on the other hand, allows bypassing of assembly and attempts to match unassembled sequence reads directly to existing databases, typically using algorithms such as the Burrows-Wheeler aligner (15). Whether assembled or unassembled data are used, the process of matching DNA sequences to existing databases allows the identification and quantification of genes and/or organisms of interest within the metagenomic data (note that, in the case of 16S sequencing [discussed below], only phylogenetic classification can occur, while shotgun metagenomic analysis provides a broader picture of genomes present in the sample as well as functional and gene differentiation). Once genes and/or organisms of interest have been identified and counted, descriptive and formal statistical tests can be conducted in conjunction with previously collected metadata (i.e., descriptive data associated with the samples, such as location, sample matrix, environmental characteristics, etc.). The specific comparisons made during statistical analysis depend largely on study design, although basic descriptions, such as number of reads, read quality, and level of host contamination, are typically reported for all metagenomic studies. After formal comparisons have been

conducted, raw data and critical output files must be stored on a secure server or backed up in another manner, such as in the "cloud." As with other sequencing studies, metagenomic datasets are often deposited as raw sequence data onto public repositories such as the National Center for Biotechnology Information Sequence Read Archive (16), as this is frequently a requirement for publication in highquality scientific journals.

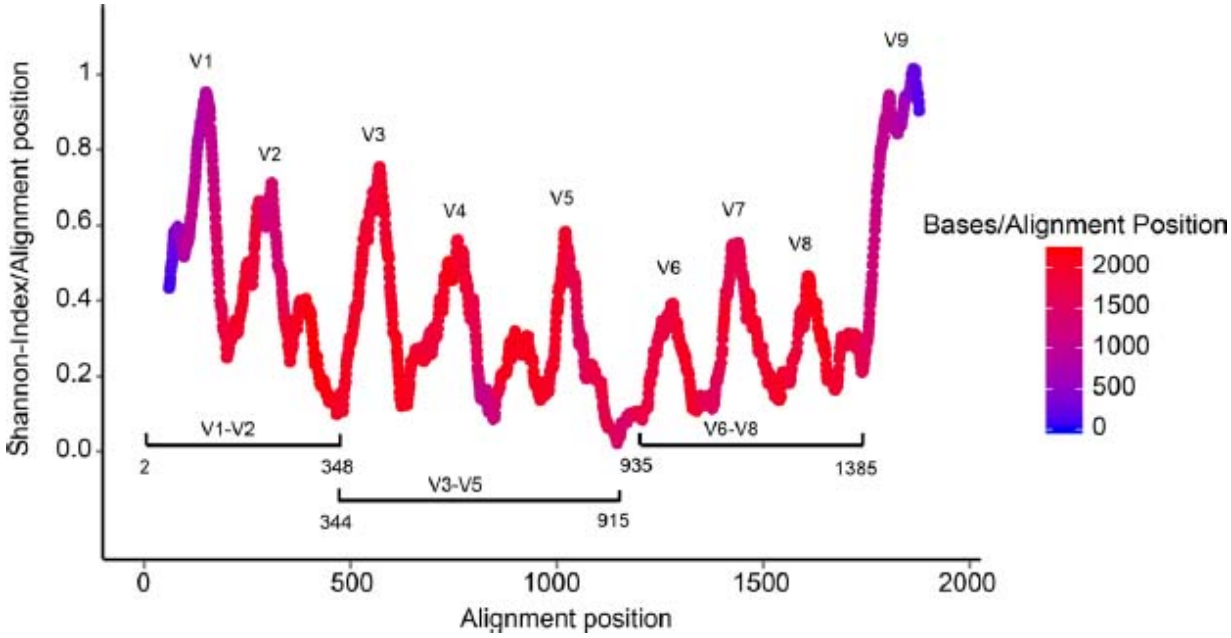

Figure 36.4. Coverage of the archaeal 16S rRNA gene by sequences included in RIM-DB. Sequence variability is expressed as a Shannon index for each alignment position using a 50-bp moving average. Sequence coverage per base is indicated by the heat map and was calculated using a 50-bp moving average. Approximate positions of frequently targeted regions (V1-V2, V3-V5, and V6-V8) for amplicon sequencing are shown for orientation and nucleotide numbering and correspond to positions in the *E. coli* 16S rRNA gene. Reprinted from reference 88.

Terminology used in discussions of metagenomic studies currently is in flux, and 16S microbiome studies and/or extensive sequencing of a single species are often referred to as "metagenomics." It is important to note that, from a purist point of view, the term "metagenomic" means "genome of genomes" and thus refers to

whole-community, unrestricted sequencing of all the genomes in a sample (known as shotgun metagenomics). Alternatively, 16S sequencing studies involve PCR amplification and sequencing of the 16S rRNA gene as a marker to investigate the taxonomic bacterial composition of a sample (17). Because shotgun sequencing is unspecific with regard to what piece of the bacterial genome is amplified and sequenced, it can be used to look at microbial community composition as well as other features of interest, such as specific genes and detailed metabolic and functional profiles (18). On the other hand, 16S rRNA sequencing uses primers that anneal to conserved genomic regions that contain segments of hypervariability (known as variable regions V1 to V9) (Fig. 36.4). The 16S rRNA gene itself is specific to bacteria and archaea and is highly conserved between species, making it a useful target for capturing most of the bacteria within a sample; the hypervariable regions within the 16S rRNA gene, on the other hand, tend to differ between bacterial genera and/or species and thus can be used to reconstruct the taxonomy of the bacteria and archaea within the sample.

While it is much less expensive than shotgun metagenomics, there are some drawbacks to 16S rRNA analysis that are caused by amplifying only a portion of the genome (as opposed to unrestricted sampling of the entire genome, as in shotgun studies). Namely, 16S rRNA sequencing reads cannot be assigned to taxa at high resolution, such as at the species or strain level (17). Additionally, because only the 16S rRNA gene is targeted and sequenced, use of 16S rRNA sequencing does not allow direct functional analysis of the communities being studied. Some pipelines attempt to perform correlative analysis between the taxonomic composition of a sample and its potential functional capacity (e.g., potential metabolic pathways). Some of these pipelines use curated databases of both genomes and so-called marker genes, the latter of which have been confirmed to correlate to both specific bacterial taxa and specific bacterial functions. It is important to note that the accuracy of such

correlative analyses is under debate within the scientific literature (19).

Bioinformatics

A unique component of analyzing large biological data sets is reducing gigabytes (or more) of data down to manageable, useful information. Bioinformatics is defined as the application of computational tools to the capture and interpretation of biological data (20). Bioinformatics is multidisciplinary, as it combines the expertise of fields such as computer science, statistics, and biology to understand and interpret the information contained in large data sets.

In shotgun metagenomics, there are many tasks that must be automated through shell scripts and algorithms in order to make them efficient. These tasks can range from simple to complex, but all of the tasks must be well understood in order to verify that the bioinformatics tools are being used appropriately. An example of a simple, but essential, tool is read trimming and filtering (i.e., quality control; see above). After raw sequences are produced by the sequencer, removal of sequencing adapters and low-quality nucleotide reads is an essential task. While this would be easy to do manually on one read, a typical study has billions to trillions of reads to process. Tools like Trimmomatic (21) provide free, open-source scripts for public use. Published tools can be focused on a specific task, such as trimming or alignment, or can be in the form of "pipelines" that wrap multiple tools into one bioinformatic workflow. Wrapping multiple tools into one computational workflow helps not only with speed but also with data reproducibility. Galaxy (22) is an example of a reproducible research system, which is an environment for executing and tracking computational analyses (23). The advantage of these types of systems is that they not only keep the analysis organized but also can be published alongside research findings for reproducibility.

On-Target Reads

When one is preparing to conduct an analysis, evaluating whether there are enough sequences in relation to the sample type and diversity is a precursor to a statistical analysis. One way to assess this is to perform rarefaction of the sequence data to produce a rarefaction curve (Fig. 36.5). A rarefaction curve traditionally displays sampling depth on the *x* axis and features (species, genes, etc.) or a measure of richness on the *y* axis. If sampling depth (i.e., the number of sequences attributed to each sample) is appropriate, the curve constructed for the sample (or group of samples) should level out when an appropriate sampling depth is reached. The depth of sequencing that needs to occur differs by bacterial community type as a function of diversity (i.e., the more diverse the matrix, the more reads are needed). While deep sequencing (i.e., sequencing a high number of samples) would be ideal for research, the cost makes "unlimited" sequencing impossible. As a result, prestudy work with a smaller subset of the sample type of interest, or relying on previously published work, needs to be considered before a sequencing depth is targeted.

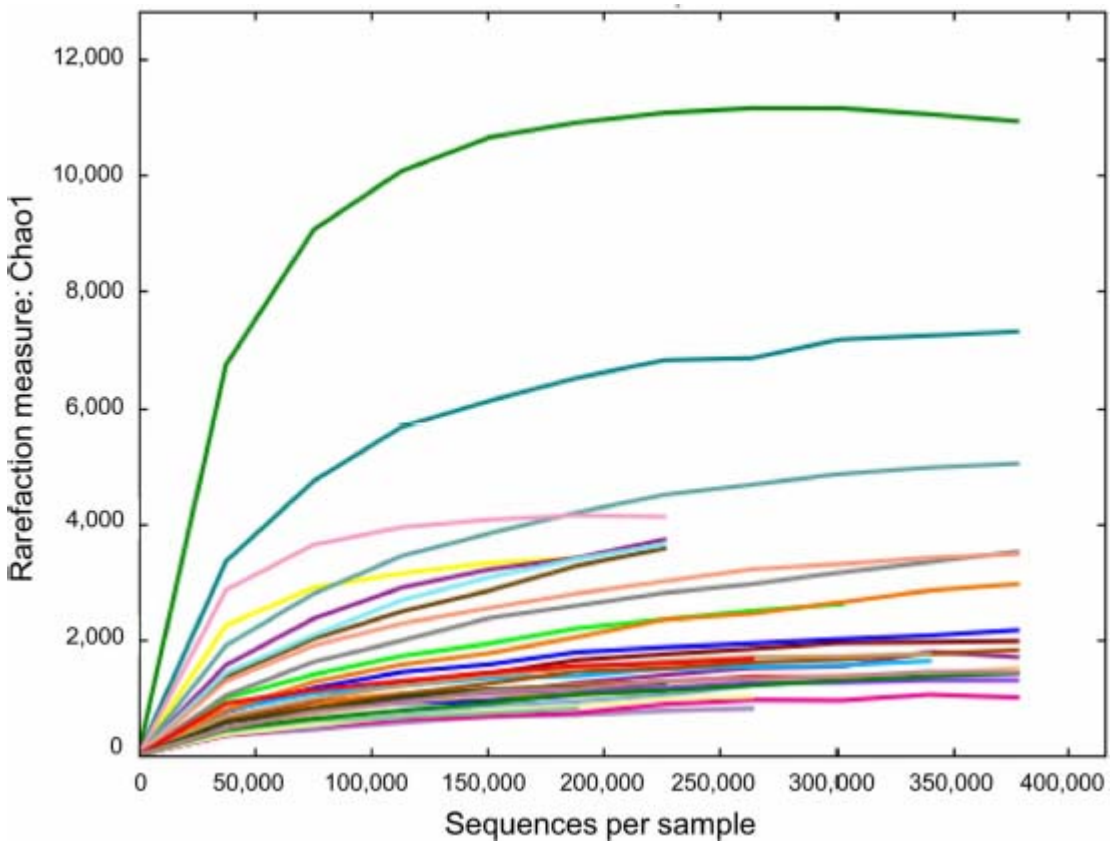

Figure 36.5. Rarefaction plot of individual liver sample from Chao1 measurements. The leveling off in all samples indicates that an appropriate sampling depth was reached to estimate the diversity of the community. Reprinted with permission from reference 72.

While appropriate sequencing depth is a concern, the number of reads that map to a feature of interest (known as a hit) must also be considered. For example, in a study conducted on beef cattle production (24) that sampled both feces and meat, only 1.5% of total raw reads aligned to the bovine host genome and were removed from the sequence data, while 99.6% of sequences in the meat were associated with the bovine genome. This study was conducted to evaluate antibiotic resistance genes in the samples, yet across all samples, only 0.04% of all of the raw sequences were attributed to one of these genes. As a result, 99.6% of the sequences in this study did not contribute to the research objectives and could be considered off-target. This is not an uncommon occurrence in metagenomic studies in which the objective is to investigate a

subset of genes within a wider population. There has been some work to combat this issue, including use of both functional metagenomics (not discussed in this chapter) and targeted sequencing. Targeted sequencing involves specifying features of interest and designing "baits" for these targets (25). Once baits have been designed, they can be used to enrich for specific sequences within the metagenomic DNA via magnetic streptavidin beads, resulting in more on-target hits than a sample without targeted sequencing.

Dealing with Different Library Sizes

There are many decisions that must be made to minimize bias when a metagenomic study is carried out. These decisions start with experimental design and carry through to data presentation. One decision that must be made is how to "normalize" the sequence data. Weiss et al. describe normalizing as "the process of transforming the data in order to enable accurate comparison of statistics from different measurements by eliminating artifactual biases in the original measurements" (26). While library preparation and sequencing technologies have improved dramatically in short periods of time, there still can be an issue with uneven sequencing of DNA from samples. This results in sequence read data sets with differing sizes. For example, equal volumes of DNA extracted from two samples can be sequenced on the same sequencer at the same time, but one may generate 20 million reads while the other may generate 40 million reads.

Table 36.1. Comparison of number of reads in a 16S rRNA sequencing study and a shotgun metagenomics study

	No. of reads		
Study type	Minimum	Maximum	Median
Shotgun metagenomics (24)	12.0 million	93.4 million	46.3 million
16S rRNA sequencing (72)	190,551	996,910	350,716

Such sequencing bias is common with NGS; Table 36.1 provides an example of a shotgun and a 16S rRNA study's minimum, maximum, and mean numbers of reads per sample. While differences in the number of sequences obtained from different samples are common, they are rarely a reflection of true biological differences, but more of sequencing inconsistency. A few factors that affect read number include raw DNA allocation during pooling of DNA for sequencing, sequencing protocol and sample matrix, and sequencer efficiency—such as variation in output from lane to lane on the same sequencer (27). Because it is currently impossible to ensure completely uniform sequencing depth, postsequencing tactics must be used to normalize for the uneven numbers of reads generated per sample.

Two common methods of normalizing are rarefying and scaling (Fig. 36.6); both provide advantages and disadvantages. Rarefying is the process of randomly sampling without replacement from each sample up to a common count (26). For example, if one sample had 1,000 reads and another had 2,000 reads, and the rarefying depth was set at 1,000 reads, the smaller of the two samples would be completely represented because all1,000 reads would be sampled. From the 2,000-read sample, 1,000 reads would randomly be drawn without replacement and the rest discarded. This would result in an equal number of sequences for each of the two samples (i.e., 1,000), and these reads would be carried forward into statistical analyses. The minimum number for rarefying could be selected as the lowest number of reads per sample within the data set; alternatively, a higher number could be chosen, resulting in exclusion of samples with a lower number of reads. Scaling, on the other hand, is multiplication of count by a number or proportion. While total sum scaling divides counts by total number of reads, a more sophisticated technique known as cumulative-sum scaling builds on this method such that counts are divided by the cumulative sum of counts up to a percentile determined by the data (28). Another approach to dealing with count data is a logarithmic-ratio transformation. However, because a log transformation can be used only with positive numbers, pseudocounts must be added to zeros

(i.e., usually adding a 1 to each observation), an issue that can result in bias (29).

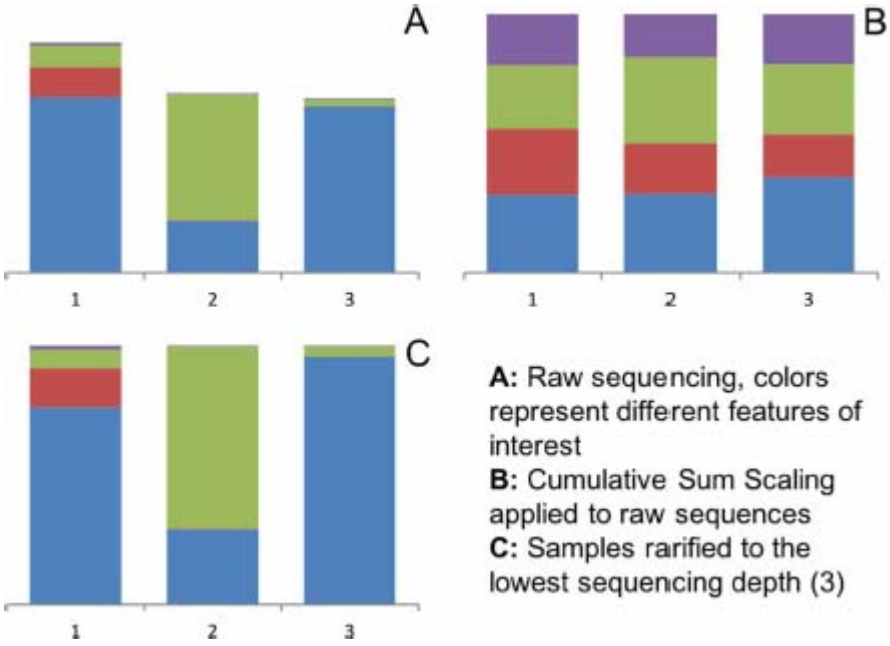

Figure 36.6. Demonstration of cumulative sum scaling (B) and rarefying (C) of raw sequences (A).

Rarefying effectively mitigates varied sample read count size and is especially versatile in handling small and uneven library sizes (26). Disadvantages to rarefying include "throwing away data" (i.e., using only a small proportion of total reads) and adding an additional uncertainty to the data (30). In contrast, cumulative-sum scaling and other scaling methods utilize all counts in the sequencing data by adjusting them by a proportion. However, scaling also has problems associated with it. It can over- or underestimate rare features in samples (26). These issues can be illustrated by looking at two library sizes, one of 10,000 counts and another of 100,000 counts. In the small library, overestimation of abundance can occur. For example, if a feature is present in both samples at a minimal number, the scaling factor applied to the smaller library may overestimate a feature that is, in fact, very rare in the population.

Normalizing is currently a necessary tool due to vastly different sequencing library sizes among samples. Unfortunately, there is no

perfect method that allows all data to be evaluated while avoiding over- or underestimations of features of interest. However, tools are being developed that incorporate more robust models to handle these types of variably sized data sets (31). This is an area that has seen recent growth and will continue to evolve as bioinformaticians and statisticians develop models that more correctly handle count data.

Data Presentation

Metagenomic data are multivariate, and studies routinely generate gigabytes and even terabytes of data. While bioinformatic tools reduce these large data sets to more manageable sizes, the way in which metagenomic results are reported and visualized often differs from that of traditional culture-based reporting methods. While, depending on the objective(s), there are many hypothesis-driven tests that can be performed, Fig. 36.7 displays examples of various descriptive graphical representations of analyses common to metagenomic studies. A taxonomy plot, or 100% stacked bar graphs, can represent individual sample diversity or the taxonomy of groups of samples that share common phenotypic characteristics. Ordination plots (including principal component analysis and nonmetric multidimensional scaling plots) are used to visualize the calculated distances between samples based on some characteristic, typically the composition of the microbiome. This allows visualization of “like” and “unlike” samples, i.e., clustering. Heat maps can be used to illustrate feature abundances (such as a species of interest or specific genes or classes of genes) across samples or groups of samples, again with the goal of visualizing clusters of like samples. Phylogenetic relationships are represented as “trees” built on how similar or dissimilar species or communities are. Uses for these trees can include illustrating the full phylogenetic diversity of a sample and comparing a subsection of data, such as the diversity of species within a genus. Network analysis is the visualization of associations between genes or other features of interest. Co-occurrence of these features is something that can be demonstrated

with a network analysis, as well as associations. While these methods of visualization are a starting point for data interpretation, there are numerous, more robust hypothesis-testing methods, such as ZIG models (28), PERMANOVA (32), and Bayesian network analysis (33), that are used in metagenomics but that are outside the scope of this chapter.

Advantages of Metagenomics

In addition to the relative reduction in cost in the past decade and the ability to study uncultured organisms, metagenomic methods have other advantages. These include the ability to assess community ecology and to study unknown pathogens of interest. The most touted advantage of metagenomics is the ability to look at an entire community of bacteria. As discussed in chapter 3, culture-based techniques often use indicator organisms, such as generic *Escherichia coli* or aerobic plate counts, as markers for pathogenic bacteria. While indicator organisms are used to indicate pathogens as a fraction of a larger population, some studies have shown only limited direct relationships between indicators and pathogens (34). Instead, in some cases, the use of indicator organisms rests on the assumption that if a reduction is induced or occurs in the larger microbial population, the pathogenic subpopulation also will decline in magnitude accordingly (35). Metagenomics, on the other hand, can be used to directly assess the presence and abundance of organisms in a microbial population, as well as the presence of specific genes of interest. While metagenomics has primarily been used to develop inferences concerning bacteria, the technique also allows indepth investigation of the virome (all the viruses in a given environment), the mycobiome (all the fungi), and the plasmidome (all the plasmids). This is of special interest in food microbiology, where processes like shelf life and aging are also heavily influenced by fungal growth.

In addition to identifying and quantifying the organisms within a given microbial community, interactions between organisms can be

studied. To assess relationships between features of interest (genes, genomes, or sets of genomes) in a bacterial population, co-occurrence and coexclusion relationships can be studied in the context of network analysis. Co-occurrence and coexclusion relationships look at whether a specific feature of interest occurs at a higher rate alongside another feature; for example, two genes that are on the same plasmid would have a higher co-occurrence than two chromosomal genes from different species of bacteria. Network analysis can provide insight into intertaxon associations to understand symbioses between community members; this allows more complex pattern discovery than traditional diversity metrics (36). Understanding associations between different microorganisms within a bacterial community can guide researchers towards specific targets for alteration or manipulation of the community—a systems approach to food safety and quality control.

Disadvantages of Metagenomics

While NGS has substantially lowered sequencing costs, there are still financial barriers. These barriers are not limited to generation of sequence data but extend to computational capabilities, data storage, and, in some cases, the need to hire a bioinformatician and/or laboratory personnel familiar with NGS. As sequencing costs are dropping rapidly, costs associated with data analysis and storage are forecast to occupy a larger proportion of total experimental costs (Fig. 36.8). After the financial cost associated with the technique has been overcome, there are hurdles related to metagenomics being a relatively new technique; namely, shortcomings associated with public databases and the availability and usability of analytical tools.

With respect to public databases used in metagenomic analysis, there are several difficulties that researchers may encounter, including incomplete databases, misannotation, and inconsistent nomenclature. While the rise in NGS has helped fuel the expansion of many databases, there are still features and organisms that have yet to be entered into a database. To combat this issue, one method

of *de novo* discovery of novel genes or organisms, called *de novo* assembly, has been developed (37). The issue of unannotated sequence data is especially prevalent for fungi; while public databases exist, they are generally a few years behind those established for bacteria (38). This is especially challenging to food researchers studying shelf life and fermentation, where fungi play an important role in bacterial communities. The second issue surrounding databases is the possibility of misannotation (i.e., that a gene or species of interest is erroneously attributed to an incorrect species due to an error in the database). When misannotation occurs, the only remedy is careful curation of the database, which is timeand labor-intensive. Finally, there is the concern over inconsistent nomenclature and taxonomic grouping "rules." This can be addressed by instituting standards for the naming of features or organisms. An example of this is found in antibiotic resistance gene naming, where a gene needs at least a 2% difference in nucleotide makeup from its closest relative for it to be designated as a "new" gene (39).

Metagenomic studies require the merging of computational and biological knowledge. Historically, these disciplines (i.e., computer science and the life sciences) have been largely separate. As life science researchers increasingly utilize bioinformatic software, the userfriendliness of these tools continues to improve (38). 16S rRNA sequencing, which has a longer track record than more costly shotgun metagenomic sequencing, can be analyzed using two widely available platforms (mothur [40] and QIIME [41]), both of which have graphical user interfaces for improved accessibility for life science researchers. For shotgun metagenomics, such tools have not

yet been established, and many analyses can still be performed only via the command line (i.e., interacting with a computer only via coded commands, with no mouse capacities or graphics to guide the user).

METAGENOMICS OF MEAT AND POULTRY

Limitations associated with use of culture-dependent methods have been known in food microbiology for many years. Before NGS became common, food microbiologists attempted to look at unculturable bacteria through other avenues. For example, 16S rRNA gene PCR and denaturing gradient gel electrophoresis fingerprinting were tools used as a precursor to the modern 16S rRNA sequencing protocol. These tools separate equal-length DNA fragments based on sequence-specific melting in a polyacrylamide gel with a gradient of a denaturant chemical (42). The difference between this method and more modern analysis of 16S rRNA is that, after extraction and PCR, fragment lengths are separated on a gel as opposed to being prepared for library sequencing. While widely employed as a precursor to modern-day microbial ecology studies, this method does have drawbacks. In addition to less-developed whole-community DNA extractions, other problems include formation of chimeric sequences (a new artificial gene created when two or more biological genes overlap and combine during PCR) affecting the band distribution, limited DNA fragment length (500 bp), comigration of DNA fragments (resulting in different fragments having identical melting behavior), and a single species with multiple rRNA copies, resulting in multiple bands and diversity overestimates (43).

As a result of these issues, shotgun metagenomic techniques are starting to be used to answer specific food safety and quality questions regarding meat and poultry. There are many areas within food microbiology in which metagenomics can aid further research. While targeting pathogenic bacteria is related to food safety and assessment of specific spoilage bacteria is more closely associated

with meat quality, both safety and quality studies are beginning to look at the entire community of organisms in an environment. In the past, metagenomics in meat and poultry production was primarily used for descriptive purposes; e.g., finding the true polymicrobial diversity of a specific food product or environment (38). As more background understanding is obtained, hypothesis testing is now beginning to emerge, using both 16S rRNA sequencing and shotgun metagenomics in randomized, controlled studies (44).

Food Safety

Mitigation of specific culturable pathogen strains or indicator organisms has been the standard in meat and poultry production as a result of the sensitivity and affordability of these methods. However, some culture methods take up to a few days to confirm a positive presence of pathogens of interest (45). While rapid diagnostic methods, such as culturing or BAX PCR, allow fast screening of potential pathogenic bacteria, results are only a presumptive positive or negative and still require a cultural confirmation through biochemical, serological, or genetic tests (46). While not currently deployable within the framework of on going food safety programs, a future goal of metagenomics is to provide confirmatory rapid pathogen detection in complex sample matrices. Currently, metagenomic research with respect to pathogenic organisms can be broken down into detection and reduction of organisms, as well as more downstream public health application within a greater microbial community.

Pathogenic Bacteria

Detection of Pathogenic Bacteria with Metagenomics

While whole-genome sequences for many pathogens are available in the public domain, there has been limited use of metagenomics as a tool in true regulatory pathogen identification. An example of limitations regarding pathogen detection in metagenomic samples

was demonstrated in a metagenomic study of a feedlot beef production system. This study highlighted both the challenges associated with genetic similarity between many bacterial species and the downfalls of short-read analysis. Because shotgun metagenomics has a nonbiased enrichment PCR step in library preparation, there is randomness with regard to what portion of any bacterial genome will be sequenced. For example, in the beef study, a 100-bp read assigned to the *Salmonella enterica* serovar Newport reference genome could have come from this serotype, but *S. enterica* serovar Typhimurium and other members of the *Enterobacteriaceae*, such as *E. coli*, also shared the same conserved genetic region (Fig. 36.9) (47). As a result of these homologous regions between bacteria of different strains, and even different species, short-read sequencing cannot offer a definitive answer regarding what strain a specific 150- to 250-bp fragment belongs to. In situations where strain-level differentiation is the difference between an adulterant in a meat product and an organism that is considered part of the natural microflora, metagenomic tools are not capable of these distinctions due to intraspecies genetic homology and limitations of short-read sequencing.

As a result, pathogen detection within unenriched samples (i.e., within metagenomic data) is still a future goal and not a current reality. In contrast, WGS is already being used in outbreak investigations, as this technique enables highly sensitive differentiation of extremely similar serotypes (even down to a single nucleotide polymorphism) (48). The reason that WGS is currently better suited to such applications is its ability to create full-length genomic assemblies from the sequence data, as opposed to metagenomic data, which typically produce very fragmented, low-quality assemblies.

With metagenomic limitations in mind, there has been some work to solve issues associated with pathogen detection in metagenomic data. The creators of SeqSero, a Web-based tool for determining *Salmonella* serotypes using high-throughput genome sequencing data from more than 2,300 serotypes, have attempted to identify

Salmonella in shotgun metagenomic data (49). While the tool is aimed primarily at WGS assembly of *Salmonella*, it does provide the option for pathogen detection within shotgun metagenomic data. The SeqSero developers tested the method by infecting mice with *Salmonella* Typhimurium and then using metagenomic sequencing of DNA extracted from the feces from the mice; they were able to identify *Salmonella* Typhimurium (Table 36.2). As a follow-up, fecal samples from patients known to harbor *E. coli* O104:H4 also were evaluated using the same tool to test for false positives; no reads from this sample group mapped to *Salmonella* spp. (49). While this work provides a framework for identification of pathogens within metagenomic data, the *Salmonella* in the mice was at an elevated level due to an active illness. In contrast, detection of food-associated pathogens would need to detect specific strains at a lower relative abundance than those present in clinical infection doses.

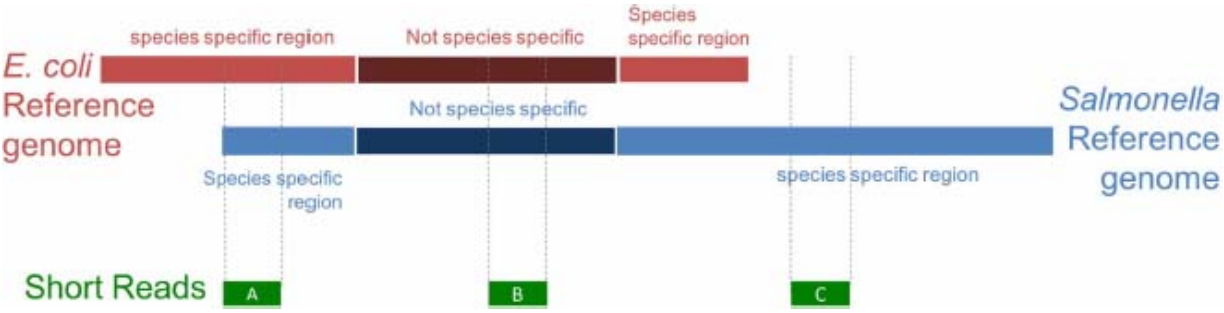

Figure 36.9. Because metagenomics is primarily associated with short-read sequences, species-specific differentiation is difficult due to different species containing the same homologous sections of nucleotides. Therefore, the section of the genome sequenced may be in a species-specific region of the genome (A or C) or may be shared by both bacteria (B) and would therefore not allow differentiation.

Detection of Pathogen Reduction Using Metagenomics

While metagenomics was not used during the 2011 European *E. coli* O104:H4 outbreak, retrospective use helped characterize the event. After the outbreak, 45 archived fecal samples from patients were evaluated using shotgun metagenomics. Using this retrospective analysis, researchers were able to create a draft sequence of the outbreak *E. coli* strain, but they were successful at detecting the strain in only 67% of the cases that were confirmed via culture (50). While not effective at overt pathogen detection, this study did provide evidence of the ability to create draft genomes from metagenomic samples. This demonstrated the usefulness of metagenomics as an approach to characterize outbreak strains and find co-occurrences of outbreaks. Metagenomics also can be paired with other NGS techniques to investigate reductions in pathogen prevalence or abundance. While not directly related to detection of pathogens, a study conducted to identify metabolic pathways of enterohemorrhagic *E. coli* demonstrated that the pairing of techniques was effective by first using 16S rRNA sequencing to

understand the bacterial community of ground beef and then looking into metabolic pathways (51).

Metagenomics in a Public Health Setting

While there are clear limitations to the clinical application of shotgun metagenomic assessments to detect pathogenic bacteria, it has been used in some instances. For example, in a clinical setting (52), a patient that presented with symptoms consistent with a foodborne illness was tested for the presence of several bacterial and viral pathogens within the feces through traditional culture methods; however, no pathogen was detected, and therefore the illness could not be diagnosed. After the patient recovered from the illness, another stool sample was obtained and the metagenomic DNA was compared to DNA extracted from the original sample collected while the patient was ill. Reads associated with *Campylobacter jejuni* were detected, which then was confirmed by PCR of the sample taken during illness but not the sample taken after recovery (52). This resulted in the ability to confirm the causative agent of a foodborne illness that was not possible through traditional culture methods. This case demonstrated the utility of shotgun metagenomics in finding a causative pathogen when it is not clear which pathogen is being sought.

Commensal Bacteria

While identification and quantification of pathogenic bacteria have been the cornerstone of food safety for years, researchers are beginning to understand the importance of commensal bacteria in modulating health and disease of both individuals and environments, such as factories and meat and poultry products. Bystander bacteria, while not harmful on their own, can carry genes of interest that escalate risk of disease (Fig. 36.10). Metagenomics allows increased understanding of the relationships between commensal microbes and pathogens, because researchers can sequence whole-community DNA to obtain a “full-resolution picture” of the microbial community. Currently, identification and

quantification of the organisms in a sample are the cornerstone of metagenomic studies, but more advanced analyses are beginning to find their way into the literature, including those designed to answer questions such as what portion of the microbiome is transmissible both intra- and interspecies, what the mechanisms of this transmission are, and what—if any—organisms in the commensal microbial population should be considered more or less risky (53).

A specific example of the role that commensal bacteria can play in dissemination of genes of interest lies in the case study of antibiotic resistance genes. Some research has demonstrated that when an antibiotic is introduced into a bacterial community, the microbial community can become stressed, resulting in increased rates of horizontal gene transfer (54). Commensal bacteria can donate and accept genes via horizontal gene transfer, and as a result, both the commensal and pathogenic bacteria can acquire, carry, and disseminate these genes (55). A widely studied commensal bacterium is generic *E. coli*. While diarrheagenic *E. coli* and enterohemorrhagic *E. coli* (also called Shiga toxin-producing *E. coli* [STEC]) are the main public health concern, understanding harmless *E. coli* aids in the understanding of pathogenic *E. coli*. This is due to the fact that horizontal gene transfer occurs at a higher frequency in bacteria that are most closely related (1).

A specific community dynamic of importance to meat and poultry production is biofilm formation in processing facilities. Shotgun metagenomics has allowed study of multispecies biofilms and their complex microbial interactions, including genetic makeup, metabolite exchange, and quorum sensing, that may occur between microorganisms in biofilm communities (56). In biofilm communities, *E. coli* O157:H7 has been shown to possess the ability to cocolonize with commensal bacteria, and shotgun metagenomics assays have been used to study microbial competition for essential macronutrients (56).

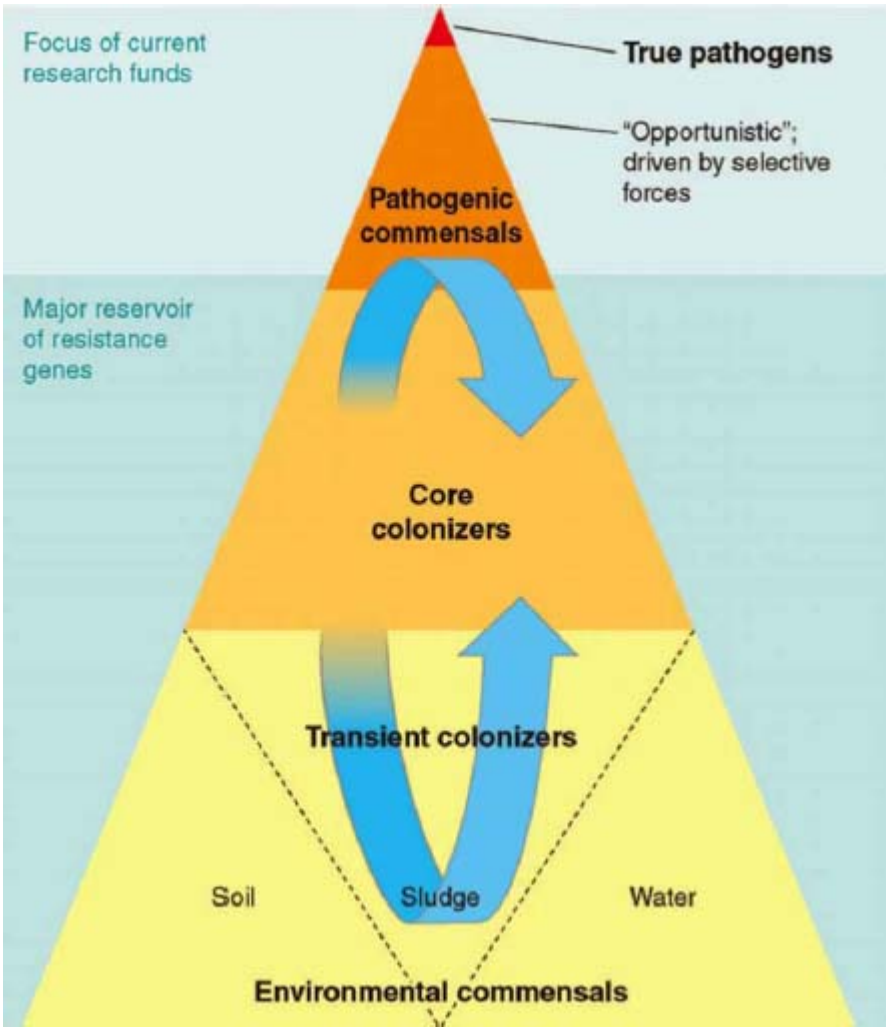
Genes of Interest

Biological hazards in meat and poultry products have primarily been described in the context of a pathogen or toxin of interest (certainly there are exceptions to this, such as *E. coli* differentiation based on virulence). However, with new technologies, instead of considering the microorganism in its entirety, specific biomarkers can be evaluated (57). In this way, pathogenic bacteria can be further delineated based on specific genetic attributes. Two common genetic components of interest in foodborne pathogens are antibiotic resistance genes and virulence factor genes.

Antibiotic resistance

Antibiotic resistance in meat and poultry products is of concern due to use of antimicrobials in the raising of food-producing animals. The apprehension surrounding antibiotic use in livestock stems from concerns that consumption of products derived from animals administered antimicrobials could increase the risk of antibioticresistant bacterial infections and treatment failure in humans (58). In the past, antibiotic resistance has mainly been evaluated using cultural methods such as those of the National Antimicrobial Resistance Monitoring System (NARMS) (59). This protocol is intended to monitor trends in antimicrobial resistance among enteric bacteria from humans, retail meats, and animals (59). However, the current workflow calls for enrichment and culturing of specific pathogens of concern in relation to foodborne illness, followed by antimicrobial susceptibility testing of cultured isolates; enrichment changes the relative abundance of organisms in the community, and therefore, biases result. Furthermore, some of the tested isolates are sequenced as part of the NARMS WGS initiative, after which the sequences are deposited in GenomeTrakr, a public database of genomes (59). Currently, however, there is no exploration of commensal bacteria in these NARMS samples, and therefore no investigation into the potential for a “commensal” reservoir of antibiotic resistance genes (60). Previous research has demonstrated that many commensal bacteria harbor antibiotic resistance genes. Hence, accessing these commensal bacteria may

be critical in furthering our understanding of antimicrobial resistance and its transmission to humans (60). While antimicrobial resistance regulatory and surveillance programs continue to rely on testing of cultured indicator organisms, the research sector has produced studies that identify and quantify all known resistance gene sequences within metagenomic DNA (i.e., the resistome) (24). Such an approach allows detection of antimicrobial resistance genes within both pathogens and commensal bacteria and potentially allows detection of horizontal gene transfer events within the microbial population (61).



Focus of current research funds

Transient colonizers
Soil
Sludge
Water
Environmental commensals

Figure 36.10. Hierarchy of commensals (not to scale). Pathogenic commensals make up only a tiny fraction of the total microbial environment. Greatly under rated and under studied are the multitudes of "core" and transient colonizers, i.e., commensals that constitute the major reservoirs of resistance genes. To some degree, commensals can be distinguished by their place in the environment and the relationships with their hosts. Some colonizers of the skin, oropharynx, and intestinal tract rarely if ever cause dis ease (e.g., the lactic acid bacteria). Yet another group is considered generally nonpathogenic, but when imbalances or shifts occur in the selective pressures on their microbial niches, these species can be propelled to the status of pathogens, made more problematic if they have acquired resistance or virulence genes from neigh boring commensals. These constitute the group of opportunistic or pathogenic commensals. *Staphylococcus aureus*, which regularly or transiently colonizes about 80% of humans, now frequently crosses this border. *Staphylococcus epidermidis* and other traditionally commensal coagulase-negative staphylococci only occasionally cause nosocomial infections and only under extreme selective pressures, such as those exerted by indwelling catheters and depressed immunologic states. Organisms that commonly harbor native or "constitutive" resistance in their chromosomes (e.g., *Pseudomonas, Stenotrophomonas, and Acinetobacter*) also may emerge under these conditions. Most commensals, however, exist as environmental residents of soil and water habitats, many of which may be come transient colonizers of humans and animals through the food chain and other routes of exposure. The accumulated evidence suggests wide spread gene exchange among these groups. Reprinted from reference 60.

Another challenge in the evaluation of antibiotic resistance genes in a metagenomic sample is the disuniform methods of analysis. From sampling to processing to data interpretation, there are no standard methods of assessing the risk of antibiotic-resistant genes in culture-free methods. While some metagenomic studies of antibiotic resistance evaluate the functional assays of resistance,

others infer risk based on the particular database being used (62). As a result of the varying analyses, it is a challenge to directly compare results from one study to the next.

Virulence factors

Virulence factors have previously been explored by food microbiologists, most notably as a means to differentiate *E. coli* strains, but primarily in the context of pathogen differentiation instead of community-wide characterization. Virulence factors are known to spread through bacterial communities using horizontal gene transfer avenues such as bacteriophages (63). While the presence of genes like *eae* and *stx* is used to classify *E. coli* O157:H7 as pathogenic, the ability to identify such genes in a shotgun metagenomic sample is challenging due to the short-read nature of the data and inability to create robust assemblies (47). Furthermore, linkage inferences between genes and bacteria are limited because library preparation and sequencing do not amplify evenly, resulting in uneven sequence depth. However, understanding what virulence factors are present in a bacterial community can allow researchers to evaluate how these genetic factors interact within the microbial community. An example of this approach was used to conduct a culture-free assessment of naturally versus conventionally raised beef cattle in North America (64).

Environment

In addition to looking at the meat and poultry products themselves, a very appropriate use of shotgun metagenomics is in characterization of processing facilities used to produce meat and poultry products. Analysis of the biogeography of all potential fomites is a discipline known as building ecology (65). In meat or food processing facilities, metagenomic analysis has been used to identify food spoilage bacteria and pathogenic bacteria on processing surfaces (66). Another valuable capability that metagenomics affords is the investigation of co-occurrence of organisms (Fig. 36.11). Such an analysis can be helpful in mitigating

pathogens and spoilage organisms because it enables identification of organisms whose abundance is either directly or inversely correlated with the pathogens or spoilage organisms of interest.

The ability to track a microbial community of a given environment is another example of how metagenomics can be used in environmental analysis. In addition to characterizing the microbes in a given environmental community, a longitudinal study allows researchers to observe changes in the composition of the microbial community over time, or to compare the characteristics/makeup of a community with those of a community from another environment. For example, in a study of cooked sausage, *Lactobacillus* spp. increased in relative abundance during production, while *Enterobacteriaceae* declined between the processing steps of meat receiving and final product (Fig. 36.12) (67).

Recent advancements in biostatistical capabilities (i.e., Bayesian modeling) also have enhanced source attribution to product or environmental contamination. For example, SourceTracker (68) takes 16S rRNA sequencing data collected from both the location of concern and potential sources of contamination and attempts to determine which potential source was the actual source of the contamination (for example, tables in a packing room for ready-to-eat products could be the location of interest and potential sources of contamination could be employee boots, packaging material receiving, and the cooler areas where meat is stored prior to packaging). While this could be a valuable tool for improving general understanding of contamination, the 16S rRNA sequencing input does not allow strain-level identification, thus limiting the tool's usefulness in identifying a pathogenic contaminant. The software MetaMLST is a more recently developed tool that allows microbial strain tracking and identification within complex shotgun metagenomic data obtained directly from an environmental sample (69). This tool works by reconstructing loci identified by multilocus sequence typing of pathogens (multiple areas of one genome) of interest from publicly available databases and comparing them to

microbial communities from shotgun metagenomic data (69). This tools holds promise for identifying pathogen contamination from different areas within a processing facility.

While not directly related to meat and poultry products, metagenomic data have also been used to better understand plant worker health. Understanding what microflora and contaminants workers are exposed to throughout their work shifts helps to develop mitigation strategies to prevent possible negative results of exposure. For example, assessment of airborne bacteria found in the air vents of a slaughterhouse could become a proxy for worker airborne exposures, including air quality (70).

Rearing of Animals

The use of metagenomics is not limited to end product food safety and abattoir sanitation. Many scientists have focused on the use of metagenomics to discover potential targets that can be used to influence the microbiome of food animals before slaughter. Objectives of such studies include reduction of pathogen levels within animals, alteration of growth status, mitigation of unwanted outcomes such as liver abscesses in cattle, and manipulation of the nutrient profile of the meat being produced. As methods have become more refined and we have accumulated knowledge of animal microbiomes, research goals have correspondingly evolved. Early studies focused more on characterization of animal microbiomes (71) as a way to understand what organisms were present in normal situations. From there, specific locations within the animal's body that impacted end product food safety were mapped using a microbiome approach (72). Metagenomics then were employed to better understand movement of pathogens within livestock populations. For example, metagenomics was used to evaluate STEC in feedlot cattle populations, resulting in the observation that STEC colonization was correlated with a lower diversity of gut microflora, which increased as cattle matured (73).

Figure 36.11. Significant co-occurrence and coexclusion relationships between bacterial operational taxonomic units. Spearman's rank correlation matrix of operational taxonomic units with an abundance of ≥0.1% in at least five samples. Only phylotypes assigned to the phyla *Proteobacteria* and *Firmicutes* were considered. Strong correlations are indicated by large circles, whereas weak correlations are indicated by small circles. The colors of the scale bar denote the nature of the correlation, with 1 indicating a perfectly positive correlation (dark blue) and −1 indicating a perfectly negative correlation (dark red) between two phylotypes. Only significant correlations (false discovery rate < 0.05) are shown. Reprinted from reference 66.

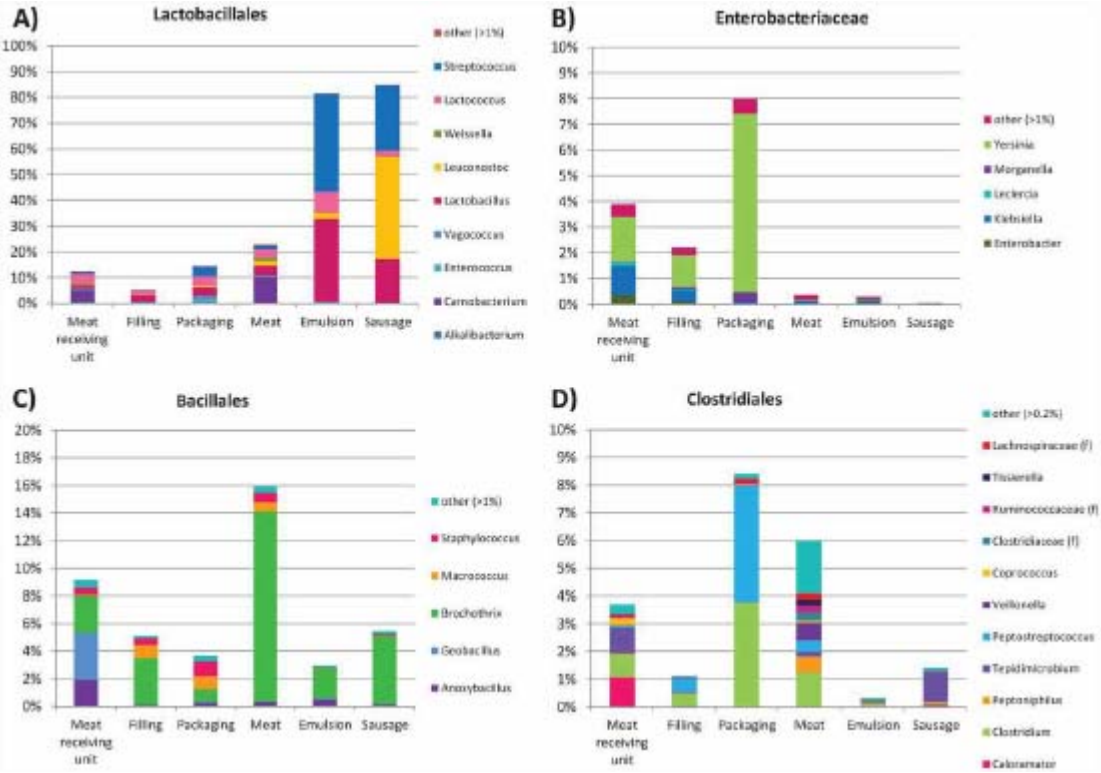

Figure 36.12. Relative abundances of sequence reads assigned as indicated. f, family-level classification. Reprinted from reference 67.

Food Quality

Metagenomics not only has increased our understanding of pathogenic and harmful bacteria but also has helped us to better

understand how all bacteria and organisms change over time and as a result of specific interventions. For instance, fermentation and aging of meat add value and longevity to the final products. While these processes have been characterized through culture-based assays in laboratories, metagenomics allows these processes to be viewed through an entirely different lens.

Shelf Life

Metagenomics has been used to understand how different processing procedures affect the bacterial community and known causative spoilage organisms. In shelf life studies, a metagenomics approach was used to characterize the impacts of different ingredients, packaging types, and processing variation on shelf life. For example, in marinated broiler meat, the addition of a marinade (which contained, among other things, oil and sugar) altered microbial communities such that spoilage-associated *Leuconostoc gasicomitatum*, *Leuconostoc gelidum*, and *Lactobacillus* spp. were favored (44).

Metagenomic investigation also has been used to understand the effects of using different types of packaging. For example, comparison of meat products packaged in mainly air, modified-atmosphere packaging (MAP), vacuum packaging, and active vacuum packaging revealed that *Brochothrix thermosphacta* made up a larger proportion of the microbiome of meat packaged in air and MAP during the early days of a 45-day shelf life study, while *Pseudomonas* spp. became more dominant in air over time (74). While many of the bacterial species present on the product had previously been associated with meat spoilage, bacteria that had not previously been associated with meat spoilage were also found (Fig. 36.13).

In addition to profiling microbes present in meat subjected to shelf life conditions, work was conducted to evaluate whether processing environments and other factors contributed to shelf life variation. One study of beef steak production investigated the microbiome of

steaks, carcass swabs, and environmental samples over time (75). The investigators discovered many different types of bacterial contaminants across the samples on day 0 of sampling, while samples from later time points showed that phyla associated with spoilage outcompeted skin-associated bacterial environmental contaminants (*Propionibacterium acnes*, *Staphylococcus equorum*, and *Staphylococcus* sp.) to become the most dominant phyla in the community. Other metagenomic studies have demonstrated that variation in production systems, including assessments of lot variation in beef that was packaged in modified atmosphere, can also have an effect on the abundance and composition of phyla present (76).

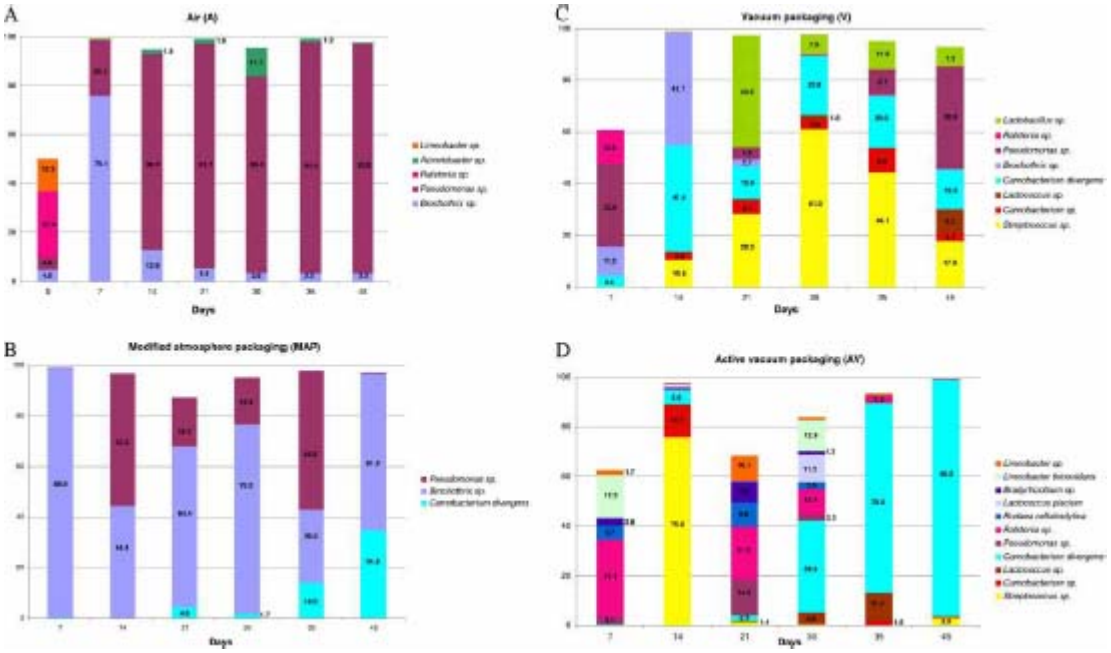

Figure 36.13. Incidence of operational taxonomic unit tracebacks based on bTEFAP (bacterial tag-encoded FLX amplicon pyrosequencing) analysis of allthe DNA samples directly extracted from meat at different times and under different storage conditions. Only taxa with an incidence above 9% in at least one sample are shown, and only percentages above 1% are displayed in the histograms. Shown are results for storage in air (A), MAP (B), vacuum packaging (C), and active vacuum packaging (D). Reprinted from reference 75.

Fermentation

Culture-based studies associated with fermented meats, such as salami, have been plentiful, but these studies have focused on a few organisms and were not reflective of an entire microbiome. A 16S rRNA sequencing study of Italian salami highlighted the complexity of the ripening process by documenting a diverse bacterial community with higher-than-expected numbers of *Lactobacillus* spp. and *Staphylococcus* spp., as well as the presence of previously undocumented rare bacterial families (Fig. 36.14).

Regulatory Issues

Currently, metagenomic methods are primarily used in the research setting (77). For a method to be adopted as a benchmark for regulatory compliance, it must be verifiable, sensitive, specific, precise, and accurate. Current metagenomic methods do not meet all of these thresholds, but there is clearly regulatory interest in advancing the technology to meet such goals. The current gold standard for monitoring foodborne outbreaks is PulseNet USA. The aim of the network is to rapidly detect multistate outbreaks caused by foodborne pathogens through pulsed-field gel electrophoresis (PFGE) of outbreak samples with subsequent comparison to a national database of PFGE patterns. While still relying on PFGE, PulseNet also has piloted WGS for use in both outbreak investigations and routine surveillance of foodborne pathogens (78). Though not currently implemented, use of WGS in PulseNet and other regulatory frameworks is likely the precursor to regulation of meat and poultry pathogens from a metagenomics perspective (78). The ability to trace pathogens using metagenomic methods may be the ultimate tool for identifying specific environmental sources of contamination (47, 79).

Future Directions

In relation to other techniques applied to the area of meat and poultry microbiology, metagenomics is still an emerging

methodology. While many laboratories and researchers have demonstrated versatility and utility of metagenomics for advancing knowledge within a specific discipline, there still are many areas in which use of metagenomics has yet to be fully explored. In attempting to forecast what metagenomics may mean for meat and poultry science, it may be useful to understand how metagenomics has advanced scientific knowledge within human-oriented fields. Beyond characterizing different niches in the human body, research was conducted on links between the microbiome and different disease conditions ranging from irritable bowel syndrome to some cancers (80). Broad areas within meat and poultry research that could benefit from further development of metagenomic methods include improved usability and accuracy of bioinformatic and statistical techniques, single-cell sequencing, and intervention-based studies.

Figure 36.14. The rare microbiome in Salame Piacentino DOP samples: distribution of families accounting for less than 5% of the total bacterial diversity in the 63 samples analyzed. The total number of sequences retrieved and the number of genera represented are reported for each rare family. A heat-mapping color scale indicates the relative distribution of positive samples among producers, ripening times, and presence or absence of starter addition. Reprinted from reference 92.

The field of bioinformatics is rapidly expanding, and new techniques are being developed in tandem with rapidly decreasing sequencing costs. An area that has seen growth in the past few years, and that will continue to mature, is the development of graphic user interfaces that will allow more biologists access to informatics tools. In terms of bioinformatics development, advancements in assembly algorithms specific to metagenomic data are continuing to evolve, such as the release of metaSPAdes (81). There are other nonconventional methods for bioinformatics development as well, such as crowd-sourcing development. Through an open call with associated prize money, crowd-sourcing developed 89 new sequence alignment algorithms, 30 more efficient than the previous benchmark, in just 2 weeks (82).

Single-cell sequencing is another area where growth will likely occur. In shotgun metagenomics, diversity of the microbial community decreases the ability to detect strain-level variation and specific genes. Multiple displacement amplification enables amplification of a single bacterial genome. Use of this technique in conjunction with NGS can yield almost complete bacterial genomes (83). This method has been used in built environments where bacteria of interest are low in abundance, such as in hospitals. Use of this method could lead to more complete understanding of low-abundance pathogens and their transmission between the environment and a host or a product (83). Because processing facilities deal with the same dynamics (i.e., a built environment with low pathogen presence, such as a meat plant), the usefulness of this technology is certainly an area worth exploring.

Use of metagenomics will likely continue to transition from primarily exploratory and descriptive studies to causation and intervention-based studies. Examples of this within the human literature include studies of *Clostridioides* (formerly *Clostridium*) *difficile* infections and gene editing. In individuals with *C. difficile* infections, characterized by a proliferation of *C. difficile*, low-volume fecal transplants from healthy donors allow repopulation of the intestinal microbiome with “healthy” microbes. Recent 16S

rRNA sequencing studies have shown high abundance of *Bacteroidetes* and *Firmicutes* in donor feces, leading to the possibility of treating *C. difficile* infections with a probiotic specifically enriched for these taxa (84). Gene editing, specifically via the CRISPR (clustered regularly interspaced short palindromic repeat)-Cas9 system and others, holds promise for targeting specific genomes in a metagenomic sample. This technology allows the deletion, insertion, and modification of the DNA sequences of cells, which, in turn, allows control of function of specific genes and regulatory elements (85). This method already is being examined in the context of food safety research. Using the CRISPRCas9 system, researchers were able to specifically cleave Shiga toxin genes in bacterial cells, leading to significant reductions in numbers of STEC (86). These authors believe that this system could be further harnessed to decrease foodborne pathogens and other genes of interest in certain microbial communities.

Food Microbiomes: A New Paradigm for Food and Food Ecology

INTERSECTION OF HUMAN AND FOOD MICROBIOMES

Culture-independent next-generation sequencing technologies have fueled a renaissance in our understanding of what it means to be human. Targeted and targetindependent metagenomic data have been used to describe microbial ecologies from soils to clouds and from body surfaces (skin) to internal processes (gut) (1–4). Even the human immune system can no longer be understood without also considering the 100- to potentially 1,000-fold more abundant complement of microbial genes compared to host genes (5, 6). This paradigm shift has also occurred in our understanding of the foods we consume and the complex microbial ecologies along the farm- to fork continuum. These ecologies are important both for food safety (exposure to pathogens) and for issues of nutrition, allergy, and immunology. Despite the emphasis on "purity" in the Pure Food and Drug Act of 1906, which led to the creation of the Food and Drug Administration, the Act was written at a time when the word "purity" completely excluded microbes. It is now understood that almost every food (except, potentially, highly processed foods) has a bacterial, fungal, viral, and potentially archaeal component to its "naive" (pure) state. Food science finds itself at a new and exciting interface of microbiology, nutrition, and immunology. We are reevaluating nutritional sciences, using a more comprehensive inventory of the prebiotic and probiotic potential of foods (Fig. 37.1).

The convenience and affordability of next-generation sequencing technologies, improved bioinformatic pipelines, and converging reference databases have enabled the description of culture-independent microbiota associated with numerous environmental, human, and food microbiomes that were previously poorly understood. The complex network of interactions between the microbiota of mammals, agricultural reservoirs, and food plants is a frontier of exciting research. Years of descriptive characterizations of food and food ecologies are beginning to fuel nutritional

hypotheses at the human-food intersect. Numerous states of human health and disease are already correlated to dysbiotic human microbiomes (7, 8). From 1950 to 2000, we witnessed a significant decline in acute illnesses such as mumps, measles, rheumatic fever, tuberculosis, and hepatitis, the control of many of which can be attributed to the use of vaccines. During the same period and extending to the present, we have been witnessing an increase in chronic illness associated with immune responses, such as type 1 diabetes, Crohn's disease, multiple sclerosis, obesity, and asthma (9). It is possible that some of these chronic diseases are on the rise in response to non-target effects of the use of antibiotics in medicines and foods, unintentionally having disrupted internal ecology and physiology we have yet to even characterize. Additionally, the exposure to an increasingly sophisticated array of chemicals (such as preservatives, pesticides, herbicides, insecticides, sterilizers, etc.) over the past 50 years of food production may have resulted in an unintended antibiotic impact on American microbiomes. This public health phenomenon positions food in a more important role than ever before. Food itself may function as an epigenetic "fix" for numerous states of disease that have been correlated with states of dysbiosis and nutritional deficiency. Thus, the full understanding of the microbial load in our food and the impact of the food matrix itself on the human microbiome (as a prebiotic, probiotic, or antibiotic) is of vital importance to public health.

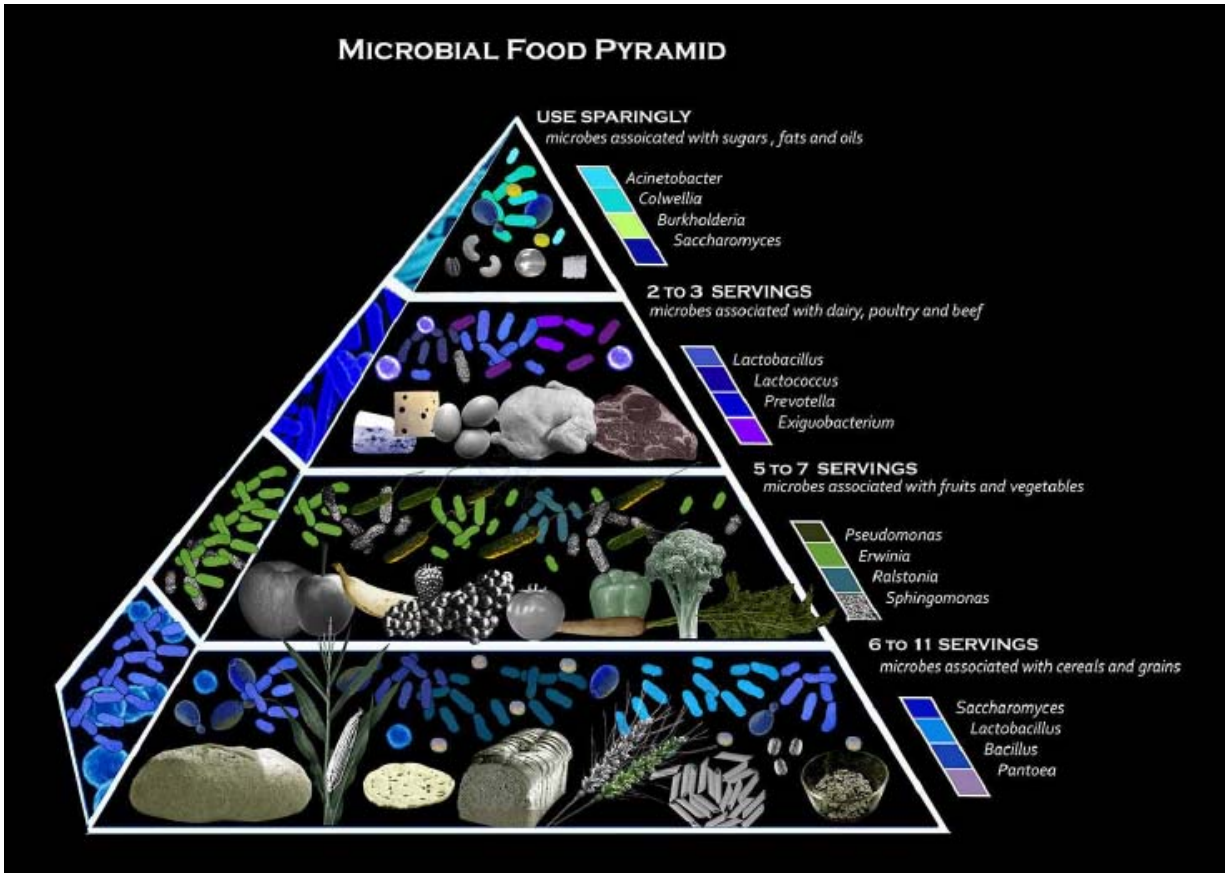

Figure 37.1. Microbial food pyramid. This graphic is designed to highlight the fact that healthy diets must consider not only foods themselves, but also the microbial content of foods. Even if a food is completely devoid of microbes, the food matrix itself will interact with the human microbiome in some manner that will impact nutrition and health.

SEQUENCING TECHNOLOGIES: GENOMETRAKR AND METAGENOMETRAKR

From 2005 to 2011, most metagenomic sequencing endeavors relied on Solexa (the first iteration of Illumina sequencing) and/or Roche 454 pyrosequencers. As early as 2009, Pac Bio platforms were inconsistently providing long reads (20 to 50,000 kb), primarily used to help navigate complex genome assemblies, especially for organisms with AT-rich areas and/or highly repetitive elements.

Recently, newer Pac Bio platforms have been used for higher-throughput long-read metagenomic studies, with exciting results (10). Since about 2011, Illumina platforms have been the workhorses of programs such as GenomeTrakr (11), designed to rapidly identify foodborne pathogens by clustering whole-genome sequence (WGS) data of bacterial isolates following illness outbreaks. New programs such as MetagenomeTrakr, designed to provide more comprehensive ecological fingerprints of foods and rapid metagenomic response to foodborne outbreaks, are also being coordinated by scientists at the Center for Food Safety and Applied Research using the MiSeq platform in the same way that WGS programs have been implemented.

Small state and university labs around the world have the ability to perform their own metagenomic and genomic sequencing due to the relatively affordable cost of MiSeq "desktop sequencers." These machines have become standard equipment in many labs, and targetindependent metagenomic surveys are relatively commonplace for all types of research. Sequencing cores and high-throughput laboratories have relied on Illumina HighSeq platforms (higher-throughput Illumina machines); these are now being phased out, to be replaced by Illumina's newer NovaSeq platforms, which provide billions of bases for half the price of previous machines. From 2006 to 2018, the amount of data produced by a single Illumina run went from approximately 1 Gb to 6 Tb, with newer machines being capable of generating as many as 20 billion reads in a single run. At the same time, long reads are now being produced by a tiny handheld device called the MinION. While not yet financially practical, the technology itself has become much more reliable in past years and holds great promise for field studies and rapid on-site or *in situ* real-time sequencing of full genomes and PCR targets from the palm of one's hand (12, 13). All of these technologies (and more) have contributed to the vast collection of data that now spans numerous food and food environments.

PATHOGEN DETECTION IN THE FARM-TO-FORK CONTINUUM

By the time a fresh fruit or vegetable or even a highly processed food makes it to the point of human consumption, it has traveled through multiple diverse, yet interwoven, ecologies. Despite modern, sophisticated approaches to food handling, pathogen-contaminated foods still result in human deaths, as occurred in Germany with the *Escherichia coli* O104 outbreak of the summer of 2011 (14) and recently in South Africa, where as many as 180 deaths from listeriosis were linked to meat products. The more we learn about the ecologies along food production continuums, the better positioned we will be to identify and mitigate risk factors. Fresh produce is of course a commodity of significant importance, since it is often prepared and consumed without heating or other "kill" steps. Comprehensive surveillance of biological and ecological risks in fresh produce production will help us minimize risks at critical control points in farm-to-fork agroecologies.

Metagenomic Description of Fresh Produce: Tomatoes, Sprouts, and Leafy Greens

Certain cases of *Salmonella* contamination of tomatoes have been hypothesized to occur in agricultural field settings because of the fact that multistate incidents were traced to specific geographic growing regions, suggesting that contamination occurred early in the distribution chain, potentially in the field (15, 16). Thus, there has been much focus on preharvest ecologies. Early metagenomic work focused on providing baselines for numerous crops, where no such information was previously available (17). This type of "profiling" of agricultural environments has been applied to many components within specific agroecologies, including the phyllosphere (plant surfaces), soil, water, air, fungicides, fertilizers, pesticides, biogeography, and other agricultural management practices (18–21).

In a metagenomic survey of tomato plants at harvest time from a geographical region to which outbreak strains of *Salmonella* had been traced, Ottesen et al. (19) described distinct groupings of microbial communities that were associated with different organs of *Solanum lycopersicum* (tomato) and a gradient of compositional similarity that was correlated to the distance of a given plant part from the soil. Unique bacterial phylotypes (at 95% identity), such as *Microvirga*, *Pseudomonas*, *Sphingomonas*, *Brachybacterium*, *Rhizobiales*, *Paracoccus*, *Chryseomonas*, and *Microbacterium*, were associated with fruits and flowers of tomato plants. The most frequently observed bacterial taxa across aerial plant regions were *Pseudomonas* and *Xanthomonas*. Dominant fungal taxa that could be identified to the genus level included *Hypocrea*, *Aureobasidium*, and *Cryptococcus* (19). These types of data for crop ecologies provide a new resolution for our understanding of risk factors along the farm-to-fork continuum. Other work, focused on the study of biogeographical microbiology of crops, documented a completely distinct bacterial ecology for tomato phytobiomes from East-versus West-grown tomatoes (22). These distinct ecologies also appeared to correlate with completely different risk factors for the crop.

Sprouts are another crop with a long history of association with illness outbreaks. Since 1996, the FDA has been involved in investigating 48 outbreaks associated with sprouts resulting in a total of 2,499 cases, including 179 hospitalizations and 3 deaths. Most outbreaks were attributed to alfalfa sprouts, although clover, mung bean, and sprouted chia were also implicated. *Salmonella* was the most common pathogen identified, followed by *E. coli* O157:H7 and then *Listeria monocytogenes* (23). In response to the contamination events associated with sprouts, there has been substantial interest by commercial sprout growers in using metagenomic approaches to examine the entire sprout production process to improve understanding of the growing ecology that has resulted in multiple illnesses. In a recent study, coordinated by a commercial sprout grower, a shotgun metagenomic approach was used to study the microbial dynamics of a sprouts crop over the 4

days the seeds take to mature (24). The diversity of bacteria, fungi, protists, and viruses associated with sprout water was described. (A baseline profile of the water was also taken to better understand how the water itself may seed downstream sprout ecology.) Dominant bacteria included *Klebsiella*, *Pseudomonas*, *Acinetobacter*, *Enterobacter*, *Curvibacter*, *Delftia*, *Flavobacterium*, *Escherichia*, and *Pantoea*. From the first day of growing to the last, there was an increase in the relative abundance of *Curvibacter* and *Delftia*. *Escherichia* was more prominent on days 2 and 3 and then appeared to be moderately suppressed by day 4.

One goal of the research was to identify naturally occurring opportunities for biological control, in the same way that data from metagenomic tomato crop research identified *Paenibacillus* as a potential inhibitor of pathogens like *Salmonella*. Once the dynamic microbiology of all crops is more comprehensively understood, there will be opportunities for more natural, potentially safer, biological controls. In fact, the previously mentioned biogeographic profiling of tomato microbiota from agricultural regions in the eastern and western United States identified a statistically significant enrichment of *Firmicutes* taxa in the phyllosphere of tomatoes that correlated with a lower incidence of *Salmonella* contamination events. This led to the fruitful hypothesis that *Firmicutes* genera with similar antibiotic potential (*Paenibacillus*) that occur naturally in tomato ecologies in the eastern United States might be successfully harnessed for biological control of *Salmonella* in agricultural settings in this region, and more widely, as postharvest biological controls for foodborne pathogens (25).

Another important food type that has been consistently linked to foodborne illness outbreaks is fresh leafy greens. Of all hospitalizations due to illnesses contracted from leafy vegetables between 1973 and 2012, 46% were caused by Shiga toxin-producing *E. coli* (STEC) (26). Fresh bagged spinach was linked to six deaths and more than 100 hospitalizations from hemorrhagic colitis and hemolytic-uremic syndrome resulting from STEC infections. The infectious dose for STEC has been estimated to be 10 to 100 CFU;

thus, methods for detecting STEC in foods require a high degree of sensitivity. Work by Leonard et al. (26) on leafy vegetables demonstrated that shotgun metagenomics can be utilized to detect the presence of *E. coli* contamination in fresh leafy produce amidst the complex microbial native background of spinach, while simultaneously detecting multiple virulence genes as well as the molecular somatic O and flagellar H types (26). This approach relies on a brief enrichment step in order to reliably detect low STEC contamination levels in spinach (0.1 CFU/g) due to the bioinformatic confusion that can occur from the high level of indigenous microbiota and nonpathogenic *E. coli* strains.

METAGENOMICS AND QUASIMETAGENOMICS

While metagenomics has been extremely valuable for the description of numerous food and agricultural ecologies to identify critical control points in the food chain, it is still difficult to use culture-independent pathogen detection for conclusive identification of specific pathogenic strains from diverse and complex food or agricultural environments. Similar to the work with *E. coli* described above, the abundance of organisms like *Salmonella* in environmental settings is low, and they occur among numerous close relatives, which precludes effective source tracking from true metagenomic (culture-independent) sampling. Thus, as with *E. coli* in spinach in the work by Leonard et al. (26), some type of enrichment step is still necessary to obtain high-resolution phylogenetic source tracking of these clonal foodborne pathogens from complex food environments. While PCR targets may confirm the presence of the genus *Salmonella* or *Listeria*, for most source tracking efforts, a much higher-resolution analysis of the serovar or subtype of these highly clonal organisms is needed in order to trace the source.

To address this conundrum, researchers have begun using an approach known as quasimetagenomics for applied metagenomic source tracking (27). Because the word “metagenomics” refers to the “genomics of uncultured organisms” (28), “quasimetagenomics” is now used to describe the application of metagenomic methods like PCR and shotgun sequencing to environmental matrices that have undergone some degree of enrichment. Enriched samples are, by their nature, subsets of true community diversity, so they cannot be accurately described as “metagenomic”; hence the application of the term “quasimetagenomics.”

Proof of Concept for Quasimetagenomic Source Tracking with *L. monocytogenes*-Contaminated Ice Cream

A quasimetagenomics approach was used to retrospectively study samples of contaminated ice cream as they went through FDA, U.S. Department of Agriculture (USDA), and Food Safety and Inspection Service methods to enrich *L. monocytogenes* from ice cream. Results of the study demonstrated that the microbiological enrichment protocols for all agencies performed equally well for efficient recovery of *L. monocytogenes*. Genomic data recovered from the shotgun-sequenced enrichments at specific hours were even capable of identifying all of the strains of *L. monocytogenes* that had been associated with the outbreak (29).

Figure 37.2 shows the enrichment of *L. monocytogenes* over the 48 hours of pre-enrichment, which is the first step in the recovery process.

Levels of *Listeria* were very low in the first hours of the enrichment, as *Listeria* organisms struggled to compete with numerous other taxa during early hours. At hour 20 and 28, it gained a strong foothold and began to dominate the samples. Using shotgun data from hours as early as hour 20, single-nucleotide-polymorphism clustering and multilocus sequence typing trees placed strains of *L. monocytogenes* from quasimetagenomic data in exactly in the same

phylogenetic relationships as genomic data from WGS of pure independent isolates (Fig. 37.3). This is an exciting source tracking frontier for the future, requiring half the time of current state-of-the-art WGS standard operating procedures.

LOOKING TOWARD THE FUTURE OF AMERICAN FOOD

The Food Safety Modernization Act established rules and standards to describe minimum standards for safe growing, harvesting, packing, and holding of fruits and vegetables grown for human consumption (30). The new standards cover requirements for agricultural water quality, employee health and hygiene, exclusion of wild animals from agricultural areas, biological soil amendments of animal origin (such as compost and manure), equipment and tool management, and building sanitation. There are also requirements for the use of biological soil amendments of animal origin, which include manure and compost, which are added to soil to improve its ability to support plant growth. The more data that can be generated for all of these microbially complex ecological components of agriculture production, the more apt future recommendations will be.

One thing that is not mentioned among the risk factors delineated by the Food Safety Modernization Act is the possibility that air pressures in agricultural ecosystems influence the microbiotas of crop plants. Airborne environmental pressures have been documented to play important and previously unrecognized roles in driving the epiphytic microbiome of food plants in field settings (31). The better we are able to fully describe all microbial constituents of agricultural ecologies that contribute to microbiota that ends up on or within our foods, the better positioned we will be to protect those foods from contamination by pathogens. This continuously evolving knowledge base will also facilitate improved management strategies, improved regulatory requirements, and

hopefully more sustainable, less toxic biological controls for the management and preservation of food crops.

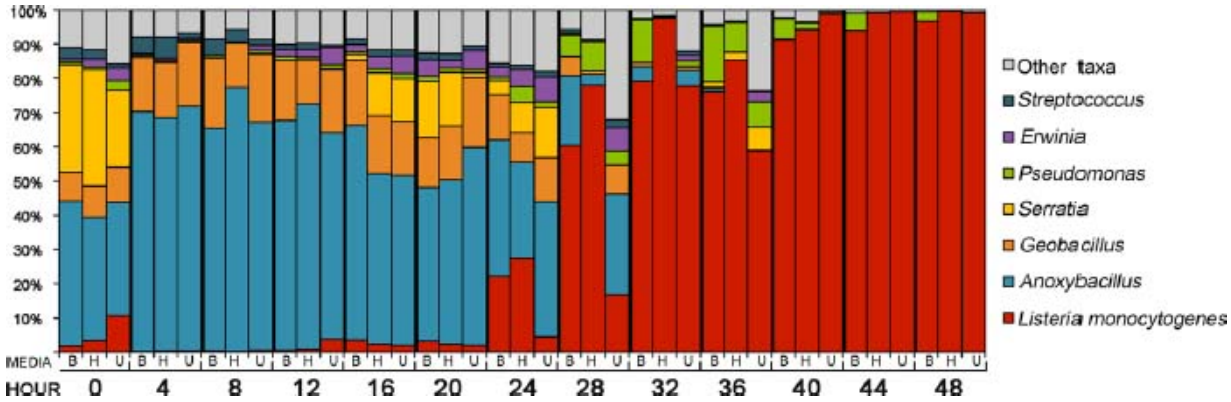

Figure 37.2. Quasimetagenomic survey of the FDA, USDA, and ISO enrichments for the recovery of *L. monocytogenes* from ice cream. B, buffered *Listeria* enrichment broth (FDA BAM method); U, University of Vermont modified broth with Fraser broth (USDA method); H, half-Fraser broth with transfer to Fraser broth (ISO method). All methods performed equally well for recovery of *Listeria*. Exciting source tracking utility was documented as early as hours 20 and 28, when genomic data for *Listeria* could be used to subtype strains with the same precision as WGS methods, in half the time (32). Adapted from reference 32.

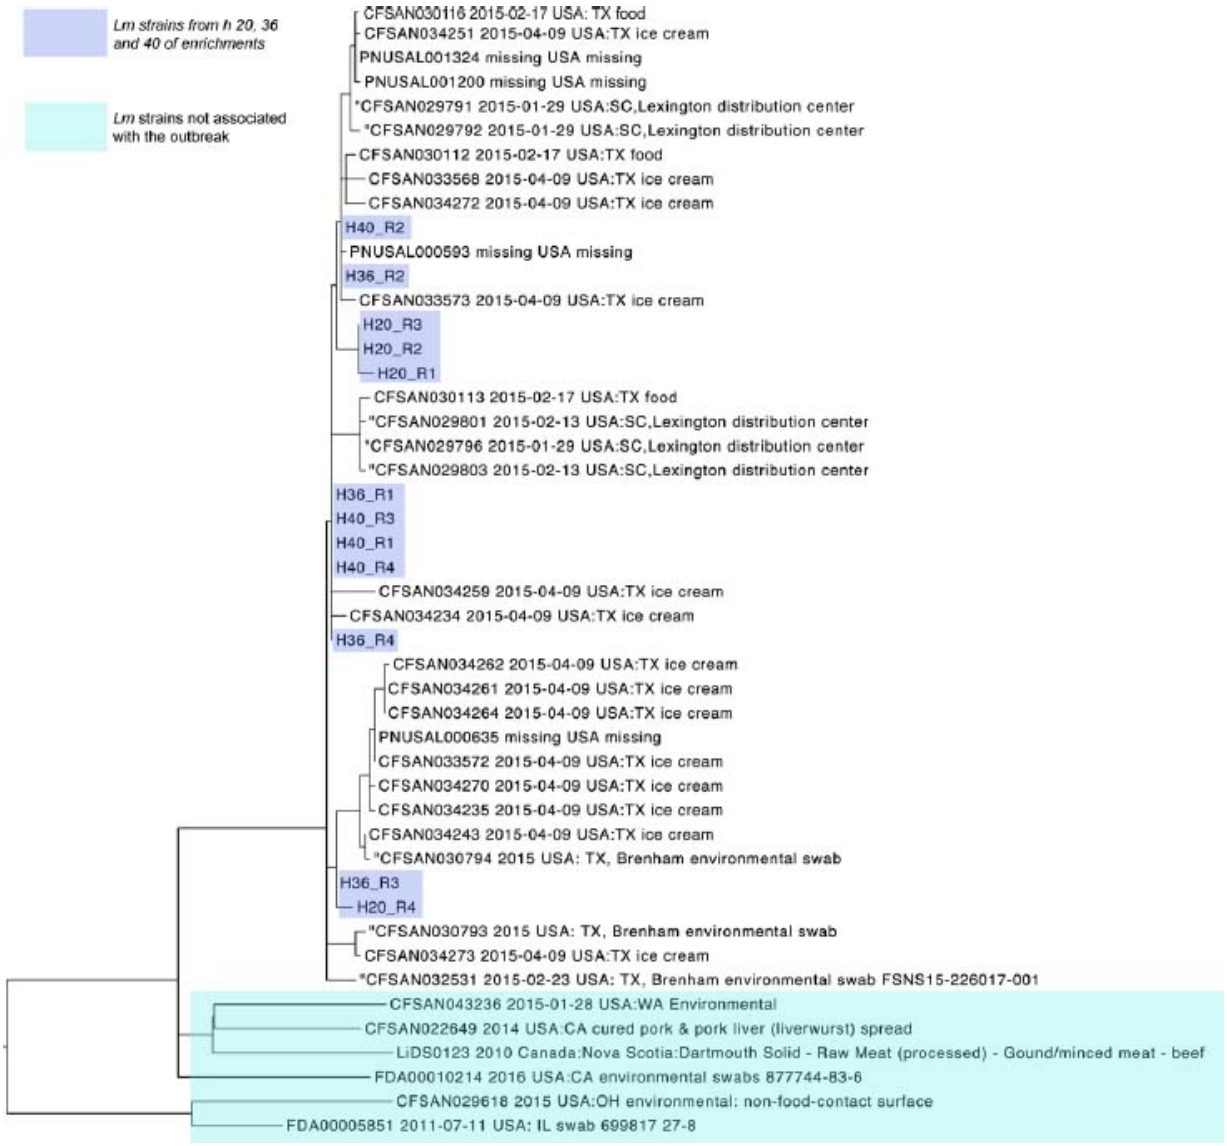

Figure 37.3. Using the NCBI data for the 2015 Blue Bell ice cream outbreak (abbreviated collection shown here) to assess the phylogenetic utility of a quasimetagenomic approach to source tracking, we show that single-nucleotide-polymorphism and MLST data from quasimetagenomic data of enrichments can be used to infer the same phylogenetic source attribution information that was achieved with WGS strains (data in purple are from hours 20, 36, and 40 of *Listeria* enrichments). This approach took half the time of traditional WGS and thus holds great promise as a method to reduce the time needed to source track pathogens from foods (32). *Lm*, *L. monocytogenes*.

Plants, like humans, comprise differentiated cell types, which make up organs. Microbial constituents of human organs such as skin have been shown to be niche driven (2) and unique in comparison to one another, and this is also true for plants (19). As we continue to better understand human microbiomes, a critical complement to public health research is the continued study of food microbiomes. The food microbiota intersects with the human microbiota and influences both health and disease, either by direct introduction of microbes or by the introduction of matrices such as fibers, sugars, and starches that function as prebiotics for resident microbiota. While early work describing phytobiomes and food ecologies emulated methods and protocols pioneered by the Human Microbiome Project, the field is now leading its own path back to human health, not only through improved food safety by reduction of pathogens but also by the characterization of microbiomes, metabolomes, and the vast array of bacterial, fungal, viral, protist, and multicellular eukaryotic organisms that play key roles in the architecture of food and food ecologies. The physics, chemistry, and microbiology of our foods will continue to impact our human microbiomes and influence states of health and disease. Now, more than ever before, the study of foods, ingredients, additives, preservatives, fungicides, bactericides, and all of the other diverse chemistry that is used to stabilize, preserve, and protect our foods must also be considered from the standpoint of the human microbiome. How will these chemistries affect nontarget members of gastrointestinal microbiota? The more data we gather, the more responsibly we can underpin new guidance and recommendations for food handling practices that will contribute to production of safe and nutritious American foods.

We would like to acknowledge Errol Strain for his contribution to Fig. 37.3.

Molecular Source Tracking and Molecular Subtyping

Bacterial subtyping may be defined as the characterization of bacteria below the species (or subspecies) level. Such characterization allows bacterial isolates to be placed into groups that are more or less similar to one another based on one or more (usually many) characteristics and may also reveal how such groups relate to each other. Subtyping can thus be used to study the population structure of a particular bacterial species, to determine the possible evolution of the subject microorganism, or to study the molecular epidemiology of a microbe. The types of methods used for subtyping and the approaches to data analysis and interpretation may vary greatly with the reason for specific subtyping. This chapter focuses almost entirely on subtyping for molecular epidemiology.

The term “molecular epidemiology” in the context of foodborne bacteria is usually applied to the subtyping of bacteria that cause foodborne disease and the ways in which such subtyping data contribute to understanding the transmission of those bacteria to humans. Molecular epidemiology can be applied to identifying the source of a particular outbreak or to a broader understanding of the role of certain foods or processes in outbreak-related or sporadic infections.

REASONS FOR PERFORMING MOLECULAR SUBTYPING

Perhaps the most easily appreciated reason for molecular subtyping is to facilitate the identification and investigation of foodborne disease outbreaks. By identifying isolates with the same molecular subtype, one can determine which isolates are most likely to have a common source. When isolates of foodborne pathogens with the same subtype are found to cluster temporally, especially if they also cluster geographically, it may indicate an outbreak of foodborne disease. Such cluster detection is the principal focus of the PulseNet system (1). PulseNet is described in more detail below. Once clusters are recognized, epidemiologic investigations can determine if a cluster actually represents an outbreak. Molecular subtyping can further facilitate epidemiologic investigations by determining which infections, of all those occurring at the same time as the outbreak, are most likely to be outbreak related (those sharing the same subtype or very similar ones). Subtyping contributes to tracking the source of an outbreak in two ways: by facilitating the epidemiologic investigation and by matching the subtype of isolates from food products with those from patients.

Table 38.1. Properties of methods commonly used for molecular subtyping of foodborne pathogens

Method	Strain discrimination	Interlaboratory reproducibility	Supply costs	Specialized equipment	Automatable	Unambiguous output
Plasmid profiling	Moderate	Moderate	Low	No	No	No
PFGE	High	Moderate	Moderate	Yes	No	No
rep-PCR/ERIC-PCR [a]	Moderate	Low	Low	No	No/yes [b]	No/yes [b]
PCR-RFLP	Low to moderate	High	Low	No	No	No
MLST [c]	Moderate	High	High	Yes	Yes	Yes
MLVA [c]	High	High	High	Yes	Yes	Yes

[a] ERIC, enterobacterial repetitive intergenic consensus.

[b] "No" refers to the standard method; "yes" refers to the DiversiLab system.

[c] Comments refer to the method as performed using automated DNA sequencing equipment and software.

There are many reasons for performing molecular subtyping other than cluster detection and outbreak investigation. Public health laboratories use subtyping to identify new and emerging bacterial pathogens, such as *Salmonella enterica* serotype Typhimurium DT104, which was identified in the 1990s. Food processing plants may use subtyping for tracking microorganisms through the plant to determine where they enter or reside within the plant and to monitor efforts to eliminate them. The types of subtyping methods used depend on the microorganism under study and the specific application (Table 38.1). Subtyping methods are described in detail in the next section, and specific applications are discussed in subsequent sections.

Regardless of the subtyping method being used, the importance of considering subtyping data in the context of other available data cannot be overemphasized. Factors such as the discriminative power of the subtyping method, the genetic diversity of the microbes being analyzed, and the occurrence and distribution of common molecular subtypes must all be considered in interpretation of subtyping results. Whenever possible, interpretation should be made in the context of epidemiologic and environmental investigations. Subtyping can only indicate which isolates are more likely or less likely to be related to an outbreak, food, or environmental source. Subtyping data alone cannot prove such a link.

COMMON SUBTYPING METHODS

Phenotypic Methods

Although the focus of this chapter is molecular methods, it is important to consider them in the context of earlier phenotypic methods, such as serotyping, phage typing, biotyping, and antimicrobial susceptibility typing. Most of these phenotypic methods have long and successful histories of use in subtyping for the same purposes for which molecular methods are now used. In fact, most of them are still used prior to, or in conjunction with, molecular

methods. Serotyping of *Salmonella* is an excellent example. Serotyping is so widely practiced that microbiologists tend to think of it more as identification than as subtyping, but serotyping is itself a powerful method of subtyping, with more than 2,500 named serotypes of *Salmonella*. With relatively rare serotypes, serotyping alone may provide a sufficient level of subtyping. For more common serotypes, phage typing systems with good strain discrimination have been developed, but these systems are serotype specific and are available in few laboratories, so molecular methods are generally used to provide further strain discrimination.

Although molecular methods typically provide greater strain discrimination than phenotypic methods, this is not always the case, and it is only one reason why molecular methods are generally preferred. Perhaps the most important reason for using molecular methods is that they do not require specialized reagents or expertise and can thus be performed in almost any laboratory with basic molecular biology capabilities. This ease of performance is also the most obvious drawback to molecular subtyping, as it allows every laboratory to perform and interpret subtyping according to their own criteria, making interlaboratory comparisons difficult unless laboratories can agree to standardized protocols.

Plasmid Profile Analysis

One of the first molecular methods used for strain identification or source tracking is plasmid profile analysis. Plasmids are small pieces of extrachromosomal DNA that are typically circular and supercoiled. Plasmids range in size from a few hundred to several hundred thousand base pairs and are present in most bacterial species. Plasmid DNA is extracted using a method that separates plasmid from chromosomal DNA, and the plasmids are then separated by agarose gel electrophoresis. How the plasmids travel in the gel depends on both size and conformation. Sensitivity can be increased by restriction digestion of the plasmid DNA so that different plasmids of the same approximate size can be distinguished.

One of the first successful uses of plasmid profile analysis in epidemiologic investigations occurred in 1981, when exposure to marijuana was associated with a cluster of *S. enterica* serotype Muenchen infections (2). Early uses of plasmid profile analysis included identifying outbreak-associated strains of *Salmonella* serotype Typhimurium (3, 4) and linking patient and hamburger isolates of *Escherichia coli* O157:H7 (5). Plasmid analysis continues to be useful today. During an outbreak of *Salmonella* serotype Typhimurium DT104 in England and Wales in 2000, all isolates analyzed by pulsed-field gel electrophoresis (PFGE) had the same profile, but 67% of the isolates could be classified as outbreak associated based on plasmid analysis (6). One major drawback of plasmid profiling is that bacteria may gain or lose plasmids during the course of an outbreak, resulting in different plasmid profiles and confounding interpretation.

RFLP Methods

DNA may be digested by restriction endonucleases, which are enzymes that cut the DNA at specific nucleotide sequences (the recognition sequence). The number and size of the resulting DNA fragments (restriction fragments) are unique to a particular strain; different strains yield different restriction fragment patterns. This is the principle behind all restriction fragment length polymorphism (RFLP)-based methods. In the initial methods, the DNA was digested with high-frequency cutting enzymes like EcoRI or HindIII, and the resulting fragments were separated by standard agarose gel electrophoresis (7). The resulting restriction patterns were very complex due to the huge number of fragments obtained,

resulting in poor resolution of individual fragments and difficulty in interpreting results. To overcome this problem, several variations on the basic method were developed, of which PFGE remains critical for surveillance and outbreak investigations of foodborne diseases.

PFGE Methods

The problem of excessively complex RFLP patterns was solved by decreasing the number of restriction fragments by using infrequently cutting enzymes. This way, the actual number of fragments obtained is reduced to a manageable number. While this strategy is obvious, the size of the resulting fragments prevents them from being separated by standard gel electrophoresis. The development of PFGE in 1983 (8) eliminated this drawback. During the following few years, several different types of PFGE were devised, including transverse alternating-field electrophoresis (9), field inversion gel electrophoresis (10), orthogonal field alternation gel electrophoresis (10), and contour-clamped homogeneous electric field electrophoresis (11). Although these methods differ considerably in the physical way in which fragments are separated, they alldepend on changing the direction of current flow (pulsing) over a gradient of time intervals between changes. The contour-clamped homogeneous electric field technology is probably the only one used today.

From the early 1990s to the late 2010s, PFGE was the gold standard for molecular subtyping and source tracking for most foodborne bacteria, as well as many other bacterial agents. PFGE is so widely known and accepted that a lengthy list of applications would be superfluous. The application of PFGE to specific foodborne pathogens is described below. As with any subtyping method, PFGE can present problems in interlaboratory reproducibility and interpretation of results. Such problems can never be totally eliminated, but they can be minimized by using carefully standardized protocols and image analysis software (1, 12).

PCR-Based Methods

Although many different PCR-based subtyping methods have been reported, most methods fall into one of two categories. The first type of PCR-based subtyping methods involves using primers homologous to known, conserved, multicopy sequences. In this case, differences in amplicon lengths are the basis of subtype comparisons. Two such methods, based on the presence of repeated elements, were reported by Versalovic et al. (13). These authors found that amplification of repetitive extragenic palindromic elements or enterobacterial repetitive intergenic consensus sequences could discriminate between laboratory strains of *E. coli*, suggesting that these methods could be used for subtyping foodborne pathogens. Methods targeting repetitive elements are collectively known as rep-PCR. Although rep-PCR methods have not become as widely used as other typing methods, such as PFGE, they do have the advantages of being relatively inexpensive and easy to perform. They have been used to track fecal pollution by subtyping *E. coli* isolates in diverse settings, such as dairy and swine production systems (14) and Apalachicola Bay in Florida (15). As with other subtyping methods, successful source tracking can be improved with the use of appropriate statistical methods (16). The biggest drawback to rep-PCR may be difficulties with intra- and interlaboratory reproducibility. This problem may have been solved by the introduction of a commercial semiautomated platform for rep-PCR, the DiversiLab system (bioMérieux, Marcy l'Étoile, France). In this system, quality-controlled reagents are provided in a kit format with Internet-based computer-assisted analysis, reporting, and data storage (17). Although the system does not provide the same high discriminatory power as PFGE, it seems to be gaining acceptance in the food microbiology community (18, 19).

The second category of PCR-based methods combines PCR with restriction digestion: either PCR amplification followed by restriction digestion of the amplicon or restriction digestion of the genome followed by selective amplification of certain restriction fragments. In the first approach, the target locus is typically 1 to 2 kb, and digestion results in several fragments that are then separated by gel electrophoresis, forming a characteristic RFLP profile. A specific example of the utility of such a PCR-RFLP in subtyping *Campylobacter* is discussed in detail in the *Campylobacter* section.

DNA Sequence-Based Methods MLST

Multilocus sequence typing (MLST) was one of the first subtyping or strain-tracking methods that were based on DNA sequences rather than DNA fragment sizes. All of the RFLP-based methods described above suffer, to different degrees, from the same problems. In addition to the problems of interlaboratory variability in methods and interpretation, RFLP methods have further shortcomings. Fragments from different test strains that appear to be the same size on a gel may originate from different parts of the genome with completely different genetic content. Fragments that are very close in size may not be separated during electrophoresis and thus not recognized. The reasons for differences in patterns are not known, and strains with fewer differences are not necessarily more closely related phylogenetically than strains with more differences. DNA sequence-based subtyping yields unambiguous data that can be readily compared between laboratories and can also be used to quantify differences between test strains.

MLST was derived from the earlier technology of multilocus enzyme electrophoresis, which is a phenotypic method that detects changes in certain housekeeping loci by charting variations in the electrophoretic mobility of their gene products (20). Only changes that result in a different electrophoretic mobility are detected. MLST is a more sensitive method that detects all nucleotide changes by direct sequencing. MLST is typically performed by sequencing 450- to 500-bp internal fragments of seven housekeeping genes. Since these housekeeping genes are under little selective pressure, the accumulation of changes occurring by chance is rather low, making MLST an ideal tool for understanding the evolution of microorganisms or strains. However, this lack of rapid change in the housekeeping genes makes MLST a less-than-ideal method for investigating outbreaks or conducting traceback studies. MLST typing schemes have been described for a number of foodborne pathogens, for example, *Campylobacter* (21), *S. enterica* (22), *E. coli* (23), and *Listeria monocytogenes* (24). In order to increase the discriminatory power, MLST schemes targeting faster-evolving sequences such as virulenceassociated genes or temperate phages have been developed (25, 26). Whole-genome sequencing (WGS) has allowed comprehensive, genome-wide MLST schemes to be developed and implemented, as detailed below.

VNTR-Based Typing, including MLVA

The recent sequencing of several complete bacterial genomes has revealed that much of the bacterial genome consists of repeated short nucleotide sequences. The repeats may vary in size, location, and complexity. Repeats can be classified according to their structure, such as inverted, dyad, or direct repeats. In bacteria, the repeat units are typically 1 to 10 nucleotides, although repeating units of up to 100 bp are recognized. These repeating arrays are commonly called variable-number tandem repeats (VNTRs). Variability occurs both in the sequence of the repeating unit and in the number of repeats between strains. Slipped-strand mispairing is the molecular model that best explains the variability of short sequence repeats (27).

Stretches of relatively short arrays of repeat units, when being copied by DNA polymerase, may engage in illegitimate base pairing. This forces the polymerase to introduce or delete individual repeat units. VNTRs are often found in noncoding regions controlling gene expression, but they are also found within open reading frames (28, 29).

The sequence of the repeat unit and the number of copies repeated are characteristic of each VNTR. For highly clonal microorganisms, there may be little variability for a given VNTR, and multiple loci must be examined. This approach has been termed multiple-locus VNTR analysis (MLVA). In some ways, MLVA may be analogous to MLST, in that multiple loci must be sequenced to provide sufficient strain discrimination. As typically performed, MLVA determines the number of repeats at a VNTR locus by the size of a PCR amplicon using high-resolution capillary electrophoresis rather than by actual DNA sequencing.

The benefits of MLVA include high throughput, technical simplicity, and objectivity of the data. The interlaboratory reproducibility of the data is excellent as long as the same capillary electrophoresis platform is used. However, there are some significant sizing discrepancies between capillary electrophoresis platforms from different manufacturers due to differences in dye and polymer chemistries employed by each platform. When different instrument platforms are employed, interlaboratory data sharing can be facilitated by a calibration strain set that is used to normalize the allele types to be comparable to the actual sequenced copy number (30). The assays also are highly species and even serotype specific, and prior knowledge about the sequence is required for the protocol development.

One of the first, and perhaps one of the most important, applications of MLVA was the subtyping of the highly monomorphic potential agent of bioterrorism *Bacillus anthracis* (31). It has also proven useful for subtyping two other potential agents of bioterrorism for which other methods had not proven adequate, *Yersinia pestis* (32) and *Francisella tularensis* (33). In recent years, MLVA has also been widely used to subtype foodborne microorganisms either as a primary method or as a complementary technique to PFGE. These applications are discussed below.

DNA Microarrays

A DNA microarray is a molecular platform in which a few hundred to thousands of specific DNA oligonucleotides or short sequences (capture molecules) are bound to a matrix. The array is used to detect specific DNA sequences (target sequences) in a test sample of DNA from the microbe being investigated by hybridization to capture molecules followed by detection of the arraybound test DNA.

DNA microarrays once represented an attractive platform for use in bacterial identification and subtyping, especially on the genome scale, because they allow rapid and accurate analysis of large numbers of different DNA molecules. Reported applications of the DNA microarray technology include pathogen identification (34–36), detection of virulence and antimicrobial resistance markers (37–40), single nucleotide polymorphism (SNP) typing (41), and genome comparisons (42). However, the increasingly routine practice of WGS in recent years has made microarrays largely obsolete as a genome-scale subtyping platform. All of the aforementioned subtyping analyses using microarrays can now be readily performed using WGS, as detailed below.

WGS

Advances in sequencing technology over the last 2 decades have made WGS-based subtyping approaches the method of choice for many foodborne pathogens. Sequencing platforms can be roughly categorized into two groups, platforms producing short (<1,000-bp) reads (Illumina platforms; Ion Torrent [Thermo Fisher]) and platforms producing long (>1,000-bp) reads (Pacific Biosciences; Oxford Nanopore MinION). While sequence data generated by long-read platforms are essential for the assembly of closed genomes (i.e., a genome sequence that represents the entire contiguous genome, without gaps in the assembly), at the time of writing, the cost, accuracy, and output of short-read platforms make them the platform of choice for most WGS-based subtyping approaches. Bioinformatics approaches underlying WGS-based subtyping can be either reference mapping based, *de novo*, or a combination of both approaches. For reference mappingbased approaches, reads are aligned (mapped) to a reference genome (typically a closed genome) or a sequence database. Sequence depth and coverage, along with single nucleotide or insertion/deletion differences, are then used to infer genome-wide variants or allelic differences. *De novo* approaches use genome assembly or graph-like representations to infer genomic variants or allelic differences. Reference mapping-based approaches are usually faster and less computationally intensive than *de novo* approaches, while *de novo* approaches are critical to assess variation in regions that are not present in the reference genome or in the sequence database, such as genomic insertions or mobile genetic elements.

SNPs

The emergence of WGS for bacterial subtyping came with the prevalent choice of SNPs as the subtyping targets. A SNP is a change in a single nucleotide in one sequence relative to another caused by nucleotide mutation, horizontal gene transfer, or intragenic recombination events. Many prevalent foodborne bacterial pathogens, especially closely related strains, display a clonal population structure with little recombination within the population. For these organisms, SNPs identified along entire genomes are reliable and high-resolution markers for phylogenetic reconstruction. During outbreaks, the clonal transmission of pathogens can be reflected by phylogenetic trees, with the close phylogenetic distances between isolates suggesting epidemiological association between cases. Therefore, outbreak clusters can be robustly identified from SNP-based phylogenies. Furthermore, the identification of SNPs is more straightforward and accurate than that of other mutations, such as insertions and deletions, using short sequencing reads. High-fidelity SNPs can be reliably detected by mapping short sequencing reads to an appropriate reference genome (43).

While whole-genome SNP typing usually provides maximum discrimination for outbreak investigations and is highly useful for population studies, it is difficult to standardize. The choice of reference genomes and bioinformatics tools can affect the results of SNP analyses (44). For this reason, SNP profiles of analyzed strains are not amenable to standard nomenclature, which is important for data reporting and exchange among surveillance laboratories. Additionally, the tools used for SNP calling require specialized bioinformatics skills and access to local high-performance computing, both of which are not readily available to allend users, particularly public health laboratorians performing surveillance. Specific examples of utilizing SNPs for characterization of foodborne microbes are given below.

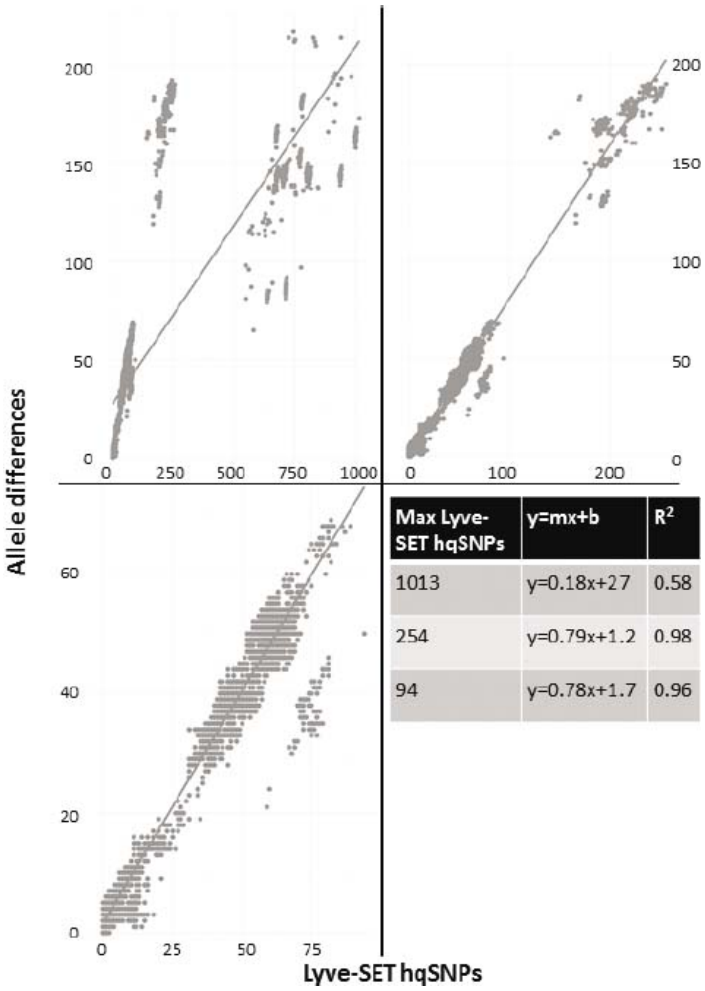
wgMLST

Whole-genome MLST (wgMLST) is a natural extension of classical MLST, in that it extends the number of loci interrogated from typically seven gene fragments to hundreds or

thousands of genes in the whole genome, depending on the organism or wgMLST scheme. The tremendous increase of the number of interrogated loci naturally brings an increase in resolution, making it a subtyping method that is relevant for both species-level population structure inference and potential outbreak cluster detection. In its most extended application, variations in the genes in the whole pangenome of the set of reference strains used to create the wgMLST schema are assessed. In core genome MLST (cgMLST), only genes that are shared by allgenomes (core genes) are used. It is also possible to create schemas tailored to specific tasks (e.g., source attribution of sporadic illness) and containing any number of genes from the core and/or accessory genome that vary in presence within a bacterial species (45). wgMLST is the most discriminatory of the approaches; however, cgMLST is often more practical, as it allows a database with a small but stable set of genes that are found in most newly sequenced genomes. cgMLST and wgMLST approaches provide a higher level of discrimination than older subtyping methods, such as PFGE, and allow standardized nomenclature of cgMLST and wgMLST types (43) when centralized databases are used, which may improve communication between national and international public health centers.

Using wgMLST reduces the complexity of wholegenome analysis from an entire genome (3 to 5 million positions in a typical foodborne pathogen genome) to hundreds to a few thousands of genes. Because the complexity is reduced, the analysis can be run on a local computer instead of a powerful centralized server. Furthermore, the analysis itself is simplified (in the proprietary software packages BioNumerics and SeqSphere+ and numerous open-source packages), allowing most biologists without advanced knowledge of bioinformatics to run the analysis. Typically, a wgMLST analysis using an assembly-free approach takes only several seconds on a local computer while retaining correlation with SNP analysis (Fig. 38.1). Because of the reduced complexity, wgMLST delivers the power of a whole-genome analysis but in less time, with less required expertise, and on a less powerful computer.

WGS for Other Subtyping Schemes



By providing genetic information of the entire genomes, WGS can be used to predict a variety of genotypic and phenotypic subtypes. A growing list of WGS-based subtyping tools is making WGS an inclusive platform for molecular subtyping. For example, traditional MLST (46–49), plasmid profiling (50), serotyping (51–53), and antibiotic resistance profiling (54) can all be performed using WGS data. These bioinformatics tools extract subtyping markers from assembled genomes (46, 47, 52–54), raw sequencing reads (48, 49), or both (51). The ability to predict subtypes directly from raw reads avoids the computationally intensive and sometimes error-prone process of *de novo* genome assembly, leading to more rapid turnaround and better scalability for high-throughput applications.

While in theory any genotypes can be determined from WGS, the challenge of assembling complete genomes without gaps from short sequencing reads (i.e., between 100 and 300 bp) prevents the incorporation of certain molecular subtyping schemes into a single WGS platform. For instance, draft genomes assembled from short reads are often too fragmented to predict PFGE patterns, which depend upon a few large fragments of the genomes, and MLVA profiles, because the short repeats do not assemble accurately.

Web Resources for WGS Databasing and Subtyping Analyses

WGS-based subtyping and source tracking of foodborne pathogens require reference databases and related informatics tools. Integrated, Web-based resources for WGS data depository and subtyping analyses include, among many others, EnteroBase

(enterobase.warwick.ac.uk) and National Center for Biotechnology Information (NCBI) Pathogen Detection (www.ncbi.nlm.nih.gov/pathogens/). EnteroBase currently houses databases for *Salmonella*, *Escherichia*/*Shigella*, *Yersinia*, and *Moraxella*. It provides both classic seven-gene and genomewide schemes for MLST analyses. The NCBI Pathogen Detection system is focused on active and real-time surveillance of foodborne pathogens using sequencing data. A Web-based portal (www.ncbi.nlm.nih.gov/pathogens/isolates#/search/) integrates genotypic (e.g., SNP, sequence, and resistance gene) and phenotypic (e.g., antibiotic susceptibility) information and metadata to facilitate the detection of potential foodborne contamination sources. This system collects data deposited at NCBI, including genome sequences submitted by a number of public health agencies in the United States and other countries that use WGS for routine pathogen surveillance. Besides EnteroBase and NCBI Pathogen Detection, PATRIC (www.patricbrc.org) (55) is another major Web resource of pathogen genomes and analytical tools. Unlike the former two, PATRIC is geared for general purpose query and bioinformatics analysis.

Max Lyve-SET hqSNPs	y=mx+b	R^2
1013	y=0.18x+27	0.58
254	y=0.79x+1.2	0.98
94	y=0.78x+1.7	0.96

Figure 38.1. MLST correlates strongly with SNP analysis when the number of SNPs is lower than 255. A scatterplot was generated using all allelic distances from wgMLST and SNP distances from SNP analysis for three *L. monocytogenes* outbreak clusters. The top left plot shows all pairwise distances, the top right limits the data points to those with <255 SNPs, and the bottom left limits the data points to those of <100. Adapted from reference 43.

APPLICATION OF MOLECULAR SUBTYPING METHODS TO SPECIFIC FOODBORNE BACTERIA

Salmonella

Bacteria of the genus *Salmonella* are so widespread in animals, humans, and the environment that virtually every commonly used subtyping method has been applied to the molecular epidemiology of these bacteria. Although it is not generally thought of as a subtyping method, serotyping of *Salmonella* is actually a very sensitive subtyping method, with more than 2,500 recognized serotypes. With rare serotypes, simply determining the serotype may be sufficient to at least suggest a source or epidemiologic connection. For example, an outbreak of *Salmonella* serotype Hartford infections occurred among visitors to a theme park in Orlando, Florida, in 1995 (56). Serotype Hartford is a sufficiently rare serotype that further subtyping was not needed to suggest an association with drinking orange juice at the park. The association was further strengthened by the isolation of another rare *Salmonella* serotype, Gaminara, from the implicated brand of orange juice as well as from a person with a serotype Hartford coinfection. Ironically, the PFGE subtypes of serotype Gaminara from the patient and the orange juice were different, which could have led to erroneous conclusions if the epidemiologic evidence had not been considered.

Since maintaining the wide panel of diagnostic antisera that is required to perform serotyping is time-consuming and difficult, several molecular methods have been developed to predict the serotype. These methods may be grouped into two types: methods that target the serotype-determining genes (*rfb*, *fliC*, and *fljB*) and surrogate methods that provide subtypes that may correlate with the serotype but do not target the serotypedetermining genes. If a method that targets the serotypedetermining genes is used, the system will be compatible with the Kauffman-White scheme, which contains the phenotypic descriptions of all*Salmonella* serotypes (57), and hence backwards compatible with historical data sets based on the Kauffmann-White scheme. Two protocols based on PCR amplification of the serotype-determining genes with subsequent detection of the targets using a DNA array have been published (36, 58, 59). The surrogate methods are methods that were developed for other purposes but happen to correlate with the serotype, e.g., PFGE (60) or rep-PCR (61), or methods that target non-serotype-specific sequences present in some but not all serotypes (62). The surrogate methods reliably identify a serotype only if its molecular profile is already present in the correlation database. Any isolate with an unrecognized profile by a surrogate method has to be confirmed by a method that utilizes the Kauffmann-White scheme, i.e., traditional serotyping or its molecular counterpart. As mentioned above, *Salmonella* serotypes can now be accurately predicted from WGS data. SeqSero (51) is the first reported bioinformatics tool for bacterial serotyping using WGS. By exclusively targeting serotype determinant genes, SeqSero is able to predict more than 2,200 serotypes and provide close continuity with the Kauffman-White scheme.

For the more common serotypes, such as *Salmonella* serotypes Enteritidis and Typhimurium, serotyping alone typically does not provide sufficient strain discrimination for source tracking. Some of the earliest descriptions of molecular strain typing involved the application of plasmid profile analysis to *Salmonella* serotypes Muenchen (2), Typhimurium (3), and Enteritidis (63).

Since the establishment of PulseNet (1), PFGE has been routinely used to support surveillance and outbreak investigation of *Salmonella* serotype Typhimurium (64) and many

other serotypes (65). In addition to outbreak investigations, PFGE has been successfully applied to tracking *Salmonella* in production environments. Liljebjelke et al. used PFGE to reveal that isolates of *Salmonella* serotypes Typhimurium and Enteritidis from processed poultry carcasses from one farm were indistinguishable from isolates obtained in the poultry house environment and at a company breeder farm, suggesting vertical as well as horizontal transmission (66).

MLVA has also been used to subtype *Salmonella* serotypes Typhimurium (67, 68) and Enteritidis (69, 70). In Denmark and Norway, MLVA has been included in the routine surveillance of *Salmonella* serotype Typhimurium since 2004 and has proven to be superior to PFGE in both surveillance and outbreak detection (71, 72). Dyet et al. investigated the ability of MLVA to discriminate between different serotype Typhimurium phage types in New Zealand (73). They observed good discriminatory power among DT104 isolates but limited discrimination among phage types DT101, DT160, and RDNC (reacts but does not conform to a recognized Typhimurium phage type). PulseNet USA has also used MLVA as a complementary technique to PFGE to further characterize PFGE-defined clusters of *Salmonella* serotypes Typhimurium and Enteritidis with common PFGE patterns and temporarily associated PFGE-defined clusters with closely related patterns (74).

Besides PFGE and MLVA, MLST (25, 75, 76) and DNA microarrays (35, 37–40) have been evaluated for *Salmonella* subtyping and characterization. It was found that MLST was not as discriminating as PFGE when applied to *Salmonella* serotype Typhimurium isolates (76).

The first application of WGS in a retrospective investigation of a *Salmonella* outbreak was reported in 2011 (77). Between July 2009 and May 2010, a multistate outbreak of *S. enterica* serotype Montevideo occurred in the United States. Nearly 300 illnesses were reported in 44 states and the District of Columbia (https://www.cdc.gov/salmonella/2010/montevideo-5-4-2010.html). Epidemiologic evidence suggested that black and red peppers used to prepare salami were the source of the infections, but PFGE was unable to distinguish food and clinical isolates of this outbreak from previous isolates associated with a pistachio contamination. However, pistachios were quickly excluded as a possible source of the outbreak, since no patients had been exposed to them. WGS afforded sufficient subtyping resolution to confirm the results of traceback investigation and identify pistachios as a confounding food vehicle of the outbreak strains.

PFGE is also not discriminatory enough for some strains of *S. enterica* serotype Enteritidis, one of the most prevalent serotypes in the United States and worldwide (78). Among the *Salmonella* serotype Enteritidis isolates reported to PulseNet, approximately 45% display a particular PFGE pattern (JEGX01.0004) using XbaI (79), making PFGE ineffective for strain-level subtyping of these isolates. WGS has addressed this issue. In a retrospective investigation that comparatively evaluated WGS-based SNP typing and other molecular subtyping methods, such as PFGE and MLVA, WGS-based SNP typing was the only method able to resolve all16 outbreak clusters of *Salmonella* serotype Enteritidis detected between 2001 and 2012 in the United States (79). Rapid surveillance of *Salmonella* serotype Enteritidis using WGS was demonstrated by conducting both retrospective and prospective investigations at the state level in the United States (80). Besides detecting additional putative outbreaks, the investigators were able to attribute additional putative cases to confirmed outbreaks. Some of these isolates would have been excluded from the corresponding outbreak by PFGE because their PFGE patterns differed from that of the outbreak strain.

In the United Kingdom, real-time nanopore sequencing was recently evaluated for outbreak investigation (81). By retrospectively analyzing *Salmonella* Enteritidis isolates from a 2016

hospital outbreak, the authors demonstrated rapid species identification, serotype prediction, and phylogenetic placement within 20 min, 40 min, and 2 h after the start of sequencing, respectively. At the international level, WGS was used to confirm cases of a multicountry outbreak of *Salmonella* serotype Enteritidis illness linked to eggs in Europe (82). Besides surveillance and outbreak investigation, the ability of WGS to provide robust phylogenetic inference with high epidemiological correlation has also promoted the understanding of population structure and evolution of this pathogen (83–85).

STEC O157 and Non-O157 STEC

One of the first applications of PFGE to foodborne disease investigations occurred during the large hamburger-associated outbreak of *E. coli* O157:H7 in the western United States in 1993 (86). The demand for PFGE subtyping to support investigations of *E. coli* O157:H7 outbreaks was the driving force behind the creation of PulseNet USA, the national molecular subtyping network for foodborne disease surveillance (1). PFGE was the PulseNet standard method for subtyping *E. coli* O157 until WGS took over that role in 2019. A standardized PFGE protocol for the six most prevalent serotypes of non-O157 Shiga toxin-producing *E. coli* (STEC) was released by PulseNet in 2009 (https://www.cdc.gov/pulsenet/index.html). The relative clonality of the bacterium limits the applicability of MLST (87). Foley et al. compared PFGE, MLST, and rep-PCR for typing isolates from food, cattle, and humans and concluded that PFGE was the method of choice (88).

Multiple partially overlapping MLVA protocols for subtyping STEC O157 have been reported in recent years (65, 67, 89). All reports indicate the ability of MLVA to discriminate between apparently unrelated isolates with indistinguishable PFGE patterns. In the United States, MLVA data have been used in outbreak investigations since 2008 to narrow the case definition and strengthen the association with the vehicle, particularly when the outbreak strain displays a common PFGE pattern and the presumptive source of exposure is a common one. Also, Dyet et al. reported a better epidemiologic concordance of MLVA data than of PFGE data when they used the PulseNet standardized MLVA protocol to characterize 118 isolates from New Zealand (73). A more generic MLVA protocol covering all pathogenic *E. coli* strains was recently published by Lindstedt et al. (90). However, this assay appears to have limited discriminatory power, particularly among non-O157 STEC isolates (91).

WGS-based approaches have been developed that make it possible to rapidly identify putative STEC, subtype isolates using cgMLST, and obtain SNP information to infer putative outbreak clusters. *E. coli* serotypes can be inferred from the presence of alleles of O-antigen processing genes *wzx*, *wzy*, *wzm*, and *wzt* and alleles of the flagellin genes *fliC*, *flkA*, *fllA*, *flmA*, and *flnA* in a genome (52). Additionally, the presence of Shiga toxin genes can be inferred from WGS to confirm the STEC pathotype (92). Lindsey et al. further demonstrate that WGS-based inference of serotype, pathotype, and resistance profile is more efficient timewise and economically than traditional subtyping methods (92). While *E. coli* O157:H7 is considered relatively clonal, SNP diversity is large enough to be valuable for outbreak investigations. A pre-WGS, microarray-based study reported 906 SNPs in 523 chromosomal genes (41). A recent WGS-based study included isolates from seven North American outbreaks and found 3,313 SNPs (93). That study further assessed within-outbreak SNP diversity and proposed criteria for WGS data in outbreak investigations. Crowe et al. recently reported using high-quality SNP data as part of the case definition in order to improve specificity in a large high-profile STEC O121 outbreak associated with flour (94). Based on the WGS data, the

investigators were able to exclude background cases from the case definition and link cases with variant PFGE patterns to the outbreak.

L. monocytogenes

Since the inception of PulseNet and until 2013, PFGE was the gold standard for molecular subtyping of *L. monocytogenes* (95, 96). As the standard method for PulseNet, it has contributed to identifying clusters of *L. monocytogenes* infections and tracking the source of outbreaks (95, 96). It also has been and still is used to track *L. monocytogenes* strains in food processing plants (97). Gudmundsdottir et al. used PFGE to identify potential sources of contamination of cold-smoked salmon in a processing plant in Iceland (98).

Other subtyping methods have been developed for *L. monocytogenes*. Multiple partially overlapping MLVA protocols have been reported for subtyping *L. monocytogenes*, but none of them appear to provide discriminatory power comparable to that of PFGE, particularly among lineage I isolates (71, 99, 100). MLST was also reported to identify a larger number of subtypes of *L. monocytogenes* than PFGE, but this study did not determine the epidemiologic utility of the method (101). A variant of MLST named multi-virulence-locus sequence typing included virulence and virulence-associated genes to better distinguish closely related isolates, such as those with indistinguishable PFGE patterns (26, 102). Increasing the number of genotyping markers was another strategy to improve subtyping resolution for *L. monocytogenes*. A multilocus genotyping assay examined 60 SNPs, indels, or truncations in 22 genes distributed across the *Listeria* genome (103). The method identified strains belonging to the known epidemic clones ECI, ECIa, and ECII in *L. monocytogenes* lineage I. This method was subsequently expanded to lineage II, III, and IV strains (104) and optimized for lineage, serotype, and epidemic clone identification of *L. monocytogenes* (105). DNA microarrays have also been used for genome-wide (34, 106) and pangenome-scale subtyping of *L. monocytogenes* (42). Despite the wide array of reported methods, PFGE remained the method of choice for highly discriminatory subtyping of *Listeria* before the arrival of WGS.

In 2013, a collaboration was initiated among the Centers for Diseases Control and Prevention (CDC), the U.S. Food and Drug Administration (FDA), the Food Safety Inspection Service (FSIS) of the United States Department of Agriculture (USDA), and the NCBI to carry out WGS of all*L. monocytogenes* isolates found in routine surveillance and share the WGS data publicly in real time. SNP subtyping was used at the onset of this collaboration (43, 107). Through international collaboration, a cgMLST scheme was developed (108). Because of its ease of use, amenability to nomenclature standardization, and concordance with high-quality SNP analysis (43), wgMLST replaced SNP subtyping in routine *L. monocytogenes* surveillance. Since implementation of real-time WGS of *L. monocytogenes* in combination with epidemiologic surveillance, more potential outbreak-related clusters are being detected (109).

Sequencing all isolates from routine surveillance has informed us about the use of PFGE patterns to define clusters. In some cases, WGS clusters contained diverse PFGE patterns, while in other cases, multiple WGS clusters were found in PFGE-defined clusters. Furthermore, WGS can aid in finding the food vehicle for “cold” cases and sporadic cases, as WGS can phylogenetically link isolates from human cases and food. Furthermore, because of sequencing of both food product- and patient-derived isolates, outbreaks can be confirmed following product testing, allowing an early association of an outbreak with a contaminated food. Finally, WGS can help create a rapid and precise definition of outbreak cases and thus productively redirect epidemiological resources (109).

Campylobacter jejuni

Unlike the situation for *Salmonella*, STEC, and *L. monocytogenes*, there has been a lack of consensus on the method for subtyping *C. jejuni*. The plasticity of the *Campylobacter* genome, caused by horizontal genetic exchange, and the relative lack of identifiable outbreaks have led some authors to question the utility of real-time molecular typing (110, 111) for outbreak detection.

PFGE was suggested as an epidemiologic tool for *C. jejuni* as long ago as 1991 (112). It was used to discriminate between outbreak and sporadic isolates of *C. jejuni* within a single serotype as early as 1994 (97) and continues to be used (113). Despite these successes, several investigators have expressed concerns about the effect of genomic instability on PFGE type. There was clear evidence that genomic rearrangement and genetic exchange between strains alter PFGE patterns *in vivo* in poultry (114, 115), although at least some strains appeared to be genetically stable (116). This lack of stability made it more difficult to use PFGE to trace the source of *C. jejuni* contamination or to establish links between animal sources and human infections. Unfortunately, PFGE was not the only method affected by genetic instability.

Another early molecular typing method for *C. jejuni* was based on amplification of the flagellin gene *flaA*, followed by restriction digestion of the amplicon and separation of the fragments by gel electrophoresis (117). The sensitivity and specificity of this method were improved by sequencing of the *flaA* gene, and typing was further simplified by focusing on the short variable region within the gene (118). Both of these approaches were affected by recombination within the flagellin locus (119) and are generally not as sensitive as other available methods.

MLST has also been reported to be useful, especially when combined with antigen gene sequence data from targets such as *flaA* (120, 121), *flaB*, and *porA* (122). Some alleles have host specificity, and for that reason MLST has emerged as a tool for microbiological source attribution of campylobacteriosis (123) and for study of the population dynamics and geographic spread of *Campylobacter* (124, 125).

To improve subtyping resolution, another genotyping method has been developed to examine the presence and absence of a larger set of genes than that of typical MLST assays. One example, termed comparative genomic fingerprinting, targets a total of 40 genes (126). Another similar approach, called PCR binary typing, included a total of 68 genes (127).

As with other foodborne pathogens, molecular subtyping of *C. jejuni* and other *Campylobacter* species is being transformed by WGS. Cody et al. reported a retrospective evaluation of WGS for routine subtyping of *C. jejuni* and *Campylobacter coli* (128). WGS data from 384 clinical *Campylobacter* isolates collected over 4 months in Oxford, United Kingdom, were analyzed using a 52-locus ribosomal MLST scheme and a 1,643-locus wgMLST scheme when additional resolution was needed (129). Discrimination among *Campylobacter* clonal complexes and between closely related isolates was achieved by the whole-genome gene-bygene subtyping approach that was reference genome free and scalable to large data sets.

FUTURE OF MOLECULAR TYPING OF FOODBORNE PATHOGENS

With the increasing international trade of food and food animals, a foodborne infection in one country may have its origin in another country, even one on another continent. It is therefore

crucial that molecular subtyping methods for foodborne pathogens be harmonized worldwide to facilitate the rapid comparison of strains isolated in different countries. This harmonization for comparison is best done in the framework of surveillance networks. Such networking systems have been in place for 2 decades in Europe—first as the Salm-net, then the Enter-net (130, 131), and now the European Centers for Disease Prevention and Control Food and Waterborne Diseases and Zoonoses Network (FWD-Net) (https://ecdc.europa.eu/en/about-us/partnerships-and-networks/disease-and-laboratory-networks/fwd-net)—as well as in the United States with PulseNet (98), and most recently with the extension of the PulseNet network internationally onto six continents (132). The WHO Global Foodborne Infections Network (formerly Global Salm-Surv) also focuses on surveillance of foodborne infections internationally, building capacity through training workshops (http://www.who.int/gfn/en/). The future success of these networks will largely depend on the development and adoption of cutting-edge subtyping methods. The GenomeTrakr network, founded by the FDA in 2012, is a network for surveillance of foodborne pathogens in food and the food production environment. The network uses a publicly available database of raw sequences for foodborne pathogens from different sources and of diverse geographic origins housed as bioprojects at the NCBI (National Institutes of Health) (133).

An ideal subtyping method should type all strains, should discriminate between all isolates that are epidemiologically unrelated while identifying all related isolates, and should be 100% reproducible, universally applicable, and inexpensive. The results obtained should be definitive, fully portable, and easy to interpret. New methods should correlate with previously used methods so that the data obtained with the new methods can be related to historical data obtained with the previous methods. It is evident that no currently used subtyping method fulfills all these requirements, and it is likely that none ever will. Nevertheless, new methods are constantly being developed and evaluated and are bringing the science closer to the ideal.

With the ongoing implementation of WGS, we now have an opportunity for the first time in the history of foodborne disease surveillance to establish universal global standards for subtyping foodborne bacteria that will result in easily exchangeable data and global nomenclature. PulseNet International recently laid outits vision to adopt wgMLST as its primary surveillance tool, replacing both PFGE and traditional reference characterization assays with a single efficient workflow (134). Their goal is to place the allele and strain nomenclature databases in the public domain so that all participants, regardless of the analysis software platform they use, will detect the alleles in the same way and use a common nomenclature. Thorough validation studies using well-defined sets of historical isolates with global geographic representation are required to evaluate the allele databases. Additionally, the level of natural variation in the genome sequence that occurs *in vitro* as a result of culture manipulations (e.g., single colony picks from a pure culture or serial culture passages) and *in vivo* during short-term, single-point source outbreaks or zoonotic outbreaks and long-term, recurring single-source outbreaks needs to be determined.

The level of expected variation among isolates not epidemiologically related to one another needs to be defined, too. Tedious validation studies, as described above, are necessary in order to properly analyze and interpret WGS data from the context of molecular epidemiology. Without a doubt, the use of WGS data for cluster detection will result in detection of more clusters than PFGE. Resources for the epidemiological follow-up of all clusters are currently not available in most countries, and for that reason, defining rules to ensure epidemiological follow-up of clusters that represent outbreaks that are most likely to be solved is crucial (135).

Appropriate quality assurance standards and the need for accreditation will also need to be addressed, given that information that can be extracted from the WGS data, such as species identification, serotype, and virulence and antimicrobial resistance profiles, could be used for making decisions about patient management. While the current short-read technologies are still too slow to be used for real-time diagnostics at a physician's office, the Oxford Nanopore MinION sequencer holds some promise for rapid field diagnostics (136). However, the platform currently suffers from a high sequence error rate, so advances in technology need to take place before wider application in public health surveillance is possible.

The WGS technology currently being implemented for bacterial foodborne disease surveillance is dependent on the availability of pure cultures. The increasing use of culture-independent diagnostic tests by clinical laboratories has decreased the availability of isolates for surveillance, and this trend is likely to continue. Therefore, methods that may detect and subtype foodborne bacteria directly from the primary samples are urgently needed. Shotgun metagenomic analysis of the primary sample is likely going to be the long-term solution for the lack of pure cultures. The analysis method needs to provide detection, virulence characterization, and subtyping of the pathogenic organisms at the same time, thereby creating the potential to detect public health events, e.g., outbreaks, in real time, with no delays caused by isolating and growing the organisms as pure cultures. Additionally, outbreaks due to more than one pathogen or strain can be characterized.

While some proof-of-concept studies have already shown the feasibility of this method for characterization of the types of primary samples encountered in foodborne disease surveillance (137, 138), the technology is still too complex, slow, and expensive for routine use and faces formidable challenges that need to be tackled. There are also challenges due to low levels of pathogen in comparison to background microbiome and human DNA and similarity between pathogens and members of the background microbiome (e.g., *E. coli*). Some of the challenges can be addressed using clutter mitigation (removing human and background flora DNA from samples/sequences), read binning to separate pathogen and microbiome sequences, building comprehensive sequence reference libraries containing not only a representative diversity of pathogenic microbes but also the human microbiome, and building bioinformatic analysis pipelines capable of handling metagenomics data in local public health laboratories.

Addressing these challenges is expected to take several years, requiring a shorter-term "bridge gap" solution if the demise of culture-based methods progresses rapidly. Amplicon-based targeted sequencing directly from the clinical or food sample, while not optimal because prior knowledge or hypothesis is required about the etiologic agent, may provide such an approach. Additionally, when amplification is performed, pathogens present at low levels in the specimen are more likely to be detected. Similar to WGS-based isolate subtyping using wgMLST, amplicon targets can be designed by tiling primers along loci that provide enough resolution to do strain-level subtyping. There are enzymatic and microfluidics-based approaches that can be used to multiplex hundreds or thousands of potential loci to be amplified, which can then be used as a library to be sequenced on a next-generation-sequencing machine. However, whatever advances the new technologies provide for characterizing pure cultures or primary samples, it must be remembered that subtyping data will continue to be just one part of the picture and cannot replace epidemiological or environmental investigations.

Note in Proof

Since the writing of this chapter, PulseNet USA has gradually (2018–2019) implemented WGS, primarily cgMLST, as the standard subtyping method for all major foodborne pathogens. At the same time, WGS was implemented for routine identification, serotyping, detection of virulence and antimicrobial resistance determinants, and plasmid profiling of pathogens under PulseNet surveillance whenever relevant.

Predictive Microbiology and Microbial Risk Assessment

PREDICTIVE MICROBIOLOGY

Predictive microbiology is often considered to have its origins in the early 20th century, when Bigelow and Esty (1), Bigelow (2), and Esty and Meyer (3) proposed a log-linear model to describe bacterial death kinetics by thermal processing (i.e., heat). This model was widely applied in the food industry, particularly in the canning industry. Now, about 100 years later, these results are still applied by the food industry to reduce pathogens such as *Clostridium botulinum* in low-acid canned foods. During this period, other areas of research, such as fermentation microbiology, have also contributed to the development of predictive microbiology. The term "predictive microbiology" in the food safety domain was coined by Roberts and Jarvis (4), establishing the conceptual basis of modern predictive microbiology.

In predictive microbiology, mathematical models are used to predict the behavior, such as the growth, survival, and inactivation responses, of microorganisms under different environmental conditions. Mathematical models are developed by culturing microorganisms under a variety of conditions, such as different temperatures, pHs, and water activities (a_w), and fitting the data to a mathematical equation. A database of predictive models can be established, which allows the microbial behavior to be predicted under conditions not specifically tested in the original experiments. Bacterial numbers can change during allstages of food production and processing, depending on the way the food is handled. Predictive microbiology can be used to assess the effects of processing, product composition, storage conditions, etc., on the final contamination of a product at the time of consumption. This permits comparison between the efficacies of individual control steps to limit the numbers of pathogens consumed. For instance, the overall impact of steps to limit raw product contamination at the farm or processing facility could be contrasted to the ability to prevent growth during storage (5). The focus has also shifted from the number of pathogens consumed to the probability of illness during the last few decades. This integration of predictive microbiology and the likelihood of illness enables researchers and other concerned stakeholders to conduct risk assessments and other food safety management procedures, such as hazard analysis and critical control points (HACCP).

Types of Models

Models can be classified into three categories: primary, secondary, and tertiary (5). Primary models measure the response of the microorganism over time to a single set of conditions. The response can be changes in microbial population density with respect to time. These primary models include growth models (6–8), the growth decline model (5, 9, 10), *D* values (or thermal inactivation) (11), inactivation/survival models (10, 12), growth rate values (13), and even subjective estimation of lag time (14). The most common types of primary growth models are the three-phase linear model (7), Baranyi model (15, 16), Gompertz model (17), Huang model (18), and logistic model (6, 19). The modified Gompertz model is an empirical sigmoidal relationship, while the Baranyi model is a differential equation based in part on the concept that the rate of bacterial growth is controlled by the rate of a bottleneck biochemical reaction. The three-phase linear model is a simple approach that assumes a constant bacterial population during the lag phase and the stationary phase and log-linear growth in the bacterial population during the growth period. The Huang model is based on the fundamental observations of the classical bacterial growth process, which exhibits the three phases—lag, exponential, and stationary—as well as the bacterial adaption process in the lag phase. This model

utilizes a transition function to simulate the bacterial adaption process and to define the lag phase of a growth curve, allowing the model to transit smoothly from the lag phase to the exponential phase.

The secondary models indicate how parameters of primary models change with respect to one or more extrinsic or intrinsic factors. Examples of extrinsic factors include temperature, relative humidity, and storage atmosphere, whereas water activity, pH, naturally occurring organic acids, added preservatives, and interactions between groups of microorganisms are some of the examples of intrinsic factors. The secondary modeling may represent simple situations (e.g., one where the storage temperature is the only important factor influencing microbial kinetics), but in many foods, the environmental parameters that influence microbial kinetics are complex and dynamic and include the combined effects of extrinsic and intrinsic factors. Response surface (20), Arrhenius (21), squareroot (22), and Bělehradek (13, 23) models based on the gamma concept, such as those described by Rosso et al. (24), are some examples of secondary models. Arrhenius and square root relationships are suitable where temperature is the primary factor of concern. When other factors, such as organic acid or nitrite concentration, are also considered, polynomial regression equations are more suitable. The response surface or polynomial models are very flexible, with squared, cubic, and cross-product terms, but they have a less mechanistic interpretation than other secondary models.

In the tertiary-level models, the process of primary and secondary models is reversed to obtain the prediction or estimation. Intrinsic- and extrinsic-factor values of interest are entered into the secondary models to obtain the parameter values of the primary models. The primary model is then solved with respect to time to obtain the growth, survival, or inactivation curves expected from the corresponding combination of extrinsic and intrinsic factors.

Lag Phase Duration and Growth Rates

Since the transition from the no-growth phase to the exponential growth phase is continuous rather than abrupt, the lag phase (λ) has no clearly or uniquely defined duration. Traditionally, the lag time has been determined in two ways; graphically as the intersection of the tangents to the growth curve at the lag and exponential phases, as shown in Fig. 39.1, or through nonlinear regression by fitting the experimental data with a growth model that has lag time as one of its adjustable parameters. Although what follows might be considered a hair-splitting argument, both lag time determination methods are conceptually problematic. One potential difficulty with the lag time, determined by either method, will always arise when the growth curve has a steep slope at the inflection point and a very moderate climb in the region preceding it. The problem with the curve-fitting method is that different growth models might yield very different values when used to fit the same experimental data. These problems should not come as a surprise. They are the inevitable penalty of attempting to assign special significance to a point on a segment of a curve that rises (or falls) monotonically—the inflection point being a notable exception. Although in many cases either method provides a marker of the onset of the accelerated growth regimen, the rendered value need not accurately indicate when the acceleration of the growth started.

Many food microbiologists consider the maximum specific growth rate (μ_{max}) the measure of the growth potential of an organism and hence of its physiological vigor. As a result, most secondary models, notably the Arrhenius equation, Ratkowsky's square root model, and their various modifications and combinations, have been developed exclusively for this parameter and how it is affected by temperature and the properties of the habitat. Mathematically, μ_{max} is defined as the slope of the (sigmoid) growth curve at its inflection point. If allmicrobial growth curves were symmetric or approximately symmetric and if they had the same time range and asymptotic growth level, μ_{max} would indeed be a universal growth parameter. This refers to comparisons of the growth of the same organism at different temperatures or under different conditions, such as different pHs, different a_w values, different salt or sugar concentrations, the presence or absence of antimicrobials, etc. The μ_{max} issue always arises in comparison to the growth patterns of the same or different organisms if the degree of symmetry of their growth curves, or asymmetry, is not the same and/or if they achieve different growth levels and have different lags. In all such cases, reference to μ_{max} alone might be of

very limited value, if any, because the difference in the other growth characteristics might be much more significant in practice. Here again, an attempt to establish the universality of a link between the μ_{max} and the lag time (λ), which might not even exist, would be difficult to justify (25).

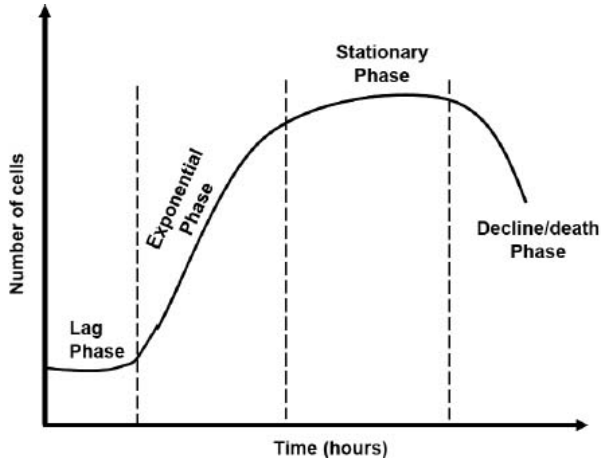

Figure 39.1. Bacterial growth cycle.

Most growth models consider the lag phase in their basic framework. A correlation between the generation time or growth rate and lag phase is often presumed (26, 27). The lag phase is clearer when the inoculum cells are in the same physiological state and have the same cultural history (8). The lag phase duration can be modeled independently of the growth rate with a modified Arrhenius relationship, which assumes the log of the growth rate to be inversely proportional to the reciprocal of the absolute temperature (13). This relationship is based on the control of the rate by a single rate-limiting enzymatic reaction:

$$\ln(1/\lambda) = C_o + C_1/T + C_2/T^2$$

Where λ is the lag phase duration, T is temperature (in kelvin), and C_O, C_1, and C_2 are coefficients to be determined.

Zwietering et al. (17, 28) investigated the effectiveness of several models for describing the effect of temperature on the growth kinetics of *Lactobacillus plantarum*, an organism for which they had a large database of experimental values. They concluded that two reparameterizations of the square root equation were the optimum way to model growth rates and maximum population densities. However, they concluded that the effect of the lag phase was better described by a hyperbolic function:

$$\ln(\lambda) = p/(T - q)$$

Where λ is the lag phase duration, T is temperature (in kelvin), p is a parameter that accounts for the decrease in lag phase duration as the temperature is increased, and q is the temperature (in kelvin) at which the lag phase is infinite.

The square root model (22) is probably the most studied and widely used for the effect of temperature on microbial growth. Below the microorganism's optimum growth temperature, the square root of the growth rate constant (R) and the reciprocal of the lag phase duration (λ) are linearly related to the temperature according to the following relationship:

$$R^{0.5} = b(T - T_{min})$$

$$\lambda^{0.5} = b(T - T_{min})$$

where b is the slope of the regression line, T is the incubation temperature (in kelvin), and T_{min} is the notational minimum growth temperature (in kelvin), which is derived by extrapolating the regression

line to zero. As the incubation temperatures increase beyond the microorganism's optimum growth temperature, growth rates begin to decline. Ratkowsky et al. (29) further expanded their model to include a term that takes into account this depression of growth rate:

$$R^{0.5} = b(T - T_{min})\{1 - \exp[c(T - T_{max})]\}$$

where T_{max} is the notational maximum growth temperature (in kelvin), and c is constant.

When more than one variable has to be considered to predict the growth rate of a microorganism, the type of model employed is dependent on the number and independence of variables. If temperature and another variable are independent of each other, modification of the Ratkowsky model is effective. For example, Miles et al. (30) studied the effect of temperature and water activity on the growth of *Vibrio parahaemolyticus*. The combined effects of the two variables could be described by a simple multiplicative expression:

$$R^{0.5} = b(T - T_{min})(a_w - a_{w\,min})^{0.5}$$

While it is assumed that additional variables could be included using the above approach, the response surface technique has been the primary method for developing models for more complex foods that are dependent on four or more primary variables, particularly if the variables are interactive. This approach employs the regression analysis techniques to generate the best-fit, multidimensional response surface equations that describe the effects and interactions of the experimental variables.

Fluctuating Temperature Conditions

Bacterial populations exposed to sudden temperature variations can experience adaptation delays in growth, known as intermediate lag phases (31). It has been reported by several authors that a combination of several temperature shifts might cause intermediate lag phases of significant duration (16, 32). In general, investigators have found that growth rate adapts immediately to the new temperature as long as the temperature changes are within the range for growth of the organism (15, 16). However, Baranyi et al. (16) found that during fluctuations to temperatures below the minimum for growth, predictions for *Brochothrix thermosphacta* became unsatisfactory, and it was hypothesized that cells had undergone a physiological change. In contrast, Mitchell et al.(33) found that when *Salmonella enterica* serovar Typhimurium was exposed to cyclic temperature changes between 48°C and 22°C, lag periods were not induced and growth rate adapted instantaneously to the new temperature, although some loss of viability was observed at the lower temperature. They concluded that the time periods below the minimum temperature for growth in their experiments were insufficient to perturb growth.

Parameters for Predictive Model Performance

Various indices have been proposed to indicate the quality or goodness of fit of a model. Error mean square, F, and R^2 values from regression analysis are frequently reported that use the absolute difference between the predicted and observed values. Simultaneously plotting data and estimates from the model is necessary to observe whether there are any specific areas within the interpolation space where the model is poorly fitted. The regression analysis assumes that data are normally distributed. If they are not, data should be transformed before modeling. This requirement also applies to nonlinear curvefitting procedures. Determining whether a data set is normally distributed, either before or after a transformation, is not always easy, particularly in cases where only a few replicates are conducted. Because variation clearly increases with increasing value for microbiological parameters, such as generation time or lag phase duration, the logarithms of these values are typically taken.

Although formal hypothesis tests provide a convenient framework for displaying the statistical results of empirical comparisons, standard tests should not be used without consideration of underlying measurement error structure. As part of the validation process, predictions of microbial

concentrations are often compared with the microbial concentrations measured in the experimental studies. Measurements of these microbial concentrations are subject to variability from several sources, including temporal and spatial sampling, sample preparation and analysis, and data entry or recording. Adjustments for measurement error must be made before statistical tests can be used to empirically compare experimental data with model predictions. It is important that users of the predictive model have an understanding of both the limits of the predictive model and the range of its applicability. When considering performance, of most immediate interest is whether the model is fail-dangerous or fail-safe, i.e., whether it underestimates or overestimates the risk of spoilage or extent of pathogen growth. In general, it is accepted that models should predict as closely as possible the observed behavior to avoid wastage of product, but it is better to overestimate the risk rather than underestimating. Ross (34) suggested accuracy and bias factors to assess the level of predictive model performances.

$$\text{Accuracy factor } (A_f) = 10^{(\sum |\log(\text{predicted/observed})|)}$$

$$\text{Bias factor } (B_f) = 10^{(\sum \log(\text{predicted/observed})}$$

These indices have been widely used in predictivemicrobiology research. There is currently no consensus as to what values of these indices constitute a model that provides acceptable predictions of pathogen growth in broth or on food. Although Ross et al. (35) recommended *Bf* values from 0.7 to 1.15 for growth rates, different researchers use different ranges as acceptable performance levels. However, these indices have a few major limitations, as suggested by Oscar (36):

1. These indices are mean values that do not detect some forms of prediction bias.
2. These indices are subject to bias by outliers.
3. Prediction cases involving no growth are excluded from the calculation of A_f and B_f In such cases, these indices overestimate the performance of the models because the “no growth” prediction cases are excluded from the calculation of A_f and B_f.
4. A_f and B_f values are not consistent with each other. More specifically, acceptable values for B_f are independent of the number of model variables, and the criteria for acceptable bias factor consider whether predictions err more in the fail-safe direction (value < 1). In contrast, acceptable A_f values are dependent on the number of model variables, and A_f does not consider whether the model errs more in the fail-safe or fail-dangerous direction.

Oscar (36) introduced a simplified and graphically represented acceptable prediction zone method, which overcomes some of the shortcomings of the A_f and B_f indices. Although this method is fairly simple and easy to interpret, the drawback is that it provides the number of observations falling inside the acceptable range, without giving any statistical information. This method does not provide any information on how close the observed values are to the predicted values.

Predictive-Microbiology Application Software Tools

Current applications of predictive microbiology are broad but can be summarized into three groups of activities (37): product innovation, operational support, and incident support. These three categories of tools or software provide food safety information during new-product development, manufacturing of food, and foodborne-illness outbreaks or recalls. The product innovation-associated applications assess the speed of microbial proliferation, growth limits, or inactivation rate associated with particular food formulations and/or process conditions in order to develop new products and processes. Based on this information, these tools can be used to reformulate existing products and determine storage conditions and shelf life. The operational support tools support food safety decisions that need to be made as part of establishing or running a food manufacturing operation, such as designing infactory heating regimens, setting critical control points in HACCP, and assessing the impact of process deviations on microbiological safety and quality of food products. The incident

support tools estimate the impact on consumer safety or product quality in case of problems (such as an outbreak of foodborne illness or a recall) due to potentially contaminated products reaching the market. Table 39.1 summarizes the common software and tools used in predictive microbiology. Some of these tools are available at no cost, whereas others are commercially available.

Limitations

Even though predictive models are widely used after being appropriately validated, there are several limitations because of the complex behavior of microorganisms and food systems. Some of these limitations are as follows:

1. Predictive models are simplified representations of complex microbial behavior in food and environment systems, and in many cases, not every important variable or factor that affects microbial behavior is included in the model.
2. Predictive models should not be extrapolated outside the range in which they are developed, because these models are derived from experimental data and thus do not consider microbial behavior outside the parameters studied (e.g., temperature range). For example, the square root growth model (Ratkowsky model) for bacteria growth cannot be extrapolated to temperatures above the optimum temperature for growth. An extrapolation will provide a high growth rate, whereas in reality the growth rate actually declines, as represented by the modified Ratkowsky model. Thus, predictions outside the experimental range are not only inaccurate but nonsensical in many instances.
3. Some sigmoidal curves, such as Baranyi and modified Gompertz models, represent growth rates that are higher than the actual growth rates. This is because of the calculation of maximum specific growth rate (μ_{max}) (growth at the maximum rate actually occurs during a limited period during the exponential growth phase) and not simple growth rates.
4. Predictive models are derived from experimental data that do not always reflect real food systems. Usually, predictive models are not designed for the specific conditions that microorganisms may be exposed to in foods. Thus, several models tend to give consistent underpredictions (fail-dangerous) or overpredictions (fail-safe).
5. Most of the predictive models describe the changes in microbial behavior for homogeneous populations, whereas in reality, microbial competition affects the food environment.
6. Models developed under static conditions may or may not be applicable in the fluctuating conditions of temperature, pH, or relative humidity. More research needs to be done on how the lag phase duration or the growth rate changes with the fluctuations in temperature and other relevant conditions.
7. The preinoculation history of bacteria has a considerable impact on their lag phase duration and growth rate.

Table 39.1. Software and tools commonly used in predictive microbiology

Software or tool	Source	Year of creation	Accessibility	Brief description
Baseline	http://www.baselineapp.com/	2012	Free; Internet access	Simulates the growth and inactivation of 5 pathogens in different food systems, using predictive models from the literature
ComBase	http://www.combase.cc/	2004	Free; Internet access	Provides a database with >50,000 records to describe the evolution (growth and inactivation) of several microorganisms in culture media or foods. It also provides some fitting and simulation modules for growth and inactivation. 15 microorganisms are accounted for.
Dairy Products Safety Predictor	http://www.aqr.maison.dulait.fr/	2012	Commercial; Internet access	Simulates an exposure or risk assessment model previously developed for a specific microorganism in a specific dairy product. Users have personal accounts where their model(s) is uploaded and they can then test new parameters.
FDA-iRISK	https://irisk.foodrisk.org/	2012	Free; Internet	Allows

			access	prioritizing food risk by implementing risk assessment models for different pathogens and food matrices. Templates for risk assessment models are proposed.
FILTREX	http://genome.jouy.inra.fr/logiciels/filtrex/	2013	Free; downloadable	Assesses the parameters of primary growth and inactivation models and provides support for optimal sequential design of challenge test experiments
FISHMAP	http://www.azti.es/fishmap	2011	Free; downloadable	Simulates the growth of 8 spoilage species on fish matrix
Food Spoilage and Safety Predictor (FSSP)	http://fssp.food.dtu.dk/	1999	Free; downloadable	Predicts the growth of 3 pathogens, 3 spoilers, and generic microorganisms in meat and seafood products; 12 environmental parameters can be integrated in the simulation in dynamic conditions.
GInaFiT	http://cit.kuleuven.be/biotec/software/GinaFit	2003	Free; downloadable	Allows fitting of 10 inactivation models on experimental data and selection of the best model
GroPIN	http://www.aua.gr/psomas/gropin	2013	Free; downloadable	Simulates the behavior of 66 microorganisms,

				including pathogen and spoilage species, in different food matrices. A database of predictive models is also provided and can be implemented with new models. Monte Carlo simulations are also proposed to take into account the variability.
iPMP	www.ars.usda.gov/northeast-area/wyndmoor-pa/eastern-regional-research-center/docs/ipmp-2013/	2013	Free; downloadable	Analyzes experimental data commonly encountered in predictive microbiology and in the development of predictive models
Listeria Meat Model	http://www.cpmf2.be/software.php	2012	Commercial; downloadable	Simulates the growth of the pathogen in meat and different meat products
MicroHibro	http://www.microhibro.com/	2011	Free; Internet access	Assesses and validates the parameters of a primary model based on experimental data. Implementation of risk assessment models, followed by a sensitivity analysis of the model, is also possible based on the

				combination of several basic processes and using the database of predictive models provided.
MRV (Microbial Responses Viewer)	http://mrviewer.info/	2008	Free; Internet access	Growth/no-growth interface based on ComBase database. It provides a visualization of the specific growth rates.
NIZO Premia	No Internet access	1995	Commercial; no Internet access	Predicts behavior of pathogens and spoilage microorganisms. Predictions are performed mainly in dairy products; other substrates are possible if their characteristics are provided by the user.
PMM-Lab	https://sourceforge.net/projects/pmmlab/	2012	Free; Internet access	Simulates the behavior of pathogens and spoilers in different food matrices.
PMP (USDA)	https://pmp.errc.ars.usda.gov/default.aspx	1990s	Free; downloadable; Internet access	Predicts the growth and inactivation of foodborne bacteria, primarily pathogens, under various environmental conditions
Prediction of Microbial Safety in Meat Products	http://dmripredict.dk/	2006	Free; Internet access	Predicts and simulates the behavior of four pathogen

				species on meat products
SHELF	Mishra et al. (75)	2016	Free from authors on request	Optimizes the temperature for leafy greens considering refrigeration cost, sensory quality, and microbial safety
Sym'Previus	http://www.symprevius.org/	2003	Commercial; Internet access	Simulates growth and inactivation of 6 pathogens and 13 spoilers in several food matrices in both static and dynamic conditions; deterministic and probabilistic approaches can be used.

MICROBIAL RISK ASSESSMENT

Risk Analysis

In food processing, a hazard is a biological, chemical, allergenic, or physical substance that has the potential to cause harm to consumers. Not all hazards are equally serious or pose equally immediate threats. Some situations can be more hazardous depending on the levels, sizes, quantities, or doses of unwanted substance or conditions. When it comes to food safety, how hazardous a substance or condition is may vary greatly. The level of danger can depend not only on the type of hazard but also on who might consume a food product. Usually, there is a threshold level below or above which the presence of a hazard is considered tolerable, or acceptable.

In the past 2 decades, research in the food safety discipline has addressed the assessment of hazards in foods within the framework of risk analysis, a new science-sed paradigm intended to ensure human health protection. The objectives of risk analysis are to estimate the risk to human health of a hazard associated with food consumption and, most importantly, to assess appropriate management strategies in the "farm-to-fork" food chain capable of mitigating the risks. Risk analysis represents a structured decision-making process with three closely connected components: risk assessment, risk management, and risk communication (Fig. 39.2).

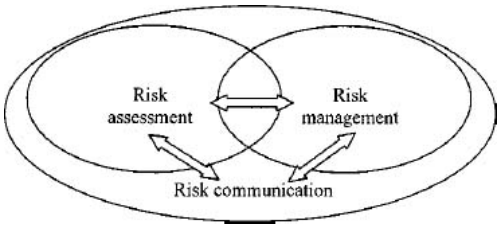

Figure 39.2. Codex Alimentarius risk analysis framework.

Risk assessment is the central scientific component of risk analysis. Building a risk assessment model is central not only for the characterization or estimation of the potential adverse effects on health resulting from exposure to hazards (i.e., risk) but most importantly for the prediction of the risk reduction attained by each of the potential intervention strategies under consideration. On the other hand, risk management is the process of evaluating policy alternatives in consultation with stakeholders and is generally performed by a food safety authority. It encompasses the identification and selection of risk management options or intervention strategies as well as their implementation. Risk managers are responsible for verifying that the risk mitigation measures that were selected and implemented are in fact achieving the intended results, which they carry out by monitoring and surveillance activities (38). Lastly, risk communication refers to the sharing of goals, information, and data between risk assessors and managers in addition to other stakeholders, such as the public and industry. Risk communication plays an important role in ensuring that the results and other important details of a risk assessment are clearly understandable and communicated to all parties; it is essential in ensuring transparency in risk analysis. Experience has shown that regular communication between all parties is necessary to ensure that the risk assessment has maximum value to the risk managers and that risk management decisions are understood and accepted by the public and various stakeholders; thus, risk communication should encompass both risk management and risk assessment as proposed by the risk analysis framework published by the Codex Alimentarius Commission (39). The main goals of risk communication are as follows:

1. promoting awareness and understanding of risks (among researchers, government officials, consumers, and other concerned stakeholders)
2. promoting consistency and clarity about the risk analysis process
3. providing an understanding for risk management decisions
4. strengthening good working relationships and promoting respect
5. promoting appropriate involvement of all stakeholder groups
6. exchanging information, knowledge, attitudes, practices, and perceptions among those involved

Microbial Risk Assessment

Microbial risk assessments can be either qualitative or quantitative. The risk management questions typically address the approach and spectrum of risk assessment (40). Qualitative risk assessments express risk as a grade or category (e.g., low, moderate, or high risk) rather than as a number, as in a quantitative risk assessment. Quantitative risk assessments can be either deterministic or stochastic (probabilistic). The mean growth rate is multiplied by the mean storage time to predict the amount of microbial growth. In real-life conditions, there is inherent variability in such parameters, often represented by standard deviations or confidence intervals, but the algebraic calculations consider only the means for both input parameters and the calculated values. This approach is a deterministic, or point estimate, analysis.

Making a worst-case estimate is another example of deterministic analysis. Quantitative risk assessment involves the distributions of the model parameters into the calculations. The sources of the distributions about the mean values are from variability and uncertainty (41). Variability refers to the inherent differences in outcomes obtained from a process. Uncertainty is lack of knowledge. Uncertainty and variability are often described using distributions, such as normal, lognormal, beta, binomial, triangle, histogram, or program evaluation and review technique distributions. If the input parameters of a model or a food process are distributions, the calculated output will also be a distribution. To make these calculations, Monte Carlo simulation is generally used. In this method, a value is randomly selected from each distribution according to the characteristics of that distribution and the model output is calculated. A new set of values from each distribution is selected and the process is recalculated (iterated). Its mean or median can describe this distribution, but the entire shape and spread of the distribution are important in the interpretation of the process (5). For a

disinfection calculation, for example, the disinfection received by the lowest 10% or 1% of the model simulations may be more relevant to setting critical control point parameters than the mean or median values. This type of analysis is called “probabilistic” or “stochastic” and provides a more comprehensible description of the risk being assessed than the deterministic analysis (42).

Quantitative microbial risk assessment (QMRA) is a science-based process used to quantitatively estimate the adverse health effects resulting from exposure to microorganisms. In particular, QMRA is used to tackle food safety problems caused by the intake of food products contaminated with potentially hazardous microorganisms. Risk assessment, which is an integral part of the risk analysis process, is interrelated with two other components: risk management and risk communication (43).

Risk Assessment Steps

The Codex Alimentarius Commission (39), established by the Food and Agriculture Organization of the United Nations and the World Health Organization and recognized by the World Trade Organization as the relevant organization for international food safety standards and guidelines, defines risk assessment as “a scientifically based process consisting of the following steps: (i) hazard identification, (ii) hazard characterization, (iii) exposure assessment, and (iv) risk characterization” (39).

Hazard Identification

The first step of risk assessment describes a microorganism and the disease it causes, including symptoms, severity, and death rates from the microorganism. This step also identifies sensitive populations that are particularly susceptible to infection.

Hazard Characterization

Hazard characterization describes the nature and extent of the adverse health effects known to be associated with the specific hazard. If possible, a relationship is established between the different levels of exposure to the hazard in food (i.e., the dose) at the point of consumption and the likelihood of different adverse health effects such as infection or illness. It describes the dose-response relationship.

Exposure Assessment

The aim of exposure assessment is to determine the frequency and magnitude of exposure to pathogens via food consumption. In exposure assessment, quantitative information about pathogen concentration in food is needed. Additionally, data on the exposure of humans (the size of the exposed population, the nature of the exposed population [e.g., vulnerable groups], and frequency of exposure) are also required.

Risk Characterization

During risk characterization, the results of the two previous steps, exposure assessment and hazard characterization, are integrated to generate a risk estimate. If a risk assessment is quantitative, the risk may be characterized in terms of risk per serving, risk per annual rate of consumption, or even in number of cases for a target population. In microbial risk analysis, the derivation of efficient management strategies should be assisted by three elements: food chain data availability, predictive microbiology, and sampling strategies.

Uncertainty and Variability

Uncertainty is defined as the lack of knowledge or availability of data concerning inputs for the risk assessments, appropriate models, and assumptions (44). Both subjective and objective aspects are important in assessing the degree of uncertainty, which is defined as the degree of the lack of confidence that one has concerning the validity of the information obtained (45). A document

outlining the general guidelines for characterizing and communicating uncertainty in exposure assessment was released by the World Health Organization in 2008 (46). A more detailed guideline for uncertainty assessment and uncertainty communication has been developed for risk assessment by the Netherlands Environmental Assessment Agency (47–49). Unlike uncertainty, variability refers to the inherent heterogeneity or diversity of data in an assessment. It is "a quantitative description of the range or spread of a set of values" (50) and is often expressed through statistical metrics such as variance, standard deviation, and interquartile ranges that reflect the variability of the data. The primary difference between the two is that uncertainty can be reduced or eliminated with more or better data, whereas variability cannot be reduced, but it can be better characterized.

In many cases both variability and uncertainty are present. For example, a particular drinking water may be contaminated with *Cryptosporidium* oocysts. The number of oocysts in different water samples will vary. If the oocysts move randomly in the water—that is, they move independently, neither clustering together nor dispersing—then the probability that a given number of oocysts will be found in a given water sample can be described by a Poisson distribution (51):

$$\text{Prob}[x \text{ oocysts}] = \lambda^x \exp(-\lambda)/x!$$

Where λ is a parameter. One property of this distribution is that the mean is equal to λ. One can think of λ as the long-run mean, that is, the mean if an infinite number of samples from the same Poisson distribution are averaged. Because a finite sample is not guaranteed to be perfectly representative of the population from which it is drawn, even after the mean (median, variance, etc.) for a sample is obtained, there is still uncertainty as to the population mean (median, variance, etc.). It is uncertainty due to this sampling variability which is quantified through statistical methods.

It is common to first assess an appropriate functional form for $f(x)$ and then, given the chosen form of $f(x)$, assess the uncertainty in the parameters of $f(x)$. In the classical statistical framework, these parameters are fixed values. Based on a sample, estimates are obtained for these parameters. However, given sampling variability, these parameter estimates have variability in them. This variability can be assessed and the standard deviation of the estimate of the parameter quantified. This standard deviation of a parameter estimate is termed a standard error. Thus, uncertainty in model parameters (due to sampling variability and only sampling variability) is captured by these standard errors. In the Bayesian framework, model parameters are treated as themselves being random variables. In this framework, the λ value for a Poisson process would follow a probability distribution with a mean (reflecting the central tendency of λ) and a variance (reflecting uncertainty as to the true value of λ). In the classical framework, it is not quite correct to describe the parameters of models as following uncertainty distributions. Instead, the standard errors are used to include or exclude different possible values of the model parameters with various levels of confidence. It is not clear that any harm is done in simply treating model parameters as random variables with means equal to their estimates and standard deviations equal to their standard errors. This view essentially adopts the Bayesian framework even for models estimated in a classical framework. It is often a convenient approach to adopt in risk assessments where probability is used quite generally to describe a wide variety of uncertainties (51).

Uncertainty and Variability in Hazard Identification

The hazard identification step involves the determination that a health hazard is or may be associated with a biological, chemical, or physical agent present in foods. This step provides a dichotomous answer—that is, the factor is or is not thought to be a human health hazard. The uncertainty involves the correct classification of the agent (i.e., it is or is not a human health hazard). If the agent is tested for prevalence in the food sample multiple times, it is predicted to be either positive or negative with a certain degree of precision that is related to the performance of the microbial test. Uncertainty associated with the analysis of a microorganism in this study derives from knowing whether the sampling method is actually capable of predicting a positive (or negative) response.

Three issues are considered potentially significant contributions to uncertainty and variability in hazard identification. First is the misclassification of an agent—either identification of an agent as a hazard when it is not one or failure to identify an agent as a hazard when it is one. Second is the issue of the reliability of the screening method for appropriately identifying a hazard and the reliability of the microbial sampling to give the same result each time the sampling is performed. Third is the issue of extrapolation, because all screening methods are used to extrapolate the information provided by the test to predict human hazards. Epidemiological studies are used to predict the impact of exposures on human populations in the future.

Uncertainty and Variability in Hazard Characterization

Hazard characterization is the process of defining the site, mechanism of action, and at minimum the dose-response relationship (proportion responding or severity of response). In this step, it is likely that a series of models may be developed. The models vary from purely mathematical representations to biologically based representations. As a result, each has varying degrees of representation of the actual human disease process and thus varying degrees of uncertainty (52).

Model uncertainty is likely to be an important issue in the hazard characterization step. Mathematical dose-response relationships have the greatest uncertainty in actual representation of the biological processes. Despite the admittedly large uncertainty, dose-response models are currently the most commonly used methods for predicting human health effects and have often proved useful in establishing policy. As interest in risk assessment has grown, the sophistication of the models, including the accuracy and completeness of their representation of the biological processes, has also grown. An important issue of both variability and uncertainty that arises in hazard characterization is in the variance in the dose response at the dosages for the species studied. To increase the power and the value of a negative study, large exposures are typically used in studies. These exposures are generally substantially greater than usual human exposures. That means that models including exposure response information gathered at high exposures may not be accurate at the low exposure levels of concern for human risk assessment. In addition, there is variance among animals' responses at a given dose, despite the fact that most experimental animals are genetically in Model uncertainty is likely to be an important issue in the hazard characterization step. Mathematical dose-response relationships have the greatest uncertainty in actual representation of the biological processes. Despite the admittedly large uncertainty, dose-response models are currently the most commonly used methods for predicting human health effects and have often proved useful in establishing policy. As interest in risk assessment has grown, the sophistication of the models, including the accuracy and completeness of their representation of the biological processes, has also grown. An important issue of both variability and uncertainty that arises in hazard characterization is in the variance in the dose response at the dosages for the species studied. To increase the power and the value of a negative study, large exposures are typically used in studies. These exposures are generally substantially greater than usual human exposures. That means that models including exposure response information gathered at high exposures may not be accurate at the low exposure levels of concern for human risk assessment. In addition, there is variance among animals' responses at a given dose, despite the fact that most experimental animals are genetically inbred and are therefore expected to be genetically identical. If outbred animals are used, the variability in the dose-response relationship is expected to be larger, and if humans are exposed, the variance is also expected to be large. Another issue of both uncertainty and variability that arises in hazard characterization is the need to extrapolate between species. Approaches used for extrapolation between species include both uncertainty about the appropriate model for performing the extrapolation and variability in the parameters used for extrapolation (53).

Uncertainty and Variability in Exposure Assessment

Any model used to represent exposure should include several pieces of information (52):

1. the level of an agent measured in a commodity or the levels measured in soil, plants, irrigation water, or animals that supply this commodity
2. the depletion/concentration ratio, which defines changes in the level of an agent as a result of processing, preparation, and dilution
3. the frequency and magnitude of human intake of a commodity
4. the level of exposure, or the amount of the commodity an individual is likely to ingest
5. the average time for the type of health effects under consideration to be clinically detectable

These factors typically converge in the process of defining the distribution of population exposure. The population at risk for exposure refers to the population that consumes food containing the hazard. An exposure assessment is the key input to the assessment of dose, which reflects the amount of the agent delivered to the target organ or tissue, where the adverse effect can be induced. Defining exposure pathways is an important component of the exposure assessment. An exposure pathway is the course a biological, chemical, or physical agent takes from a known source to an exposed individual. In the case of agents in food, concentrations of chemicals and/or organisms (microbes, parasites, etc.) can change between what is measured in soil, plants, water, animals, and raw food and what is ingested by an individual. In the case of chemicals, there can be some increases of contaminant concentration due to processing (i.e., distillation), but more likely, the storage, processing, and preparation of the food product will result in a reduction of contaminant concentration. For microorganisms, there might be significant increases of microbe or contaminant concentration due to replication under favorable environmental conditions (temperature, pH, and water activity). Thus, significant Uncertainties might be expected in the ratio of the concentration of a bacterial agent in food at the time of consumption to the concentration measured in raw foods or measured in animals, plants, or soil (**54**).

Uncertainty and Variability in Risk Characterization

Once hazard characterization and exposure information has been collected, risk characterization is carried out by constructing a model for the distribution of individual or population risk. This is done by summing the effect over all exposure routes. Because of the uncertainties and variabilities involved in its constituent steps, the overall process of risk characterization might involve potentially large uncertainties.

An important final step in the risk characterization process is the characterization of uncertainties. In order to directly characterize uncertainties in risk assessments, it is necessary to take a tiered approach to uncertainty analysis. Three tiers can be used. First, the variance of all input values should be clearly stated and the impact of these variances on the final estimates of risk assessed. Second, a sensitivity analysis should be used to assess how model predictions are impacted by model reliability and data precision. The goal of a sensitivity analysis is to rank the input parameters on the basis of their contribution to variance in the output. Finally, variance propagation methods should be used to carefully map how the overall precision of risk estimates is tied to the variability and uncertainty associated with the models, inputs, and scenarios (55).

Separating Uncertainty and Variability by Two-Dimensional Monte Carlo Simulation

A two-dimensional (or second-order) Monte Carlo simulation was proposed to estimate the uncertainty in the risk estimates stemming from parameter uncertainty (56, 57). A two-dimensional Monte Carlo simulation is a Monte Carlo simulation in which the distributions reflecting variability and uncertainty are sampled separately in the simulation framework, so that variability and uncertainty in the output may be estimated separately (55). This framework has been used in various domains of risk assessment (58, 59) and is now used in the food safety domain (60, 61). Nevertheless, variability and uncertainty are gathered in some risk assessment studies through a one-dimensional

Monte Carlo simulation (62, 63), because separating uncertainty and variability is computationally challenging and often confusing. In order to enable two-dimensional Monte Carlo simulations such as the one proposed by Cullen and Frey (57), one needs to quantitatively describe the uncertainty associated with the parameters in the risk assessment model. The bootstrap resampling method, Bayesian derivation, and expert elicitation are some of the available methods (64).

Bootstrapping

The bootstrap method is a fairly easy tool for numerically calculating the uncertainty of a data set of measurements, by repeatedly drawing results randomly from the data set. In some cases, an analytical formula is available to estimate the standard error of a parameter. For complicated model forms, such formulae may not be available. Bootstrapping is a standard method to assess the uncertainty in parameter estimates due to sampling variability. The concept underlying bootstrapping is that of treating the sample obtained as the probability density distribution function of the model. Each point has probability $1/N$, where N is the number of observations in the sample. This assumption allows us to create alternative samples from the data. One randomly draws N observations from the observed data set to create an alternate data set. These observations are drawn with replacement, meaning that a particular observation is not eliminated from subsequent draws after it is sampled. It is this "sampling with replacement" that allows each alternative data set to be slightly different from the original data set, since some observations will appear multiple times in the alternative data set and some will not be sampled at all (65). Uncertainty can be described using this method, with the assumptions that the sample is unbiased and random and represents the entire population.

The next step is to estimate the desired parameter (or summary statistics, such as mean, variance, 90th percentile, etc.) for each of the alternative data sets. Each combination of generating an alternative data set and estimating the quantity of interest is termed an iteration of the bootstrap procedure. The values for each data set are then considered discrete samples from the probability distribution of the parameter. Means, variances, and percentiles for the parameter estimate can be found from this discrete sample. Thus, the standard error of the parameter estimate can be estimated as the standard deviation of the different parameter estimates obtained from each iteration. This is essentially a Monte Carlo approach to assessing parameter uncertainty, and, as with all Monte Carlo analyses, the number of iterations conducted should be large, preferably as large as 10,000 (64). A smaller number of iterations may be acceptable if convergence of estimates can be observed. In this case, one would track the estimate of interest across different iterations. Values will fluctuate greatly at first, as the estimate is based on a small number of iterations, but these fluctuations will decrease as a larger sample size is obtained. Convergence is achieved when the estimate no longer shows fluctuations large enough to be of concern to the analysis (55).

Expert elicitation

Expert elicitation is the process of eliciting subjective judgments from experts. It is used to provide input for risk assessments when empirical data are lacking, are of poor quality, or are difficult to obtain. Since the elicitation of expert judgment involves subjectivity, sometimes it is prone to bias on the part of the expert, as well as the elicitor (person collecting the expert opinion) and the elicitation protocol used, all of which may ultimately have an impact on the validity of the decisions based on a risk assessment. Havelaar et al. (66) state that "an expert opinion may not be expected to provide an unbiased estimate of the relative importance of different transmission routes. Rather it should be regarded as a structured way to obtain consensus opinion, based on available data." The goal of an expert elicitation procedure is to reduce this bias as much as possible, and this requires thoughtful preparation. A structured expert elicitation involves the selection of the experts, explanation to the experts of the problem and the elicitation procedure, a clear definition of the quantity to be assessed, a discussion of the gaps in the knowledge, specification of the experts' opinions in a distribution, and the decision whether to aggregate the distributions of the different experts. A successful expert elicitation also implies solid training in elicitation techniques.

Well-defined procedures, including the identification of target, query, and performance variables, the selection of experts, and a systematic combination or synthesis of expert judgment, can yield valuable information on the questions posed. Formal (and sometimes complex) methods should be used to determine overall probabilities with classical or Bayesian approaches to data aggregation. Whatever method is used to assess overall probabilities, it is critical that expert elicitation contain some estimate of uncertainty (67).

Sensitivity Analysis

The risk estimate of a risk assessment model is the most important piece of information that may be presented in a risk assessment report. Often, the risk managers are more interested in the results from a sensitivity and scenario analysis that show the relative importance of different parameters and determine the impact on the output from changes in various input parameters. Sensitivity analysis is used to determine the degree of influence that a given input has on the value of the output. Most risk assessment models focus on stochastic sensitivity analysis; however, less detailed methods to conduct deterministic and worst-case sensitivity analysis have been described (68). The results, usually displayed in the form of tornado graphs, are a result of statistical analysis (stepwise least-square regression or rank order correlation) done using the input and output data generated during the Monte Carlo iterations (69). An example of a tornado graph was taken from the risk assessment of *Escherichia coli* O157:H7 in leafy greens and is shown in Fig. 39.3 (62). The results from a sensitivity analysis are extremely helpful in identifying points in the systems where additional data collection is most useful (high impact of uncertainty for a parameter) and where mitigation strategies aimed at impacting risk could be most efficient (high impact of a variability parameter).

There is no universal standard for conducting sensitivity analysis (70). In fact, multiple approaches may be legitimately used, because each approach may examine a different type of influence. The typical sensitivity analysis examines the magnitude of change in exposures for some change in inputs (i.e., Δoutput/Δinput). One challenge is determining how a change in exposures should be measured. In some cases, change in the average dose value may be satisfactory (e.g., measuring conditional expected dose). In other cases, the change in the variability of doses may be of interest. If sensitivity is measured using analysis-of-variance techniques, then changes in the average and variance can be assessed together. Correlation or other quantitative measures of association (e.g., spider plots and tornado charts) are commonly available in commercial software packages used for Monte Carlo simulation (64). Another approach used in risk assessments is regional sensitivity analysis, which estimates the impact of a number of parameters contemporaneously. Feasible parameter ranges and parameter distributions are defined prior to the analysis. Then, a Monte Carlo analysis, sometimes combined with a Latin hypercube sampling scheme, is used to produce a large number of different parameter combinations and to obtain a model response for each combination. These multiple model responses are then analyzed to obtain information about the impact of single parameters on the model response (42).

The major challenge for sensitivity analysis is that it is difficult to separate sensitivity from uncertainty in most exposure assessment models. Uncertainty about model components can result in a very mixed description of the importance of model components. Theoretically, a model input may be highly influential across part of its uncertainty range but much less influential across another part. At the least, acknowledgment of such discrepancies should be communicated to risk managers. Again, focused sensitivity analysis facilitates deeper analysis of a few components instead of superficial analysis of many components.

Scenario Analysis

A scenario analysis consists of a series of "what if" options for mitigation measures, interventions, or policy changes. This type of analysis allows the evaluation of health benefits of various measures that prevent or mitigate exposures. Scenario analysis begins the process of identifying scenarios that constitute a risk as well as those that are not a risk. It simplifies the next stage of exposure model development, quantifying the likelihood of scenarios that end in an exposure dose. In developing scenarios during the conceptual development phase, one should begin by defining the mathematical relationships between process steps. Are these additive or multiplicative? Are there correlations between different inputs? What other factors influence the relationships among inputs?

Compared to scenario development, determining likelihood and dose is usually a more mathematical exercise The relationships between model inputs need to be mathematically described; statistical methods are often employed to quantify these relationships. Also, the process of converting conceptual relationships into explicit mathematical relationships commonly involves additional assumptions beyond those represented in the conceptual model. Transparency is particularly important during this process. Before data availability or analysis is considered, the mathematical development needed to determine likelihood and dose should be determined. Once a tentative mathematical model is completed, its structure can be communicated with outside reviewers and risk managers. Typically, the mathematics will provoke discussion about the data needs of the model. A clearly defined mathematical model provides an opportunity for specialists to review and comment on the course of the project. If scrutiny of the mathematics indicates the need for change, the changes should be made before a large investment in data acquisition and analysis is completed. Frequent outreach and feedback is one manifestation of effective exposure assessment (42).

Recent Developments in Food Safety Risk Assessment

Various risk assessment approaches have further matured through application of complex computational modeling and availability of more microbiological data. One limitation of the traditional risk assessment approach is that it is static. For example, if one is estimating the growth of *Salmonella* in chicken during storage, the values of storage time and temperature from a distribution are used. This temperature is usually constant for a given iteration. In reality, the temperature is not

fixed during storage, and there is possibility of cross-contamination at any time during the storage. These variations are usually not addressed in traditional risk assessments. There have been several recent developments and studies related to food safety risk assessment; we cite some of them as examples.

Recently, a system modeling approach was introduced which reported the probability of contaminated leafy greens harvest in a major leafy-greens-producing region in California (71). A system modeling approach considers any system to comprise several subsystems which can better be understood as being interdependent, rather than isolated. Pathogen pathways in food systems such as a leafy greens farm are very complex, but the system modeling approach is very promising with regard to understanding this complexity. The system model (71) calculated the survival and contamination of *E. coli* in a leafy greens farm system continuously throughout the year and predicted the months at highest risk for contaminated harvests. These results were in good agreement with the recent reported outbreaks.

Similarly, another model was developed to describe a hypothetical cattle farm in order to compare the relative importance of five routes of exposure of leafy vegetables to pathogens. The routes were aquatic recreation downstream of the farm, consumption of contaminated ground beef processed with limited interventions, consumption of leafy greens, direct animal contact, and the recreational use of a cattle pasture. To accommodate diverse environmental and hydrological pathways, existing QMRAs were integrated with novel and simple climate and field-level submodels (72). FDA-iRISK (irisk.foodrisk.org/) is a Web-based system designed to analyze data concerning microbial and chemical hazards in food and return an estimate of the resulting health burden on a population level. The data required to execute this analysis include the food, its associated consumption data and processing and preparation methods, the hazard and its dose-response curve, and the anticipated health effects of the hazard when ingested by humans. Each of these elements contributes an essential piece of information to the model on which the final estimate of risk is based.

Strengths and Limitations of Microbial Risk Assessments

Risk assessments applied to pathogens in food products can provide valuable information for risk managers. In addition to providing estimates of the overall probability of illness or infection associated with a food product, microbial risk assessments help to identify food processing and handling steps that affect the overall risk associated with the consumption of a particular food product. For example, the USDA Food Safety and Inspection Service (FSIS) developed a QMRA for *Listeria monocytogenes* in delicatessen meats (73) in response to risk management questions regarding the effectiveness of food contact surface testing and sanitation regimens in reducing the risk of contamination by *L. monocytogenes*. Results showed that a decline in the concentration of *L. monocytogenes* may be achieved by increasing surface testing and sanitation efforts. Another FSISsponsored risk assessment, for *Clostridium perfringens* in ready-to-eat and partially cooked meat and poultry products (74), demonstrated that storage temperatures used by retailers and consumers had a significant effect on the estimated risk of disease caused by this organism.

The quality of the data sources used to develop a microbial risk assessment is very important, as it determines the accuracy of the risk estimates produced. How closely the risk assessment model describes the actual scenario being studied also affects the accuracy of the conclusions. The risk estimates may be validated by using epidemiologic data; however, the usefulness of epidemiologic data is often limited, especially if the risk assessment considers specific food products in a larger food product category (such as fresh-cut lettuce in the fresh produce category) or if specific food-handling conditions (such as consumer behaviors regarding home storage) are being evaluated. Lack of information regarding any of the supply chain steps considered in the risk assessment can also increase the uncertainty of risk estimates.

Food Safety Management Systems

INTRODUCTION

What Is an FSMS?

A food safety management system (FSMS; also called a food safety risk management system) ensures food safety across the supply chain by setting and documenting standards and expectations for activities focused on the production of safe foods. The International Organization for Standardization specifies requirements for an FSMS where an organization in the food chain needs to demonstrate its ability to control food safety hazards to ensure that food is safe at the time of human consumption (1). An effective FSMS will contain several key elements, including a hazard analysis and critical control point (HACCP) program, preventive controls, prerequisite and environmental monitoring programs, hygienic zoning, testing programs, consumer and customer feedback, traceability and recall, and documentation. Elements of an FSMS include specifications, procedures, processes, verifications, validations, and documentation that demonstrate commitment and execution of a manufacturer's FSMS.

Why Is an FSMS Needed?

Consumers expect safe food. Food producers must be committed to providing safe food 100% of the time. This is true for minimally processed foods, such as fresh produce, and for formulated, complex foods that provide consumers with a wide range of convenient options. Food holds a unique place as a consumer product.

Customs, culture, and rituals all play a part in the importance of food in society. While people interact with consumer products in many ways, all food products are intended to be ingested either in the form sold or after further preparation.

While consumers expect safe foods all the time, the statistics on foodborne illness indicate that there is significant room for improvement. The U.S. CDC estimates that each year there are about 46 million cases of foodborne illness and that about 8 million of those illnesses are caused by about 30 known pathogens (2). A global burden estimate by the World Heath Organization suggested that there are about 600 million illnesses each year attributed to 31 foodborne hazards (3). Norovirus and *Campylobacter* are the most common foodborne hazards. Determining the exact burden of foodborne illness is challenging. While these estimates consider all food sources, when the attribution is reviewed by food category, it is likely that only a small fraction of these illnesses are attributed to processed foods. However, issues with processed foods do cause numerous recalls and illnesses each year.

The best way to meet the challenge of providing safe food 100% of the time is to implement an effective FSMS. It is an internationally recognized comprehensive approach to managing food safety and compliance with regulatory, customer, and internal requirements.

What Factors Shape the Design of an Effective FSMS?

The FSMS must use a holistic approach to identify hazards, understand risks, and implement controls to reduce risks to acceptable levels. It is an understatement to say this is easier said than done. Figure 40.1 highlights the sources of information that should be used to create an FSMS. The level of rigor for a food safety risk management system will be dependent on a variety of factors. Every FSMS must consider the intrinsic risk of the food, the processing conditions, and the characteristics and behaviors of the consumers. Additionally, the FSMS must also ensure that customer expectations and regulatory requirements are met. All of this cannot

be achieved without an effective management program, including documentation for the FSMS. The final key factor for the success of any FSMS is the fundamental expectation of continuous improvement, which is a strategic approach to understanding an FSMS and identifying opportunities to drive down risks to food safety and quality. The programs that are necessary for an effective FSMS are discussed below.

Role of Regulations

Regulatory agencies are responsible for setting food safety standards and verifying compliance. In many cases, food manufacturers are under the jurisdiction of multiple regulatory bodies (federal, state, and local) charged with the oversight of safe food production. In developed countries and in most developing countries, regulations form the minimum operating standards for any food production facilities and should form the base of any food safety risk management system.

Regulations have played a historically important role in food safety. Many regulations are based on the best available science in setting standards to produce safe foods. Other regulations are in place to provide clear directions on how food should be produced and held. Regardless of philosophical approach, regulations can be considered the minimum expectations that must be met to make safe food, and compliance is expected.

Meeting the regulatory standard may not always be sufficient to ensure food safety, because many regulations do not set standards to the level of detail needed for an effective program. For example, the FDA Food Safety Modernization Act (FSMA; https://www.fda.gov/food/guidanceregulation/fsma/) sets the expectation for safe food. However, the FSMA does not mandate how to achieve the safe manufacture of any specific product. Manufacturers are expected to demonstrate that the food safety plan in place is appropriately implemented and executed to achieve

safe food. The burden of proof lies with the manufacturer, and the role of the regulator is to verify.

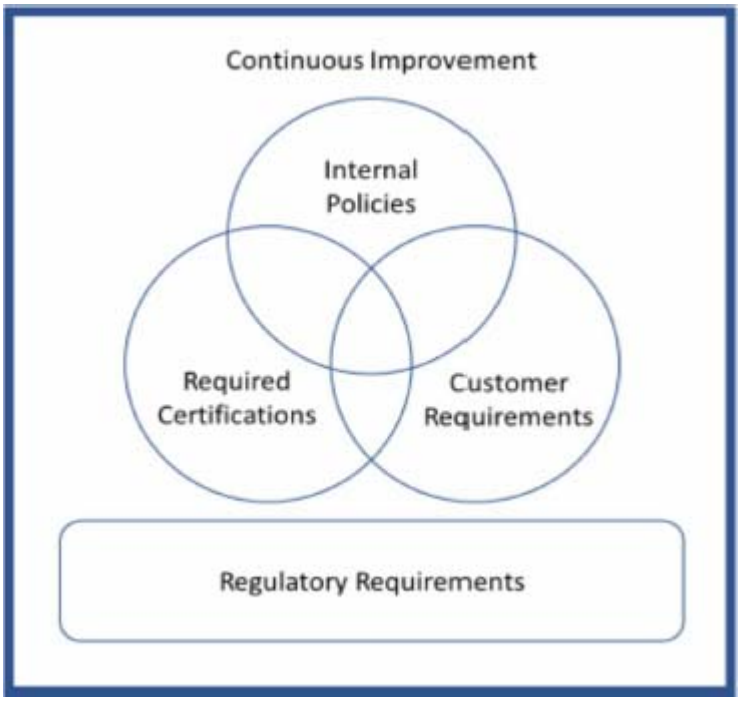

Figure 40.1. Factors to consider in developing an FSMS.

Role of Customer and Retailer Requirements

There is a distinction between customers and consumers. From the perspective of the manufacturer, consumers are the individuals who ultimately eat food products. Customers of a manufacturer may include retailers, such as grocery stores, convenience stores, club stores, and online marketers. Customers may also include food service operators and distributors as well as industrial users. In the current commercial environment, customer requirements play a role in the development of a food safety risk management system. Retailers have an intimate relationship with their customers (consumers) and play an active role in verifying that the products offered for sale meet the food safety and quality requirements of the consumers that they serve. While individual consumers are not able to set specific requirements, customers may set requirements as a part of doing business. Retailers have food safety and quality expectations of their suppliers and an associated verification

strategy. Retailer verification often includes an auditing component. In some cases, customers just accept recognized audit certification schemes. In others, customers have their own set of specific requirements. Finally, there are customers that want recognized certifications and have additional requirements. A manufacturer that supplies multiple customers will have to manage multiple sets of requirements and have a strong program in place to ensure compliance. An FSMS must take customer requirements into account and demonstrate compliance.

Role of Certifications

Nongovernment organizations that set standards for FSMSs provide a means for food production facilities to receive certifications from an independent source. These certifications can be used by the facility and customers to verify the facility has acceptable food safety procedures in place. In some regions of the world, food safety certifications are the price of entry into the business of supplying customers. The Global Food Safety Initiative (GFSI) is an example of a global FSMS certification program that has its roots in the retail sector. In 2000, the GFSI was established with a mission to provide continuous improvement in FSMSs and to ensure confidence in the delivery of safe food to consumers worldwide. There are multiple benchmarked schemes under the GFSI umbrella, including the British Retail Consortium, the Safety Quality Food (SQF) Institute, FSSC 2200, and several other organizations. In addition to informing companies of the elements of an FSMS, certifications can be a tool for manufacturers to demonstrate effectiveness of their FSMS to customers and regulators.

Role of Internal Policies

Policies provide the basis for governance of an entity such as a food company. Policies may not be needed for very small entities, but as an entity grows, at some point there will be a need for policies. Developing a standard set of rules and standards provides a framework for consistent operation. This is needed if there are

many facilities engaged in the production of food products. Even small entities can benefit from internal policies that help set the direction for safe food production.

Continuous Improvement

An FSMS is not a static set of programs and procedures. In Fig. 40.1, continuous improvement is presented as an overarching theme that should influence all aspects of an FSMS. The science of food safety continues to evolve, and new understanding of hazards should be reflected in all elements of the FSMS. In addition, food safety is generally considered a "precompetitive" activity. This allows the sharing of information across the industry. Large and small processors should be willing to allow others to learn from their mistakes. This sharing can help all processors improve. Any food safety event can damage the reputation of the category or whole industry. Therefore, sharing will have a positive impact on the industry by helping to build trust with customers and consumers.

Summary

When food safety risk management systems are discussed, it may be easy to think only about HACCP. HACCP is a tool used around the globe by companies that are committed to producing safe food. While HACCP may be the central tool for food safety, there are several other programs that also play a role in the overall food safety risk management system. The overall system also needs to address the details of programs such as approval of vendors, auditing of facilities, prerequisite programs, and traceability and recall procedures.

In this chapter, we provide an overview of the most important elements of effective food safety risk management systems. The detailed development and execution of these key elements may vary based on the intrinsic and extrinsic factors that apply to any specific food and production system. In addition, we use case studies as examples of approaches to food safety risk management systems.

The activities of Company X are fictional, but the examples are based on real activities and incidents that have occurred in the food industry.

RISK ANALYSIS FOR FOOD SAFETY

This chapter focuses on management systems for food safety. Ultimately, any operation engaged in producing foods should understand the risks associated with food. Before we introduce some key elements of an FSMS, it is important to emphasize that an FSMS is a specific type of risk management system focused on food safety. Since risk management is critical to the FSMS, it is important to understand the concept of risk.

Risk is often described as the combination of the probability that a hazard may exist and the severity of that hazard. While risk is a stand-alone term, it is implied that risks are balanced by benefits. This definition can apply across a wide range of activities, including financial transactions, medical procedures, and personal safety measures. In the financial world, hazards are based on the money or wealth that may be gained or lost. Medical procedures have the potential for life-saving outcomes, but hazards may include severe negative consequences. In the modern world, daily activities such as driving a car and using machinery have significant benefits to the user, but also include hazards such as personal harm. In the world of food production, we think of biological, chemical, and physical hazards.

This book focuses on biological hazards, and therefore, this chapter focuses on the risk analysis of biological hazards in food production. Risk analysis is composed of the following separate but linked elements: risk assessment, risk management, and risk communication (4). It is the risk assessment that informs the risk management decisions. Risk communication is the interaction and exchange of information between groups doing risk assessment and risk management.

Risk assessment is focused on the inherent or intrinsic risks that exist for food ingredients and finished products. These risks may be impacted by many factors, including the ability of pathogens to survive growth in a product or ingredient and the intended consumer population for a product. Risk managers need to decide what is an acceptable level of risk, acknowledging that even after risk management is applied, there is still some residual risk.

To simplify the risk equation, in dealing with microbiological risk, we know that, by definition, if a microorganism is a pathogen, it can cause illness. While some illnesses are more severe than others, people and companies that produce food should not be willing to accept any illnesses. Therefore, severity of the hazard is generally fixed.

Due to this approach, risk assessment and risk management are focused on the probability of a hazard being present and on ways to significantly reduce that probability. This is the foundation for building an FSMS.

Case Study—Risk Assessment

Company X sells fresh vegetables, frozen vegetables, and canned vegetables. The product format, pathogens of concern, and mitigation strategies are summarized in Table 40.1.

Vegetables are agricultural products and in the raw state are known to harbor a variety of pathogens. It is known that nonsporeformers such as *Salmonella*, *Escherichia coli*, and *Listeria monocytogenes* are likely to be present at some level. Sporeformers such as *Clostridium botulinum* are also potentially present. In addition, viruses such as hepatitis A virus may be present due to contaminated water and workers. While it is easy to identify the hazards, talking about risk gets a little more complicated.

Fresh vegetables may be sold as ready to eat (RTE) (e.g., lettuce, carrots, and tomatoes) or not normally RTE (potatoes). Risk management for RTE fresh vegetables starts with good agricultural practices, and for some commodities, washing and sanitizing may occur. Fresh vegetables can be considered a high-risk category for pathogens such as *E. coli* and viruses.

Most frozen vegetables are blanched prior to freezing. Blanching was originally designed to stop enzyme activity, but blanching is a heating step and can provide a reduction of pathogens. However, freezers have been shown to harbor *L. monocytogenes*, so risk management plans may focus on validated blanching and the exclusion of *Listeria* in the postblanching environment.

Canned vegetables go through a heating step that easily reduces the nonsporeformers and viruses to an acceptable level. Sporeformers such as *C. botulinum* are much harder to kill with heat. If these sporeformers are not killed, they may easily grow in the anaerobic environment of a can. Underprocessed cans of vegetables are likely to injure or kill many people. Therefore, the rigor of risk management is significant.

Table 40.1. Summary of vegetable case study

Consumer format	Pathogens of concern	Risk mitigation strategy
Fresh, refrigerated	*Salmonella*, *E. coli*, *L. monocytogenes*	Good agricultural practices; washing and sanitizing; finished-product testing
Frozen	*Salmonella, E. coli, L. monocytogenes*	Blanching; environmental control postblanching
Canned	*C. botulinum*	Validated and verified process for low-acid canned food

This case study demonstrates that risk assessment includes much more than just being aware of the pathogens that might be present in a particular agricultural product. It also important to know how the food will be processed and used by consumers to be able to fully understand how to implement a food safety risk mitigation system.

Risk Assessment across the Supply Chain

When a food product is at the concept stage, it is time for the first risk assessment. Even before the first prototype is made, it is likely that there is a vision for the finished product. There are several initial questions that should help inform a preoperational risk assessment.

1. How will the product be distributed and sold? (At ambient temperature, refrigerated, or frozen?)
2. Will the finished product support the growth of pathogens?
    a. If not, how will this be accomplished?
        i. water activity
        ii. pH
        iii. antimicrobials

3. What are the key ingredients for the product? a. Do these ingredients present microbiological risks?

During this stage of product development, there may still be some unknowns, but answering these questions will help inform the early risk assessment and indicate the mitigations that will be needed. If possible, it may be useful to set some design parameters to build safety into the product during this stage of development.

Once the basics of the product have been determined, it is time to take the concept to a facility where the product can be made. The next level of risk assessment considers the processing conditions. In addition to the questions about the product, additional questions must be asked to inform on risk.

4. Are there any processing steps where microbial growth might occur?

5. Are there steps that will reduce or eliminate any microbial hazards?

6. How is the product packaged?

    a. Is there an opportunity for postprocess contamination?

The questions posed above should help align the details of the site HACCP plan and the FSMS. Up to this point, the risk assessment discussion has focused on the product and the process. Every effort is made to identify risks that are reasonably likely to occur and to design mitigation of those risks through the FSMS.

We must recognize that events may occur that will compromise the FSMS. When an event or incident occurs, risk assessment must be done to determine the impact of the event. When assessing impact (risk assessment), a qualified team must assess whether the event is significant and what the required action is. Required action can range from none to product reprocessing, product destruction, or product recall.

Case Study—Event Risk Assessment

Company X routinely tests finished product for the presence of *Salmonella* as a verification of their FSMS. The firm received a positive result limited to a 24-hour production code. The site conducted a robust investigation. As part of that investigation, the site learned that there was a roof leak on the day of the positive result. The roof leak had been identified and appropriate short-term mitigations had been put into place, including an environmental swab of the leak site. The leak site was determined to be near the product zone. Genetic analysis of the roof leak swab and the product isolate determined that the organisms isolated were a genetic match. The final investigation showed that the roof leak was over the product zone and that the leaked material had made its way into the product zone. In this case, product testing was successful at identifying an issue and preventing the release of potentially contaminated product into commerce.

A new roof leak emerged at Company X. In this case, the roof leak was located away from the product zone and the product zone was protected with shielding. The firm tested samples from the roof leak, and all samples were negative for *Salmonella*. Finished product samples were also negative for that day. Appropriate investigation and mitigation were conducted in response to the roof leak, and no impact on public health was anticipated.

This case study illustrates the importance of having the following programs in place:

- procedures for identification, remediation, and mitigation of roof leaks
- corrective action response plans for finished product positive results
- appropriate sampling plans

KEY ELEMENTS OF EFFECTIVE FSMSS

An effective FSMS contains several key elements, including HACCP, preventive controls, prerequisite programs and environmental monitoring programs (EMPs), hygienic zoning, testing programs, consumer and customer feedback, traceability and recall, and documentation. In this section, we review the components and the importance of each key element.

Hazard Analysis and Critical Control Points

HACCP (pronounced “hassip”) is a simple and effective way to ensure food safety. It allows one to evaluate potential risks to food safety and to prevent them before they happen.

HACCP has its origins in collaboration between Pillsbury and NASA. In 1959, Pillsbury joined forces with NASA and began working on ensuring safe foods for astronauts. Howard Bauman, a trained microbiologist and Pillsbury’s lead scientist, and NASA’s Paul Lachance worked together to impose strict microbiological requirements, including pathogen limits, on all foods destined for space travel. Dr. Bauman and Dr. Lachance soon realized, however, that traditional quality control methods would be inadequate to guarantee the food’s safety. NASA’s further involvement stipulated the use of critical control points (CCPs), so it was a logical step to apply this same process to food manufacturing. Applying this concept to a food system was a new development and a NASA requirement.

During 1972, Pillsbury also established new internal specifications systems and training programs and hired research microbiologists to conduct the first hazard analyses and validations for the production of consumer products. The new systems and HACCP-based ingredient and product specifications were computerized and completed in 1975. Progressive food companies started recognizing the advantages of HACCP over traditional quality control

procedures in food safety management and began to adopt the HACCP system of food safety management.

A HACCP system has seven basic steps. Each one is necessary for the overall program to work.

1. Identify potential food safety hazards associated with ingredients and the manufacturing process (hazard analysis).
2. Identify CCPs—steps critical for food safety.
3. Set critical limits at CCPs.
4. Monitor CCPs—develop monitoring procedures.
5. Identify corrective actions.
6. Document and verify.
7. Conduct periodic audits to ensure that the HACCP system works properly.

More than 50 years later, HACCP continues to be the primary FSMS used globally to ensure the safe manufacture of food products. Implementation of effective HACCP programs allows manufacturers to proactively identify and manage food safety risks, prioritize resources where most impactful, and demonstrate regulatory compliance for food safety.

Preventive Controls

The FSMA introduced the term “preventive controls” to the food safety framework. Preventive controls are defined by the FDA as steps taken by a food manufacturer to reduce or eliminate food safety hazards. Examples of preventive controls include processing controls, allergen controls, sanitation controls, and other controls.

Prerequisite Programs

HACCP programs will not be successful without the successful implementation and execution of prerequisite programs.

Prerequisite programs are foundational programs that are not specific to a product or a manufacturing process. Example prerequisite programs include good manufacturing practices (GMPs), sanitation, allergen control, raw-material management, pest control, maintenance, foreign-material control, and others as appropriate. Prerequisite programs are covered in detail in other sources, so we cover just a few in this chapter.

GMPs

GMPs are the minimum requirements to produce safe foods. GMPs form the foundation for standard procedures for dealing with people, buildings, equipment, and documentation for food safety and quality.

Sanitation Programs

Sanitation programs are foundational programs for establishing and maintaining the hygienic conditions necessary to produce safe food and to maintain quality attributes of that food. Robust sanitation programs enable a manufacturing facility to manage hygiene, pest, microbiological, and allergen risks. Sanitation programs take into consideration equipment product contact surfaces, equipment non-product contact surfaces, the processing environment (floors, walls, drains, etc.), facility and equipment design, and janitorial activities.

Sanitation activities typically include a combination of cleaning activities, which remove the food debris, and sanitization activities, which serve to decrease microbial populations. Cleaning methods vary based on the equipment being used and the nature of the hazards that need to be controlled. Hazard controls may include control of microbial growth, reduction of spoilage microorganisms, pathogen elimination, allergen removal, pest control, and control for quality attributes. Cleaning methods include wet cleaning, dry cleaning, and a combination of wet and dry cleaning, sometimes referred to as controlled wet cleaning.

Wet cleaning uses a combination of water and cleaning chemicals to remove food residue and to return the food contact surfaces to a hygienic state. It is important to match the cleaning chemistry and cleaning method to the material being cleaned and the type of soil that needs to be removed. The use of appropriate cleaning chemistry facilitates the removal of organic materials and can decrease effort needed to effectively clean processing equipment. Conversely, the use of inappropriate cleaning chemistry may result in creation of challenging soils that are difficult to remove and potential increased risk. Wet cleaning is typically used for systems that produce high-water-activity or sticky products to control microbial and/or allergen risks. Types of wet cleaning methods include manual cleaning, clean-in-place methods, and clean-out-of-place methods. Regardless of method, all wet cleaning procedures include the critical elements included in Fig. 40.2. In addition, it is important to have the correct concentration of cleaning chemicals, the right temperature, for the right amount of time, and the appropriate mechanical action during the wash step.

- prerinse (removal of food debris)
- wash
    - concentration of cleaning chemicals
        - Detergent helps the removal of food from the equipment surfaces.
    - temperature
        - Cleaning chemicals have an optimal temperature for maximum effectiveness.
    - time
    - mechanical action
- rinse
    - removal of residual detergent and loose food debris

    - inspection for visible cleanliness
- sanitize
    - microbial destruction
    - System must be clean prior to application of sanitizer. Sanitizers are not effective on dirty surfaces.

Figure 40.2. Critical elements of a sanitation procedure.

Dry cleaning methods are best used for low-water-activity systems or dry systems where microbial growth is not a concern and the environment should be kept dry to prevent introduction of microbial risks. Dry cleaning methods use mechanical action to physically remove food residue from the processing lines. Dry cleaning methods may include the use of vacuum cleaners, scrapers, and brushes. High-pressure blasting and air hoses can be used; however, these methods are not effective at removing the food residue; rather, they relocate it to another part of the processing environment. An area that has been dry cleaned may not be shiny; however, it should meet the visually clean standard with little or no

remaining residue on the equipment. When allergen removal is a risk to be managed, dry cleaning effectiveness must be verified and validated to ensure that allergen removal was effective. Aqueous sanitizers are typically Not used after dry cleaning to prevent an increased microbiological risk. Some novel nonaqueous sanitizers are available on the market, and their use may add value to a dry cleaning system.

Regardless of cleaning methods utilized, the results of all sanitation activities should be monitored and verified for effectiveness. Monitoring activities may include measurement of sanitizer concentration, visual inspection, and analytical testing. Verification activities include a second level of visual inspection and document review. Periodic review of program documentation, records, and corrective actions can be useful in finding and eliminating potentially harmful trends.

Cleaning and sanitation are fundamental to the food safety system of a manufacturing facility. Effective cleaning is necessary before sanitizer application can be effective. Cleaning methods should be selected to best control the risks that are being managed.

Sanitation definitions

Below are some terms that are commonly used in discussing sanitation, with their definitions.

cleaning: the physical removal of organic material from processing equipment and the processing environment (Food Safety Preventive Controls Alliance [FSPCA] definition: the removal of soil, food residue, dirt, grease, or other objectionable material)

sanitizing: the destruction of microorganisms on previously cleaned surfaces. Sanitizing is different from disinfection. (FSPCA definition: adequately treating cleaned surfaces by a process that is effective in destroying vegetative cells of pathogens and in substantially reducing numbers of other undesirable microorganisms but without adversely impacting the product or its safety for consumers)

monitoring: a planned sequence of observations or measurements to assess whether a system or process is under control

verification: activities that determine whether a system is operating as intended

validation: the scientific process demonstrating that the system as designed can adequately control the identified hazards to produce a safe product

Environmental Monitoring Programs

EMPs are not generally considered prerequisite programs. EMPs are included in this section because of the important role that they play in the verification of the efficacy of sanitation and hygienic practices.

Every manufacturing facility has its own unique microbial population. Microorganisms are introduced to the processing environment via vectors such as ingredients, people, materials, and transport vehicles. GMPs and other control programs help in microbial control. EMPs play an important role in monitoring the processing environment for the presence or absence of microbial pathogens of concern. EMPs are designed to proactively find

potential sources of pathogens in the manufacturing environment. The best-designed programs leverage a seek and-destroy approach. Identification of potential sources of contamination allows a prudent manufacturer to mitigate and remediate before environmental pathogens can become established in the environment and potentially cross-contaminate product. It is important to note that an EMP that never yields a positive result is not a program to celebrate; rather, it is a program to reevaluate for effectiveness.

EMPs can be used to verify the adequacy of sanitation programs and to assess the potential for environmental pathogen contamination of RTE foods. EMPs are designed to monitor the pathogen pressure in the manufacturing environment and focus on finding and eliminating potential sources of contamination. Manufacturing environments are not sterile and are subject to constant change and influx of microflora from ingredients, materials, personnel traffic, equipment traffic, and transient equipment. Contaminating microorganisms are sometimes classified as either transient or resident microorganisms. Transient microorganisms do not persist or become established in the processing environment. It is expected that robust EMPs will find transient microbes periodically. Resident environmental pathogens become established in the processing environment and are challenging to remediate and eliminate. Resident environmental pathogens may persist in harborage points for long periods of time.

When an EMP is being designed, it helps to think of a manufacturing environment as having four zones, as defined by the International Commission on Microbiological Specifications for Foods and shown in Table 40.2 (5).

Once an environmental pathogen becomes established in the processing environment, remediation efforts must target identification of the root cause and elimination of the source of contamination via procedural changes, behavior changes, and potentially capital investment. Conventional wisdom would say that

finding and eliminating sources of contamination in zones 3 and 2 will decrease the likelihood of product contamination. This is illustrated in the following case study.

Table 40.2 Environmental monitoring zones

Zone	Definition	Example
1	Product contact surfaces	Conveyor belt surface
2	Non-product contact surfaces near product zone	Conveyor supports
3	Remote processing areas	Drains
4	Nonprocessing areas	Employee welfare areas

Case Study—EMP

Manufacturer X produces an RTE savory dip product. The facility performs a validated wet clean sanitation cycle every 24 hours. The facility environmental pathogen monitoring program is performed weekly, and samples are taken primarily in zones 2 and 3. One of the zone 3 samples, a drain swab, was positive for *Listeria* species. The facility investigated and reviewed the sanitation procedures. The root cause was determined to be an error in the sanitizer concentration. The drain swab being positive was an early indicator, and prompt action allowed the facility to identify the problem and remediate.

EMP Design Considerations

EMPs should not be statistically based. The programs should be biased to find potential sources of contamination. There is not a magic formula or a one-size-fits-all approach.

One of the first steps in developing an EMP is to determine what target organism to test for in a given facility environment. Environmental pathogens as defined by FDA include *L.*

monocytogenes and *Salmonella* species. *Listeria* species are recognized as an indicator organism for *L. monocytogenes*. Some manufacturers choose to test for *Listeria* species, as the test casts a wider net for locations where *L. monocytogenes* may grow. Processing conditions should be evaluated when one is deciding which organism(s) to test for. As a general rule, it is appropriate to test for *Salmonella* and *L. monocytogenes* in wet-cleaned processing environments. In dry environments, testing for *Salmonella* would be appropriate. In some cases, it is also appropriate to test for *L. monocytogenes* in dry processing environments.

Design principles for a robust EMP start with a "find it, fix it" approach. There are several factors that should be considered in advance of program development, and thoughtful development is critical to success. Factors that should be considered during plan development are listed in Table 40.3.

All positive results should be investigated and appropriate corrective action implemented. Understanding the sample details, such as sampling site, time of sampling, hygienic status, test organism, and site location, will aid in the investigation. Some examples of positive samples and possible explanations that should provide a starting point for investigation are listed below.

- positive postsanitation sample: sanitation protocol may not have been effective
- positive sample during production in raw processing area: either sanitation was not effective or raw ingredients are a source of contamination
- positive sample during production in postlethality, RTE-food processing area: cross-contamination, presence of a harborage site, or ineffective hygienic zoning

Routine sanitation programs should be effective at removing transient microorganisms before they become resident microorganisms. EMPs as a verification program are best

approached with a “find it, fix it” mentality, also known as “seek and destroy.” The purpose of EMPs is to find and eliminate environmental pathogens and any potential harborage points.

Hygienic Zoning

Sanitation, environmental monitoring, and hygienic zoning are three program elements that work together to ensure that processing facilities are designed, maintained, and monitored in a way that allows safe food to be produced.

Processors that manufacture RTE foods may employ hygienic zoning as a tool to reduce the risk of cross-contamination from raw processing areas to postlethality processing areas (Fig. 40.3). Hygienic zoning differs from zoning for environmental monitoring in that hygienic zoning differentiates facility hygiene requirements to minimize product cross-contamination, whereas zones in EMPs differentiate degrees of proximity to product contact surfaces. In an RTE-food processing facility, different areas, such as nonmanufacturing, basic GMP, transition, primary pathogen control, and sensitive high hygiene, have different hygiene requirements based on the risk of potentially contaminating product. Examples of nonmanufacturing areas include employee comfort areas, offices, and maintenance areas. Examples of basic GMP areas include raw-food, receiving, and warehousing areas. Examples of transition areas include locker rooms. Examples of primary pathogen control areas include postlethality processing areas, open product zones, and final packaging areas. Examples of sensitive high-hygiene areas include areas where food for at-risk populations is manufactured.

Table 40.3. Key elements to consider when designing an EMP

Element	Example or comment(s)
Processing area	Processing area, warehouse, packaging area
Sanitation method	Wet, dry, controlled wet
Hygienic zone	RTE, not RTE
Sampling sites Where to sample	Zones 4, 3, 2, 1
Site selection	Random sites, fixed sites, rotating sites, investigational sites
Quantity	Defined in advance
When to sample	After sanitation, at production startup, during production, at end of cycle
Target organism	*Listeria* spp., *L. monocytogenes*, *Salmonella*, quality indicators
Testing frequency	Daily, weekly, monthly, periodically
Reaction to positive results	Action plan defined in advance

Hygienic zoning tools include color-coded maps that detail hygiene zones and expected traffic patterns (Fig. 40.4). Color-coded employee uniforms, dedicated footwear, and controls for entry into primary pathogen control areas are useful for the success of hygienic zoning.

Testing Programs

Testing programs can provide valuable data and insights into the quality and safety of food products. Before any testing program (microbiological, chemical, or physical) is implemented, it is important to clearly understand the purpose of the test, to know how to interpret test results, and to understand the implications of an out-of-tolerance result.

Microbiological testing can be a strong verification tool for a well-managed food safety system; however, microbiological testing of finished food products is not a feasible tool to ensure food safety. Test results can provide valuable information; however, it is important to understand the statistical nature of the sample plan and appropriate interpretation of results. Some important limitations of finished product microbiological testing include the facts that microbiological testing is destructive and that test results are limited to the sample tested. What this means is that in order to ensure that 100% of the product is pathogen free, all product must be destructively tested.

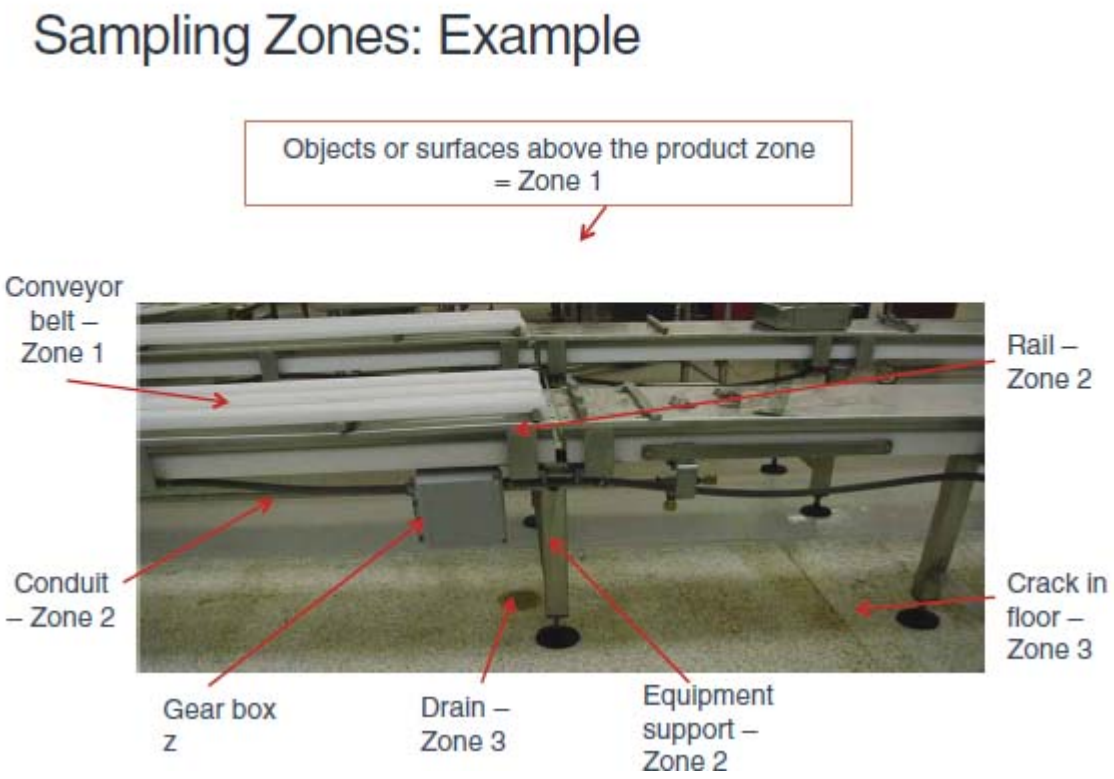

Figure 40.3. Examples of EMP zones using a single piece of equipment. This picture provides some examples. Surfaces above this conveyor belt and the conveyor belt itself are zone 1. The conduit below the belt, the gear box, equipment support leg, and rail adjacent to the belt are zone 2. The drain and the crack in the floor are zone 3.

Case Study—Finished-Product Microbiological Testing

Company X manufactures RTE rice-based meals for airline catering. The firm has a comprehensive FSMS that includes microbiological testing of finished products. Each lot produced is tested for the presence of *Salmonella* and *Bacillus cereus*. Any sample that tests positive is destroyed. All product associated with the sample that tested positive is also destroyed. The firm also has an investigative procedure that is performed any time a positive result is obtained. The firm will sample additional product as part of the investigation. It is important to note that the additional data can be used to guide the investigation; however, negative results cannot be used to negate the initial positive results.

Role of Auditing—Trust but Verify

Auditing plays an essential role in ensuring that FSMSs are functioning as expected and that employees are following expected food safety practices and behaviors. Audits can be an effective way to test the FSMS and to identify improvement opportunities. Just as testing results reflect the sample tested and not necessarily the entire lot produced, audit results are reflective of the point in time at which the audit was performed. Audit results, like test results, are a snapshot. Effective and successful audits rely on three components: (i) a trained, skilled, objective auditor, (ii) transparency and openness on the part of the auditee, and (iii) a clear robust standard and scope to be audited against.

A layered approach to auditing can be an effective approach to verifying FSMSs and fostering an environment of continuous improvement. A layered approach may include a combination of self-audits (first-party audits), second-party audits, third-party audits, customer audits, and regulatory audits. Self-audits are usually performed on a regular basis (e.g., monthly) by a crossfunctional team from the manufacturing location. The purpose is to evaluate the execution of programs against program requirements and directly observe the performance of food safety-critical tasks. Self-audits also provide an opportunity to connect

with employees on the manufacturing shop floor. Internal audits can also be performed by an internal audit team that is not connected to the manufacturing facility. Second-party audits are often used to assess suppliers and manufacturing partners. Third-party audits are audits contracted out to an independent third-party audit provider. Third-party audits can also result in a certificate which can be shared with customers, retailers, and regulators.

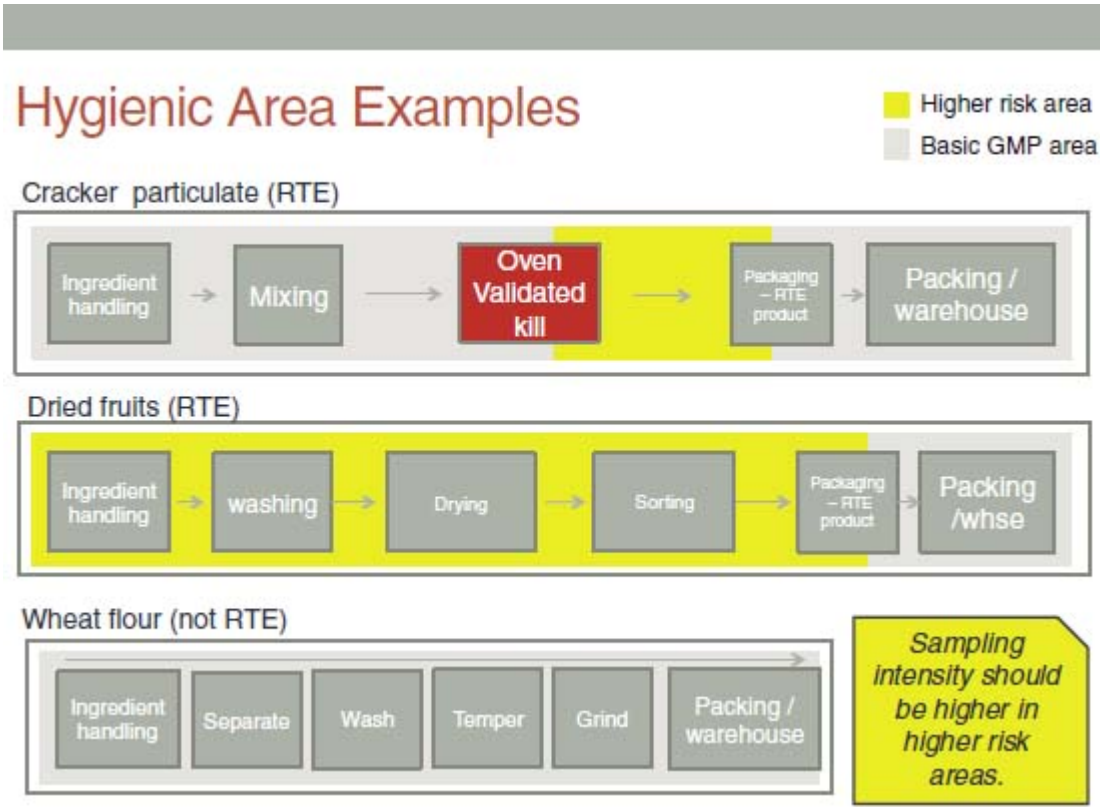

Figure 40.4. Hygiene area site selection. Shown are examples of hygienic area designations in three generic process flows. The yellow background indicates an area of high hygiene risk, and the gray background indicates a basic GMP area. (Top) In the cracker (RTE) production process, the cooking step is a validated kill step, so areas prior to the cooker are considered basic GMP areas. After the cooker, but before packaging, the product is exposed and susceptible to contamination from the environment, so this area is considered a high-risk area. After packaging, the product is no longer exposed, so this area is a basic GMP area. (Middle) In a dried-fruit production process, there is no lethality step and the product is RTE. Therefore, the entire line before packaging is a high-risk area. (iii) In a wheat flour (non-RTE) production line, the entire line is a basic GMP area because there is no RTE product. Sampling intensity should be higher in high-risk areas than in basic GMP areas to distribute verification resources in alignment with risk.

Consumer and Customer Contacts

Food manufacturers should have a way to get feedback from consumers and customers. The most common methods for feedback are the use of toll-free phone numbers and websites. In addition, the role of social media continues to evolve, and it has become a forum for consumers to share their experiences with a product. Monitoring of social media should be considered as part of developing an effective consumer contact system. Customer feedback can be both positive and negative. In a food safety risk management system, negative feedback or complaints are an important source of data.

The consumer contact system should be designed to align with the size and complexity of the food producer. Any complaints that suggest a food safety issue need to be reviewed. This can be very complicated. The system should be set up to collect the critical information needed to properly investigate an issue. The information should include a number of important details (Table 40.4). The product name, size, and code date are the most important pieces of information for investigating potential issues. Any illnesses, reactions, and incidents of physical hazards should be evaluated for the need of further review.

Each company should set up a standard operating procedure for the review of complaints alleging foodborne illness or physical harm. Common standards might include investigating all cases of alleged allergic reactions.

Table 40.4. Key information to collect for consumer and customer complaints

Product name
Package size
Code date
Date of purchase
Location of purchase
Date of consumption
Details of the issue/reaction

Case Study—Consumer Feedback

Company X produces dry, RTE snacks. Each consumer unit includes a toll-free number for consumers to reach a voice mailbox to provide feedback. Each day, all consumer contacts are categorized and entered into a database. Alleged illnesses and injuries are reviewed daily by a trained specialist. Company X sells a high volume of product and has a protocol that escalates the investigation of any alleged allergic reaction or any two alleged illnesses that are recorded over a 1-month time frame. The escalation process includes additional review by a senior food safety specialist familiar with the operation of the processes for the specific product. The investigation may include review of production records and requests for follow-up with the consumer if possible.

Traceability and Recall

Food traceability is important for food manufacturers, and increased transparency is expected by customers and consumers. Understanding the journey food takes from the farm to the consumer's eating experience can impact quality, food safety, and social responsibility. At a minimum, a manufacturer must be able to trace one level forward and one level backward. This means that a

manufacturer must be able to trace any product back to the lot codes of ingredients used and be able to trace product delivery to customers or consumers (when sold directly).

Digital technology can be used to simplify the traceability exercise and can be used to encode product information such as farm locations, harvest date, lot code, transportation journey, processing lot code, and final product distribution. All these data can be shared with consumers to aid in purchase decisions.

It is considered best practice to test the functionality of a traceability program on a regular basis. Mock recalls allow manufacturers to error-proof this traceability program and to assess procedure robustness and efficacy in tracing product one step forward and one step backward in the absence of a food safety incident. Data and insights gained from the mock-recall process can provide valuable insights and allow program improvements. Mock-recall exercises should be designed to challenge the systems as opposed to setting up the participants for success.

Documentation and Records

Documentation management can be considered the backbone of an effective FSMS. A predefined document control procedure will help ensure that appropriate processes are followed, the correct forms are completed, data are reviewed, and follow-up occurs as necessary. Review of critical paperwork should take place in a timely manner to ensure that the processing records clearly indicate that the food was produced within the framework of the established HACCP or food safety plan. A good rule of thumb is that anything that is not recorded, never happened. Whatever is documented, happened exactly in the way that it was written down.

CULTURE AND MANAGEMENT COMMITMENT

In the last decade or so, the concept of food safety culture has emerged as a potential risk factor beyond the traditional hazards and risks known in the food industry. Achieving a consistent, well-functioning food safety system requires commitment of people throughout an organization that produces food (6).

Culture is defined as an unwritten set of values, shared assumptions, and behaviors that are acted upon by both management and employees in any organization. Food safety culture is the subset of these values, shared assumptions, and behaviors that apply to the important issues related to food safety. All organizations have a culture. In some cases, the culture is positive and fosters the right behaviors and practices at all levels within an organization. That statement clearly implies that there are also cultures that foster the wrong behaviors.

Since the study of food safety culture is a relatively new area, it is still not clear how to move an organization from a bad culture to a good culture. While there are few data in this area, it seems reasonable that organizations that have a strong ethical foundation are likely to be able to have a strong food safety culture. However, ethics alone will not achieve all the right behaviors. There are very specific technical aspects of the processes that ensure food safety.

In addition to strong ethics, there must also be a culture of learning and continuous improvement. Together, ethics, learning, and continuous improvement are likely to result in a very strong food safety culture. In larger organizations, the people managing the organization are not likely to be involved in the day-to-day production of food products. Those managers must have an appreciation of what is needed to produce safe foods, so they can ask the right questions and allow money to be spent in the right areas. People involved in the direct production of food need to know the what and why of basic food safety. More importantly, they need to have the power to ask questions and challenge assumptions. In simple terms, they need to know that they can stop the line when something is not right.

EMERGING TRENDS AND TOOLS IN FOOD SAFETY

Rapid Microbiological Methods

Traditional microbiological testing methods are very slow and often require several days to complete. The development of rapid methods is not an emerging trend, and it is likely to continue until results can be achieved in near-real time. The movement from culture-based methods to newer technologies such as enzyme-linked immunosorbent assays and PCR has been evolving for decades. This trend has not slowed. Advancements in enrichment media, concentration techniques, and improved sensors have taken rapid methods to new speeds. Methods that required several days a decade ago can now be done in less than 24 hours. New and improved methods will continue to be developed and introduced into the market. It is important to understand that all methods must be validated against current standards and for the food matrix where they will be used.

Strain Characterization—WGS

In 1996, the U.S. CDC formally launched PulseNet. This approach to foodborne illness investigation radically improves the ability of public health officials to identify and stop outbreaks of foodborne illness. It has been estimated that PulseNet prevents more than 270,000 illnesses in the United States annually (7).

PulseNet relied on pulsed-field gel electrophoresis (PFGE) to characterize pathogens from clinical isolates, food sample isolates, and facility environmental isolates. While PFGE was very successful, new methods have been developed to identify and characterize isolate strains. Sequencing the whole genome can provide much greater differentiation of strains than PFGE. Sequencing methods have become easier and cheaper, and whole-genome sequencing (WGS) (or next-generation sequencing) has

emerged as an even more powerful technology for foodborne-illness surveillance.

The role of WGS in food production is still evolving. It is clear that an FSMS should include environmental monitoring as a verification of sanitation. When positive samples are found in the environment of a food production facility, it is important to understand whether the organism is transient or is an established population. Characterizing the isolate and comparing the data to historical information from the facility is the best way to determine if there is an established population present.

WGS is the most powerful technology available to characterize strains. There are other technologies, such as PFGE, ribotyping, and 16S rRNA gene sequencing techniques, available for the characterization of strains, but these technologies have less power to discriminate strains compared to WGS. It is likely that strain characterization will continue to emerge as an important technology, and companies should consider including strain characterization in the FSMS when pathogens are isolated from environmental and food samples.

Digital Technology and Traceability—Blockchain

Traceability continues to be a challenge across many sectors of the food industry. Slow and inaccurate traces are likely to put more consumers at risk for foodborne illness when events occur within the food industry. In addition, a lack of trust on the part of consumers regarding the source of ingredients can pose a challenge to the food industry. Technologies that allow more accurate, more rapid, and more transparent traceability will likely gain adoption across the industry.

One technology that is getting a lot of attention is blockchains. A blockchain can be described as a decentralized, distributed, and public digital ledger. The ledger is used to record transactions across many computers resulting in records that if altered retroactively

would trigger notification of the breach. Blockchain is the ledger technology used for cryptocurrencies such as Bitcoin.

The use of blockchain technology has been limited to pilot studies used to investigate the viability of this technology (8). Widespread adoption of blockchain or similar digital technologies is likely many years away.

SUMMARY

Producing safe food, all the time, must be a foundational goal for any individual or corporation in the business of making food. It is critical to understand the risks associated with food and take actions to mitigate those risks. FSMSs include multiple, interrelated elements that help to ensure that risks are mitigated to an acceptable level. GMPs and HACCP programs are key elements of an FSMS, but there are other elements based on policy and culture that are also important. A robust FSMS that is effectively implemented, continuously monitored, verified, and subject to continuous improvement is essential for the success of food manufacturers.

Microbiological Constraints for Use of Reclaimed and Reconditioned Water in Food Production and Processing Operations

Water is a vital component for living organisms, with humans meeting their daily requirements either by consuming it directly from freshwater sources or abstracting it from ingested foods. However, more than 4 billion people live in parts of the world where freshwater is scarce, and this scarcity threatens water security (1). In other parts of the world, there may be a mismatch between demand for and availability of water resources on a temporal scale, with water scarcity being observed more often in the summer months (2). Even in areas where water was recently considered plentiful, both climate and societal changes have been putting a strain on those resources (3). With regard to societal changes, population growth and accompanying economic development have led to competing demands for the finite water resource. The global shift in dietary preference from a vegetarian-based diet to a meat-based diet is another societal change that is also expected to lead to a higher water demand in the future (4).

Currently, on a global basis, agriculture, industry, and domestic households account for 76%, 15%, and 9% of the total freshwater withdrawals, respectively (5). Although withdrawals for irrigation constitute only 31% of the total in the United States (6), the state of California, having had an extended drought, has been forced to limit its agricultural water withdrawals (7). Therefore, to maximize existing water resources under these circumstances, two main steps have been taken by society and industry: water conservation and water reuse. This chapter focuses primarily on water reuse. As there have been many other terms used interchangeably with "reuse," Table 41.1 provides a list and definitions of those terms as well as other terms that arise from these endeavors.

On a global scale, reuse of wastewater is very low, representing only 0.59% of the total water used in 2011 (8). However, across the world, there are disparities in the amount reused by individual countries. For example, both Australia and the United States reused approximately 8% of their wastewater generated. In contrast, 16% and 30% of wastewater generated by Saudi Arabia and Singapore, respectively, was reused, whereas the countries of Israel and Cyprus reused 70% and 89%, respectively, of their domestically generated wastewater (6, 8). Disparities in efforts devoted to reuse of wastewater are also apparent within individual countries or continents. To exemplify this point, Spain and Italy jointly accounted for about 60% of the total European Union's treated wastewater reuse volume in 2006 (8). Moreover, within the United

States, it was estimated that in 2012, 90% of water reuse occurred in just four states, Arizona, California, Florida, and Texas, although other states, such as Nevada, Colorado, New Mexico, Virginia, Washington, and Oregon, were starting to increase their efforts to reuse water (6).

Table 41.1. Definitions of terms used to describe water status or the activities to alter that status

Term	Definition
Direct potable reclaimed water	Reclaimed water that is immediately added to the potable water distribution system and no further treatment is applied
Gray water	Wastewater arising from residential domestic sites that includes wastewater from sinks, showers, and laundry facilities but excludes toilet or urinal wastes
Indirect potable reclaimed water	Reclaimed water that is used to recharge groundwater aquifers or augment surface water reservoirs. The mix of reclaimed and "natural" source water receives additional treatment at a conventional treatment facility before distribution
Potable water	Water that is safe for drinking
Reused/reconditioned/reclaimed water	Wastewater or water used in a manufacturing/processing facility that is treated to reduce or eliminate microbiological, chemical, and physical contaminants that may then be used for an intended purpose
Recycled water	Water that is passed through the same series of processes, pipes, or vessels more than once (the water can be treated or untreated)
Wastewater	Water discharged from homes, businesses, and industries that enters either a septic or sewer system

At present, the dominant wastewater reuse applications worldwide are irrigation of agricultural lands, parks, and golf courses (9). Other reuse applications include groundwater recharge, industrial reuse, and urban uses other than as potable water. As for the potential to directly employ reused water as potable water, there are two main forces preventing wide-scale adoption of this application, including concerns regarding public opinion and the safety of the final product. These impediments are such that only a few small-scale facilities are practicing direct potable-water reuse in the United States (10). However, as potential evidence that such utilization does not jeopardize the health of the public consuming reused water, an operation based in

Windhoek, Namibia, has been mixing reclaimed water with conventionally treated water for potable reuse for over 45 years (11).

Although there are a host of environmental, economic, and social benefits associated with water reuse, there are also potential drawbacks. Hence, it is important to mention that while guidelines for reused water have traditionally focused on health protection measures, there is increasing recognition of the need to also ensure that the impact of reused-water applications on soils and groundwater is such that they are environmentally sustainable for the long term. To address this issue, factors to be considered are the salinity, alkalinity, and the presence of toxic ions in the reused water, as well as the hydraulic and nutrient loading rates. It is also acknowledged that the presence of chemical contaminants is a major concern with regard to the safety of these water sources. However, the focus of this chapter is on the microbiological risks to the health of individuals exposed either directly or indirectly to wastewater or different grades of reused water. Information and discussion pertaining to the presence of chemicals are included only when those chemicals affect the pathogens directly (i.e., antibiotic resistance) or indirectly (i.e., through modification of the indigenous competitive microflora).

MICROBIAL PATHOGENS OF CONCERN IN WATER

Microorganisms occur in every niche of the environment; however, a small proportion of microorganisms cause human diseases. When present in water, these pathogens can infect humans through skin and mucous membrane contact or through ingestion of contaminated water or consumption of food that has come into contact with contaminated water. Waterborne pathogens are differentiated into four groups: bacteria, viruses, protozoan parasites, and helminth parasites. Specific pathogens that may be found in each of these groups are listed in Table 41.2, along with the delineation of their relative infectivity and their ability to persist in untreated freshwater supplies (6).

This list of infectious microorganisms for which water serves as a transmission route is not exhaustive, and the complete list will continue to expand as our ability to detect and link specific isolates to human illness improves. In addition, another group of aquatic microorganisms that are not infectious but are of concern comprises aeromonads and cyanobacteria. Under conditions in which excess nutrients are present in the water systems, these organisms may multiply to densities at which they produce toxins in sufficient concentrations to adversely affect human health (12, 13).

Table 41.2. Waterborne pathogens and relevant characteristics associated with risk of causing human illness[a]

Pathogen group	Pathogen	Persistence in water supplies[b]	Relative infectivity[c]
Bacteria	*Burkholderia pseudomallei*	May multiply	Low
	Campylobacter jejuni, *C. coli*	Moderate	Moderate
	Escherichia coli, pathogenic[d]	Moderate	Low
	E. coli, enterohemorrhagic	Moderate	High
	Francisella tularensis	Long	High
	Legionella pneumophila	May multiply	Moderate
	Mycobacteria (nontuberculosis)	May multiply	Low
	Salmonella Typhi	Moderate	Low
	Salmonella enterica	May multiply	Low
	Shigella dysenteriae	Short	High
Viruses	Adenoviruses	Long	High
	Astroviruses	Long	High
	Enteroviruses	Long	High
	Hepatitis A virus	Long	High
	Hepatitis E virus	Long	High

[a] Adapted from Table 7.1 in reference 13.

[b] Detection period for infective stage in water at 20°C: short, up to 1 week; moderate, 1 week to 1 month; long, over 1 month.

[c] Based on experiments with human volunteers, epidemiological evidence, and experimental animals studies. Low, 104 organisms or particles; moderate, 102 to 104 organisms or particles; high, 1 to 102 organisms or particles.

[d] Includes enteropathogenic, enterotoxigenic, enteroinvasive, diffusely adherent, and enteroaggregative.

The primary source of waterborne pathogens is thought to be fecal pollution from humans and other animals, with transmission of disease being determined by the concentration of the pathogen and an individual's natural resistance (i.e., infectious dose). Prior to being imbibed or to contaminating food which is subsequently ingested by an individual, waterborne pathogens may travel a number of routes through the environment that include outfalls from sewage treatment plants, septic tanks, meat packing plants, and dairy waste lagoons. More diffuse sources of fecal contamination include storm runoff from urban and rural land that could transfer fecal matter from wildlife, domestic pets, and farm animals into surface waters. Given such a diverse range of sources of fecal contamination, contamination is watershed specific, although there are differences in the major groups of organisms that primarily contribute to disease in developed and developing nations. For example, in the United States, enteric viruses and protozoan parasites contribute to the majority of waterborne-illness outbreaks, whereas in developing countries where helminths are endemic, they are considered the major pathogens of concern in improperly reused and drinking water (14).

TREATMENTS EMPLOYED TO REDUCE OR ELIMINATE PATHOGENS FROM WATER

Given the large number of pathogens that could potentially be present in water, it is not surprising that there would be dramatic variations in their elimination from contaminated water, as they exhibit inherently different properties (e.g., size, nature of protective outer layers, and physicochemical surface properties). Hence, a variety of chemical, physical, and biological treatments are employed to treat contaminated water sources. In order of increasing treatment level, these include preliminary, primary, secondary, and tertiary (or advanced). Since the first three levels of treatment are actually considered water pollution control requirements (steps that would need to be taken regardless of any additional treatment), tertiary treatment is the distinguishing step for producing reused water (9). However, depending on the specific reuse application and associated water quality requirements, the degree of treatment required varies. Details as to the specific treatments that are currently employed to remove microbial contaminants are provided in the following sections, along with the effectiveness of each process. Treatments that are applied solely to remove organic contaminants are not covered. In any event, prior to establishing the treatment requirements that are to be applied for pathogen removal, an understanding of the pathogen occurrence in the untreated water source is essential. To accomplish this task, pathogen analysis should be conducted over a period of time, with care taken to include consideration of seasonal variation and storm events. When

the occurrence and distribution of human pathogens in a water source, such as wastewater, are not available, concentrations may be inferred from observational data on fecal concentrations that are being contributed to the wastewater.

Preliminary and Primary Treatments (Particulate Removal) Applied to Water

Chemical coagulation and flocculation with aluminum (2 to 5 mg/liter) or iron salts (4 to 10 mg/liter) are very important steps to remove colloidal particles and turbidity from wastewater (13). Such processes are known to aggregate wastewater constituents within the size ranging from 0.1 to 10 □m (15) by mechanisms of charge neutralization, adsorption, and entrapment (16–18). However, effective operation of the coagulation process does depend on an optimum coagulant dose that is a function of the raw water quality and pH (13).

Generally, sedimentation is applied prior to filtration to remove the bulk of the solids floc, with horizontal flow and floc blanket clarifiers being the most common forms applied. Alternatively, in dissolved-air flotation, fine air bubbles are dispersed into the floc. The solids within the floc then attach to the air bubbles, which float to the surface of the tank, where they are removed periodically as a layer of sludge. In general, coagulation and sedimentation is an ineffective process for *Cryptosporidium* removal. In support of this statement, there was only a 0.6- to 0.8-log removal when oocyst-seeded water was subjected to coagulation and sedimentation in bench-scale studies (19).

Table 41.3. Effectiveness of filtration for removal of pathogens from coagulant-treated water[a]

	Minimum–maximum reduction (log)	
Pathogen group	Slow sand filtration[b]	Rapid granular filtration[c]
Bacteria	2–6	0.2–4.4
Parasites	0.3–>5	0.4–3.3
Viruses	0.25–4	0–3.5

[a] Adapted from Table 7.7 in reference 13.

[b] Dependent on presence of schmutzdecke (biological film that develops on the surface of the filter), grain size, flow rate, and operating temperature and pH.

[c] Dependent on filter medium and coagulation pretreatment.

To improve the removal of microorganisms following coagulation and sedimentation, the treated water is then filtered (13). Two major types of filtration based upon residence time are used in wastewater facilities. Slow sand filtration is highly efficient for *Cryptosporidium parvum* removal (Table 41.3), with typical flow rates of 0.1 to 0.4 m3/m2 • h, using fine sand with an effective size of 0.15 to 0.4 mm. However, limitations in land requirements prevent many facilities in North America from using slow sand filtration. Alternatively, the majority of facilities operate rapid filtration

processes that require considerably less space. With flow rates of 5 to 30 m3/m2 • h through sand or multimedia with an effective size of 0.5 to 2 mm, rapid filtration is much less efficient than slow filtration for removal of parasites and other pathogens (20). The process, on the other hand, does remove nonmicrobial organic constituents that would otherwise reduce concentrations of disinfectant applied during secondary treatments.

Secondary Treatments (Disinfection) Applied to Water

Chlorine

An important component of many treatment regimens for removal of pathogens in water is chemical disinfection. As the most common type of chemical disinfectant, chlorine is typically applied at dosages ranging from 5 to 15 mg/liter, with a recommended exposure time of 30 min to 2 h (9). Applied either as liquefied chlorine gas, sodium hypochlorite solution, or calcium hypochlorite granules or through on-site chlorine generators (13), dissolution of chlorine in water forms hypochlorous acid (HOCl) and hypochlorite ion (OCl^-). Together, the concentrations of HOCl and OCl^- are termed free-chlorine concentrations. HOCl is a more effective biocide than OCl^- but dissociates into OCl^- at pH values greater than 7 (21). With respect to the mechanism of inactivation, chlorine reacts with both cell membrane components and nucleic acids, causing lysis and irreversible damage.

Three techniques of chlorination may be employed for disinfection. The first technique, termed breakpoint chlorination, is intended to provide a dose wherein there is sufficient chlorine to oxidize both microbial and non-microbial organic matter present in the water (designated chlorine demand) but leave a suitable amount of free residual chlorine to protect the water against reinfection from the point of chlorination to the point of use. Superchlorination followed by dechlorination also achieves the same objective as breakpoint chlorination in being able to oxidize all organic matter, but it does so with an excess of chlorine to rapidly achieve this result followed by reduction of the excess chlorine residual. The final method of chlorination, termed marginal chlorination, is typically applied to water supplies of high quality. In this method, chlorine is dosed to a desired level of free residual chlorine, as the chlorine demand is very low (13).

Regardless of the method used to achieve chlorination, the efficacy of chlorine and other chemical disinfectants is predicted based on knowledge of the residual concentration of disinfectant, temperature, pH, and contact time. This relationship is commonly referred to as the C_rT concept, where C_rT is the product of C_r (the residual concentration of disinfectant, measured in milligrams per liter) and T (the disinfectant contact time, measured in minutes). Therefore, a concentration of 1 mg/liter residual chlorine applied for 30 min corresponds to a C_rT value of 30 mg•min/liter (6).

An important characteristic of an effective disinfectant is the ability to persist in the system and protect against contamination that might occur at a later time. Consequently, to improve this property, ammonia may be added to the system, either concurrently with, prior to, or following chlorine addition to form monochloramines (NH_2Cl), dichloramines ($NHCl_2$), or trichloramines (NCl_3). Monochloramines are preferred and may be maximized by controlling the chlorine-to-ammonia ratio and pH (22). However, despite their persistence, chloramines are not as potent a disinfectant as free chlorine, as evidenced by the observation that a C_rT for free chlorine outperforms the same C_rT for chloramines (6).

Disparities exist in the inactivation of pathogens by chlorine, with bacteria being the least resistant to chlorine, viruses being more resistant, and parasite ova and (oo)cysts being the most resistant. Even among viruses, there exists a wide variation in their susceptibility to free chlorine, with rotavirus being less resistant than hepatitis A virus, which in turn is less resistant than norovirus. For example, when human volunteers were used to measure infectivity of noroviruses, a 3.75-mg/liter dose of chlorine was effective against rotavirus but failed to inactivate norovirus. More importantly, concentrations commonly used in disinfecting drinking water failed to inactivate norovirus (23).

In contrast to bacteria and viruses, which are susceptible to chlorine, protozoan parasites are considered resistant. For example, the C_rT value for a 2-log inactivation of *C. parvum* by free chlorine is 7,200 mg•min/liter at pH 7 and 25°C (24). Moreover, the resistance of *Cryptosporidium*, *Giardia*, and *Cyclospora* to chemical disinfectants such as chlorine is consistent with the recovery of oocysts from drinking water treated at facilities performing properly (25–27). However, the limitations of chlorine for inactivation of protozoan parasites may be circumvented partially by applying a two-step disinfection process. For example, increasing levels of free chlorine pretreatment were shown to reduce the subsequent monochloramine concentration and/or contact time required for a given level of inactivation, thereby demonstrating synergism (28). Chlorine disinfection was also enhanced by the application of electroporation prior to the application of chlorine, creating pores in the walls of the organisms and thereby increasing the permeability of the organism to chlorine (29).

Application of higher chlorine doses to water is not a viable option to improve protozoan inactivation. Disinfection by-products, including trihalomethanes (THM), are formed between organic materials and chlorine, and these by-products pose risks of chemically induced cancer. To minimize their presence, regulations on maximum contaminant levels (MCL) are in force. The current MCL for total THM, the sum of the concentrations of chloroform, bromodichloromethane, dibromochloromethane, and bromoform, is 0.08 mg/liter (30). Interestingly, differences between groundwater and reclaimed water in their composition of dissolved organic matter (DOM) have been demonstrated. In native groundwater, DOM consists of natural fulvic acids, while DOM in reclaimed water is a mixture of aromatic sulfonates (degradation products from bacterial activity) and natural fulvic acids. DOM isolated from groundwater produced significant amounts of THM and total organic halogen, while

DOM in reclaimed water produced minimal amounts of THM and total organic halogen (31)

Chlorine Dioxide

Existing as an undissociated gas dissolved in water, chlorine dioxide (ClO_2) is a potent disinfectant. One shortcoming of this disinfectant, however, is its volatility: if it is left in an open tank, the concentration in solution will decrease slowly.

Penetrating the organism and reacting with vital amino acids in the cytoplasm to kill the organism, ClO_2 is generally considered to have a biocidal efficiency greater than that of free chlorine or monochloramine (32). Further, in contrast to aqueous chlorine, whose effectiveness decreases as pH increases from 6 to 9, the reactivity of aqueous ClO_2 does not change greatly from pH 6 to 8 and is only approximately 20 to 30% lower at pH 10 (32). As with other chemical disinfectants, inactivation with chlorine dioxide is dependent on temperature. In the case of *C. parvum*, C_rT requirements for inactivation were found to increase by an average factor of 3.4 for every 10°C decrease in temperature.

Chlorine dioxide is a relatively stable disinfectant and forms little or no halogenated by-products (33, 34). It does react with compounds such as humic and fulvic acids to form carboxylic acids and aldehydes in the parts-per-billion concentration range. However, the major inorganic by-product of the reaction of chlorine dioxide in water is chlorite, which poses no significant risk to human health.

Ozone

Another disinfection technology that is applied to water is ozone treatment. Although the mechanism of microbial inactivation by ozone is similar to that of chlorine, ozone is a more potent biocide than chlorine. In addition to reacting quickly with microbial and nonmicrobial substances in the water, another advantage of employing ozone as a disinfectant is that it is unaffected by the range of pH encountered in water treatments. However, ozone is applied to water as a gas, and volatilization losses make it difficult to maintain stable ozone levels under either laboratory or field conditions. Therefore, the performance of ozone operations relies on achieving the desired concentrations after a given contact period. Typically, a residual concentration of about 0.5 mg/liter after a contact time of up to 20 min is targeted. To achieve this target, application doses range from 2 to 5 mg/liter, with higher doses being needed for waters containing a high level of natural background organics (13). However, regardless of the applied dose, no residual ozone is present in the effluent, and therefore precautions must be taken to prevent recontamination.

Both bacteria and enteric viruses, including norovirus, are highly susceptible to ozone inactivation. For example, reductions of >3 log were achieved within 10 s when norovirus was exposed to 0.37 mg of ozone/liter at pH 7 and 5°C (35). More importantly, ozone is one of the few chemical oxidants capable of inactivating *C. parvum* under normal water treatment conditions, at least at warmer temperatures.

To exemplify the significance of temperature, the ozone inactivation rate constant for *C. parvum* decreased by a factor of 2.2 for every 10°C decrease in water temperature of laboratory waters, whereas in natural water, it decreased by a factor of 4.5 (36). Hence, the application of ozone to water by itself is not practical in cooler climates. Another factor that should be taken into account when the disinfection efficiency of ozone for protozoan parasites is estimated is the density of (oo)cysts. In a study conducted by Haas and Kaymak (37), when the initial microbial load was low, it was more difficult to achieve a given level of reduction than when it was high.

In addition to low temperatures, another obstacle to the use of ozone for disinfection purposes is the potential for the formation of bromate, a possible human carcinogen, when the raw water being treated contains bromide. Bromide concentrations greater than 50 g/liter may result in bromate formation at levels greater than the MCL of 10 g/liter. Bromate is particularly problematic because unlike many other organic by-products, it is not biodegraded in biological filters that usually follow an ozonation step. Treatment options to remedy this problem include ammonia addition, pH depression, hydrogen peroxide addition, hydroxyl radical scavenging, and scavenging or reduction of HOBr (38, 39). Ammonia interferes by reacting with HOBr, and even small ammonia concentrations show a positive effect. Unfortunately, the method is not efficient in waters that already contain medium to high levels of ammonia. Like ammonia, lowering the pH also acts to reduce the generation of bromate by shifting the $HOBr/OBr^-$ equilibrium towards HOBr. Once bromate is formed, however, its elimination is difficult, given that the most promising treatment, activated carbon filtration, had limited success in full-scale plants (38). Consequently, the potential for bromate generation and the diminished efficacy of ozone at low temperatures are likely factors that have contributed to the fact that only a limited number of commercial wastewater plants used ozone as their chemical disinfectant in the United States prior to 2010. However, it has been noted that there are several new ozone systems for wastewater disinfection under design, under construction, or recently put into operation as a result of improvements in ozone generation and dissolution technology (6).

Ferrate

Another oxidizing agent for disinfection processes that has generated a significant amount of interest is ferrate. Its chemistry results from the formation of iron in the plus-6 oxidation state (Fe^{6+}), but its key benefit is that by-product formation is minimized compared to that of chlorine. Although highly effective against bacteria and viruses, ferrate was projected to be less effective than ozone in the inactivation of protozoan parasites (40). Although recent advances have been made in on-site production of ferrate, making it more cost-effective, implementation of ferrate technology on a full scale has not occurred to date, due to difficulties associated with (i) the instability of ferrate, which is dependent on its method of preparation; (ii) the relatively low yield of ferrate; and (iii) the limited amount of research conducted to date demonstrating its capabilities and advantages over existing water and wastewater treatment methods (41).

UV Light

Since the early 1900s, UV light (wavelength between 180 and 320 nm) has been used to inactivate microorganisms in contaminated waters and is due to the absorption of UV photons by an organism's genomic DNA. While the damage does not kill the organism directly, it does result in the failure of the organism to reproduce and establish infection in the host.

There are several advantages to using UV as a disinfectant: (i) it is a physical process that does not rely on use of chemical additives, (ii) it requires relatively short contact times, and (iii) inactivation can occur without the formation of disinfection by-products. Although UV was believed to be an inadequate disinfectant against protozoa prior to 1998 (42), those initial findings were based on analytical methods, excystation and vital dye binding, that correlated poorly to animal infectivity assays. Since then, UV has proven to be highly effective in the inactivation of protozoa as it is for bacterial pathogens; however, adenoviruses, with their double-stranded DNA, are more resistant to UV disinfection, requiring ca.10 to 20 times the dose for the same degree of inactivation (Table 41.4) (43, 44). Given that UV doses commonly applied for water and wastewater treatment are between 30 and 40 mJ/cm2 (45), adenovirus would be projected to survive treatment.

Table 41.4. Comparison of effectiveness of UV disinfection for inactivation of several types of waterborne pathogens

Pathogen	UV dose (mJ/cm^2)	Log inactivation	Reference
C. parvum	10	2	48
	25	3	48
	2	1.5	167
	5	3	167
	3–9	3–3.5	168
Encephalitozoon intestinalis	6	>3.9	169
	9	4	169
Adenovirus type 40	103	2	170

UV disinfection performance and efficiency are impacted by two key water quality issues: the UV transmittance of the wastewater and the presence of particle-associated microorganisms. With both issues, particles (>10 μm) can shield microbes from UV light. Consequently, the effectiveness of UV light as a disinfectant is enhanced when water is filtered prior to disinfection by reducing the number of large particles with embedded and shielded microorganisms and by reducing the number of small particles that reduce UV light transmittance (6).

Another challenge with applying UV light as a disinfectant is the potential for photo repair of UV-inactivated microorganisms. Repair of UV-damaged cells has been observed when *Escherichia coli* was exposed to visible light (310 to 480 nm) (43). The

ability of bacteria to repair their damage may explain the ability of enterococci to survive the UV disinfection process and persist in biofilms of the distribution system in the absence of a chlorine residual (46). In contrast, when *C. parvum* was either exposed to fluorescent light or kept in darkness, UV-induced pyrimidine dimers in the DNA were continuously repaired; however, no recovery of animal infectivity was observed (47).

When compared on the basis of germicidal UV dose, there are no differences in inactivation of organisms treated with low- and medium-pressure UV radiation (48, 49). However, up to a decade ago, energy requirements and maintenance issues initially factored into their selection for small- and large-scale water systems, with small water systems favoring low-pressure lamps that had twice the germicidal efficiency (UV dose delivery per watt of input power) of medium-pressure lamps and large systems favoring the medium-pressure lamps, as less maintenance was involved because fewer lamps were required. Fortunately, in the past decade, substantial advances have been made in the UV industry with the development of low-pressure but high-output UV systems and microwave UV systems. These innovations allow installation of UV systems with reasonable energy use values, so that they are now more affordable than water systems employing sodium hypochlorite (6).

Another disinfection method of wastewater that has proven effective is exposure of the water to solar radiation, termed solar water disinfection. This method initially consisted of placing water in transparent plastic or glass containers which were then exposed to the sun from 6 to 48 h, depending on the intensity of the sunlight and pathogen sensitivity. In this case, the mechanism associated with germicidal activity was UV radiation, but this was supplemented by thermal heating of the water by solar light. As with exposure to UV radiation alone, waterborne pathogenic bacteria and protozoan parasites are inactivated extensively if not completely, whereas indications are that viral pathogens are more resistant to solar disinfection (50). Although its small scale limited its applications initially, significant efforts have been made to scale up the process using both static and flow-through systems. Consequently, as a result of its continued simplicity and low cost, the method is in daily use throughout the developing world (Asia, Latin America, and Africa) (50).

Multiple Disinfectants

In several disinfectant processes (i.e., ozone and UV light), no residual disinfectant is present in the treated water, and hence, regrowth of pathogens may occur. In those instances, many drinking water systems also apply chlorine or monochloramine to provide protection in the distribution system after primary disinfection has occurred. Surprisingly, the inactivation kinetics of *C. parvum* oocysts with these secondary agents after ozone pretreatment were shown to be significantly faster than the kinetics with free chlorine and monochloramine alone. For example, rates of secondary inactivation were 1.1 to 2.8 (chlorine) and 2.4 to 9.2 (monochloramine) times higher than the rates of corresponding primary inactivation with these agents at 30 and 10°C, respectively (51). Given that ozone is relatively ineffective for

inactivating *C. parvum* at low temperatures (see “Ozone” above), sequential disinfection with ozone plus monochloramine or ozone plus chlorine during winter in regions in which the water temperature is low may be a viable approach.

Other disinfectant treatments applied sequentially or in tandem have also proven to be synergistic in their inactivation of pathogens. For example, inactivation of *Giardia* was much greater when disinfection with chlorine and UV light was applied sequentially to wastewater (52). Similarly, enhanced inactivation of UV-resistant adenovirus was obtained when 10 mg/liter hydrogen peroxide was added to either ground or surface waters treated with UV light (53). Application of low concentrations of chlorine (1.5 mg/liter) was also beneficial in effectively inhibiting the photoreactivation of *E. coli* exposed to UV light (54).

Tertiary Treatments

Membrane Treatments Applied to Disinfected Water

Increased emphasis on improving treatments for reuse has led to major research efforts being undertaken and to the development of commercial membranes (thin films separating two phases and acting as selective barriers) for removal of microorganisms, trace organic substances, specific ions, and dissolved solids (9). Filter types used for removal of microbial contaminants along with pore sizes are listed in Table 41.5.

Table 41.5. Membrane filter type characteristics[a]

Filter type	Nominal pore size (μm)	Microbial contaminants targeted for removal
Microfiltration	0.05	Some protozoan (oo)cysts, bacteria, and viruses
Ultrafiltration	0.002–0.050	Most bacteria and some viruses
Nanofiltration	<0.002	Some viruses
Reverse osmosis	<0.002	Some viruses

[a] Adapted from Table 6-6 in reference 6.

To drive the separation and removal of microbial contaminants and other organic macromolecules/colloids, pressure is generally used, with the pressure and associated energy requirements increasing as the pore size decreases. Consequently, in striving to make these membranes more economical or provide better value, manufacturers of membranes are constantly developing new filtration technologies or modifying their existing technologies to improve filter performance by increasing the hydraulic loading rates or increasing water quality (55). Another issue that both manufacturers and users should be cognizant of is membrane integrity. Scanning electron microscopy showed that gaps or pores present in reverse osmosis membranes were

sufficiently large for MS2 viruses to pass through and were responsible for the observed variability in virus removal (56). Hence, to minimize the impact of any manufacturing defects or variability in membrane pore sizes, it is critical that water systems employ a multibarrier approach in their operations.

For water disinfection using membranes, it was long assumed that the most critical parameter is the pore size. More recently, it was shown that pore size can be greater than the particle size for significant retention, as both sieve retention and adsorption sequestration play a role in particulate removal (57). In the case of viruses, removal is greatest at pH values approaching the isoelectric point (pI) where their equal distribution of positive and negative sites leads to a maximum virus-virus coagulation and increases the size of the particle and potential for rejection. In natural environments, however, many different types of viruses are present and their pIs can vary over a broad range. Under these conditions, when viruses are in mixed environments, they tend to coagulate not only with the same virus but also with different viruses (58).

Fouling in membrane treatment systems represents one of the most significant barriers to their more widespread implementation in both municipal and industrial wastewater treatment facilities (55). Four key factors impact or contribute to fouling, most of which are interrelated: (i) process configuration; (ii) membrane material and configuration (or geometry); (iii) process operation, including system hydrodynamics; and (iv) biomass concentration and composition. Membrane fouling may be physical, inorganic, organic, or biological. To alleviate or minimize fouling by suspended solids, pretreating the source to reduce its particulate density is the first recommended course of action. The second course of action is to operate below the so-called “critical flux,” and this level may be increased by more vigorous aeration and/or by periodic backflushing. It is important to keep in mind that limited amounts of fouling may serve to also strain the aqueous solution and thus remove organisms that are smaller than the membrane’s pore size (59).

Application of Water to Systems (Wetlands, Lagoons, and Soil) for Biological Inactivation of Pathogens

Constructed wetlands and lagoons represent low-cost biological systems that have been documented to reduce microbial loads of wastewaters (60). The primary outlets for water reclaimed through such systems have been mainly agricultural and landscape irrigation, groundwater recharge, indirect reuse as potable water, and environmental reuse. In these systems, biodegradation of organic materials and pathogen reduction are intricately connected to the interactions of the various organisms making up the biological community. Biological factors influencing survival of pathogens include natural die-off due to starvation and competition with other microorganisms, predation by microinvertebrates, and the microbicidal effects of toxins, antibiotics, and enzymes produced by organisms in the biological community. Constructed wetlands also utilize the additional biological activity of plants. By providing additional surface area for microbial growth, plants increase

microbiological activity and thus improve the biological reaction hydraulics. In addition, the oxygen released into the subsurface by wetland plants is used for subsurface aerobic metabolism and nitrification-denitrification (61).

Constructed wetlands exhibit characteristics that are similar to those of natural wetlands in that they support similar vegetation and microbes. However, with both natural and constructed wetlands, design and operation may limit their effectiveness. In the first place, the water being treated must reside within the wetland long enough for the biological activities to have a noticeable effect. Thus, when a stabilization pond with a high retention time was used to treat water, up to 100% of *Giardia* cysts were removed when the initial concentrations ranged from 0.23 to 100,000 cysts/liter (62). In contrast, removal of pathogens (*Cryptosporidium* spp., *Giardia duodenalis*, and microsporidia) was significantly lower in constructed wetlands with free-surface flow than wetlands constructed with subsurface flow, as the former did not provide sufficient time for remediation (63). Another critical component for efficient operation of lagoons or stabilization pond systems is removal of sludge buildup. In the absence of this maintenance task, the removal of helminths was overestimated (64). The last two limitations to biological systems are that they operate in uncontrolled environments where seasonal effects have been shown to affect attenuation of *Cryptosporidium* oocysts in lagoon systems (65) and that wildlife has been shown to contribute a substantial load of pathogens to wetlands (63).

Soil aquifer treatment systems are another low-technology system; wastewater is applied to basins of soil consisting of layers of loam, sand, gravel, silt, and clay. Such systems are coarse enough to allow sufficient infiltration rates but fine enough to provide adequate filtration. During this process, resident pathogens may be removed from the water stream by straining or adsorption, with subsequent inactivation occurring via desiccation stress or indigenous microbial activity. In the case of viruses, adsorption is considered the major mechanism affecting their survival and transport, which in turn is affected by the soil's pH, organic matter content, aeration level, soil structure and texture, soil surface charge, soil porosity, and virus size and surface charge (66). For instance, viruses with higher isoelectric points consistently correspond with increased adsorption. Also, soils with high isoelectric points, such as most clay types, have been shown to be better virus adsorbers than those with low isoelectric points, such as most of the sands. In contrast, high levels of organic and surfactant in water will reduce virus adsorption by competing with the virus for binding sites (67). However, one drawback of virus adsorption to soil particles is that the latter protects the former from proteolytic enzymes or other virus-inactivating substances of the indigenous soil microflora (68).

While soil may effectively strain protozoan (oo)cysts, it is not an effective medium for inactivating them. In fact, depending on the soil type and temperature, *C. parvum* oocysts may survive from several months to years in agricultural soils. For example, significantly greater inactivation occurred in silt loam soil than in silt clay loam, whereas at temperatures between 4 and 30°C, rates of *C. parvum* oocyst inactivation increased with increasing soil temperatures. Freezing may also have lethal effects.

Within 50 days, 99% of *C. parvum* oocysts exposed to soils that are frozen are inactivated (69).

REGULATIONS AND GUIDELINES FOR REUSE OF WATER IN FOOD SYSTEMS

Internationally, there are no comprehensive enforceable regulations or even guidelines (recommendations with limited enforceability) for water reuse; hence, different countries have developed different approaches to managing the process. These approaches basically follow one of two sets of guidelines, the World Health Organization (WHO) guidelines, first issued in 1989, or California's Title 22 effluent reuse guidelines, first issued in 1992. One of the major differences between these guidelines is that a much lower coliform density is specified in the California guidelines. The second major difference is that WHO specifies limits for intestinal nematodes, while California does not (70). In general, the WHO guidelines are less stringent than the California guidelines, and their requirements can be met by low-technology, lowcost, and controlled-risk treatments, such as holding in stabilization ponds. In contrast, the California criteria rely on more expensive but reliable wastewater treatment systems. Although these two approaches have served as the baseline for guidelines, countries that are actively engaged in evaluating the safety of their reused water systems using the more stringent approach have diverged in their recommendations for monitoring the treatment systems. For example, the U.S. Environmental Protection Agency (EPA) guideline suggests that MS2 coliphage (virus that infects coliform bacteria) be used for on-site validation (6). In contrast, the Australian guidelines recommend that indigenous *E. coli* be monitored mandatorily and coliphages or other pathogens such as adenovirus or enterovirus also be monitored as representative of viral contaminants (71).

As for federal oversight in the United States, the EPA guidelines, first published in 1992, were based on the California model and specify complex treatment processes as well as stringent water quality parameters (72). Since publication of that document, additional versions have been published that include itemizing regional variations of water reuse in the United States, providing new case studies from around the world highlighting how reuse application can and does work in the real world, and updates on advances in wastewater treatment technologies relevant to reuse (6). Coincident with these treatment advances has been the inclusion of guidelines directed at inclusion of appropriate disinfection processes that are capable of reducing or inactivating pathogens (e.g., enteroviruses) to low and acceptable levels (6).

Within the United States, federal regulations for water reuse do not exist; however, the federal regulations related to the Clean Water Act and the Safe Drinking Water Act must be followed (i.e., water quality standards must be no less stringent than federal standards). As a result, each state and city in the United States is responsible for its own reuse policy; this has led to dramatic diversity in those policies between states. However, among these variations is one common theme: a higher level of treatment is

advocated when the public has direct exposure to the reused water. Within this theme, though, states may differ as to whether they have specified different categories or grades of water quality based on the intended use.

Other major differences among the approaches taken by individual states are associated with the degree of specificity provided in the rules. For example, the states of California, Florida, Texas, and Washington have developed more specific water quality criteria for specific treatments, whereas other states, such as Hawaii and Virginia, have developed water quality criteria only on a case-by-case basis (73). More specifically, the Water Development Board of Texas proposed that water reclamation plants achieve a log reduction value (LRV) of 12 for viruses when the treated water is for direct reuse as potable water (74). Performance targets specified by California's Groundwater Replenishment Reuse Project, on the other hand, were more expansive, including not only the LRV of 12 for viruses but also an LRV of 10 for both *Giardia* and *Cryptosporidium* (oo)cysts when the effluent was to be used for groundwater recharge intended for indirect reuse as potable water (75). Regulations in different states also differ with regard to the standard methods being recommended for monitoring the level of efficacy achieved by the water treatment systems. For example, several states use total coliforms as the indicator organism, whereas other states use fecal coliforms. Given that performance targets for viruses and parasites are now also being included in the reused-water guidelines of some states, monitoring of viral indicators and protozoan parasites is implicit in those states (6).

Although the proportion of water used by the food processing industry is relatively small compared to the demands incurred by the community and other industries, high-quality water is typically used. In addition, food companies produce a significant amount of effluent that must be treated before it is released back into the environment. Consequently, many food businesses are looking for ways to conserve water through reuse and thus make their operations more profitable and models of good environmental stewardship. Towards that goal, 20 years ago, delegates from a number of countries sought to draft universal guidelines on water reuse for the food processing industry, but after multiple attempts, the consensus was that a general guidance for all operations was not possible. Instead, it was recommended that guidelines for water reuse should be developed for specific commodities, given the wide variation in water contamination that arises with different processing operations and the intended target purpose for reused water (76). Following that report, an International Life Sciences Institute task force concluded that instead of classifying only two categories of water (i.e., potable and nonpotable) for the food processing industry, the desired degree of water quality should be a reflection of its suitability or level of public health risk associated with its intended use. Therefore, to implement such a concept, a risk management framework in conjunction with application of a hazard analysis and critical control point (HACCP) system was considered an appropriate approach (77). In this manner, identification of acceptable levels of risk could be assigned to specific treatment options, and more stringent treatments that would meet stricter standards would not be necessary.

MONITORING OF PATHOGENS AND INDICATORS IN REUSED WATER

To assess risks associated with potential contamination of reused water, it is essential that an adequate monitoring and verification system be in place to demonstrate the level, if any, of contamination both in source water and after each treatment step. This precaution means that log reduction data provided by designers or manufacturers of treatment systems cannot be assumed to be valid; some objective empirical evidence of performance is required. An assortment of tools is available to assay specific pathogens; however, this is not typically a viable option for routine monitoring, as methods to detect low levels of pathogens are often costly and time-consuming. Alternatively, surrogates or indicator microorganisms (nonpathogenic organisms that are present in water at higher levels than pathogens and respond to stress and treatment conditions similarly to pathogens) are routinely used as measures of contamination and success of treatment processes. Examples of indicator organisms that have been investigated over the years include coliforms, fecal coliforms, *E. coli*, enterococci, bacteriophages, and *Clostridium* spores. However, a review of the literature that examined correlations between 14 potential indicator organisms and 18 waterborne pathogens (540 datasets published from 1970 to 2009) found that there was not a consistent correlation for any one indicatorpathogen pair, as some studies provided evidence of a correlation whereas others did not (78). Hence, in the absence of any one indicator being appropriate for all water conditions that could be encountered, investigators are now pursuing the potential for combinations of microbial indicators to be used as predictors of the quality of reused water (79).

Other low-cost measurement tools that are employed to provide early warning of failures in water treatment processes during operation are termed sentinel parameters, with the measurement employed depending upon the contaminant of interest and the treatment process being monitored. Examples of sentinel parameters include (ii) elevated particle counts or turbidity for filtration and UV treatments; (ii) conductivity, chloride, and ozone residual levels for chemical disinfectant treatments; and (iii) total organic carbon or transmembrane pressure for reverse osmosis treatments (80). However, inherent to the routine use of these process parameters or others that may be proposed is that they correlate with pathogen reductions that occur during the treatment(s). Hence, to accomplish that verification but circumvent the low and variable levels of pathogens that would be present in the water to be treated, challenge testing is often conducted using a “spike cocktail” added to the water system. Zimmerman et al. (81) identified the constituents which they believe should be present in such a cocktail and include both pathogens that are known to be resistant to some types of disinfection (adenovirus, enterovirus, norovirus, *Cryptosporidium* spp., and *Giardia* spp.) and indicators (enterococci, *E. coli*, somatic coliphage, F-RNA coliphage, anaerobic sporeformers such as *Clostridium* spp., and aerobic sporeformers such as *Bacillus* spp.) that have been used in previous research and survey studies. Employing such a large arsenal of targeted organisms is therefore

expected to help us develop a better predictive understanding of pathogen and process indicator attenuation in treatment systems.

Over the years, the field of pathogen and indicator detection has evolved dramatically. Traditionally, methods encompassed culture-based enumeration of bacterial pathogens and fecal indicators as well as concentration and detection of viruses and parasites by microscopy. Major limitations of these assays included an inability at times to discriminate between the targeted pathogen or indicator and other microbiota of the water sample, false-positive counts, laborious and time-consuming protocols, and occasional failure in the detection of viable but noncultivable bacterial pathogens cells (82). Then, pathogen detection shifted to molecular assays, where the organisms were disrupted and extracted nucleic acids were subjected to quantitative PCR (qPCR), fingerprinting, or sequencing (83). However, these assays are also fraught with limitations, one of the chief ones being that the presence of inhibitors in water (e.g., humic and fulvic acids) interferes in the amplification of the nucleic acids and reduces the sensitivity of the assay. To provide an alternative solution to this limitation, third-generation PCR technology, known as droplet digital PCR (ddPCR), has been developed to provide absolute quantification of the pathogen target genes with greater sensitivity and accuracy. As evidence of the success of this method, ddPCR was able to detect pathogen-specific genes (*Salmonella* spp., *Campylobacter jejuni*, and *Listeria monocytogenes*) in more pathogen–sampling-time combinations than either qPCR or culturing methods when poultry processing water samples with high organic loads were collected from final scalder and chiller tanks (84). Although water did not serve as the source of contamination, ddPCR has also been proven to be a promising method for detection of hepatitis E virus and *Cryptosporidium*, as ddPCR is less affected by inhibitors than qPCR (85, 86).

Prior to the arrival of ddPCR, preconcentration was developed to increase the sensitivity of qPCR for lowcost detection of waterborne pathogens. During preconcentration, sensitivity is enhanced by increasing the number of target organisms per unit volume. However, the drawbacks to this approach are the additional time it requires, and, depending on the method of preconcentration, there is the possibility of partial losses in the target organism (87). For example, highly turbid waters will clog filters and not only decrease the amount of water that can be effectively filtered but also lower the efficiency of the filter to capture the target organism. Hence, a method not affected by turbidity that has been applied to the collection and concentration of protozoa is flocculation. Using calcium carbonate as a coagulant, the (oo)cysts quickly settle to the bottom of the container, making this approach easy to perform and inexpensive (88). Unfortunately, viability of the *Cryptosporidium* oocysts recovered using this concentration method is suspect, as misshapen oocysts have been observed (89).

Alternatively, immunomagnetic separation is considered a more reliable method of isolation and concentration of pathogens. The method utilizes antibodies linked to the surface of magnetic particles to attach to (oo)cysts, bacterial cells, or viral particles, which are then selectively concentrated from surrounding matter using magnetic materials. Caution should be exercised with immunomagnetic separation, as lot-to-lot

variation in the specificity of commercially available fluorescent antibodies to *Cryptosporidium* oocysts has been documented (90). In addition, in the case of *Giardia*, a marked decrease in recoveries of cysts aged 20 months was noted and was attributed to declining amounts of surface-expressed antigens on aged cysts (91).

When the efficiency of wastewater treatment in reducing the pathogen populations is being evaluated, published results must be interpreted with caution. In the first place, the majority of studies have based their conclusions only on fecal indicators, and rarely has any study considered the infectivity of the pathogen. However, analyses directed at viability and infectivity of waterborne pathogens also have their limitations. For example, not only has high variability been noted in the 50% infective dose of *Cryptosporidium* for mice, but also the animal is not infected by the human-specific species *Cryptosporidium hominis* (92). Hence, infectivity assays based on *in vitro* culture were developed (92) and continue to serve as the primary assay for viability of protozoa. Over the years, other assays have also been promulgated as valid measures of viability for waterborne pathogens but have fallen short. For example, reverse transcriptase PCR targeting amplification of mRNA proved unreliable, as there were instances where the nucleic acid was not degraded soon after the inactivation treatment was applied (93, 94). In the meantime, new approaches to the detection of viable and infectious pathogens have been made, and many of those advancements have been covered in recently published reviews (82, 95–99). However, caution should be exercised in the adoption of any one of these novel approaches until it has been thoroughly vetted in multiple treatment systems and with various water qualities and conditions. To illustrate this point, the dyes ethidium monoazide and propidium monoazide, which intercalate into nucleic acids and inhibit PCR amplification, were able to differentiate viruses that were inactivated by chlorine but not inactivated by UV or thermal treatments (100). In any event, it is important to be cognizant of the method that was used in any study exploring the prevalence and fate of waterborne pathogens, as the results may be biased and not accurately portray the status of the system.

EXAMPLES WHERE TREATED WATER IS REUSED IN FOOD OPERATIONS

Production Systems

The generation of wastewater is expected to increase worldwide due to urbanization and increases in population. As such, treatment of wastewater to generate reclaimed water can be beneficial now and in the future for its capacity to be used as a source of water for irrigation of crops in the face of recurring drought and overwithdrawal of freshwater sources worldwide (6, 10). Furthermore, the use of reclaimed water for crop production offers several advantages. In the first case, the use of reclaimed water for irrigation can lessen the burden on wastewater treatment plants in their effort to minimize discharges to streams and rivers. Another advantage of using treated

wastewater for crop irrigation is the residual nutrients that are present, which allows the water source to be used as a liquid fertilizer by crops.

The quality of reclaimed water used for food production varies widely and depends on the intended use. In developed countries, regulations of reclaimed-water use for food crops are very stringent to protect public health and often require tertiary or secondary treatments with additional disinfection or filtration steps (6). However, in developing countries, the use of untreated or inadequately treated wastewater is common (101).

In the United States, California and Florida lead the way in using reclaimed water for production of crops, accounting for 90% of the total (6). One example of successful use of reclaimed water in California is in the Salinas Valley of northern Monterey. There, a water recycling project was initiated in response to excessive groundwater withdrawal, which was causing salt water intrusion in the valley. As part of this project, a reclamation facility and distribution system were built (102) that subsequently delivered reclaimed water to several thousand acres of land where farmers were growing raw and ready-to-eat food crops (lettuce, broccoli, cauliflower, fennel, celery, strawberries, and artichokes). Not only has the reclaimed water met California's highly restrictive microbial water quality criteria (<2.2 [most probable number] total coliforms/100 ml), but results from a multiyear pilot project have demonstrated that the crops are microbiologically safe for consumption.

Another successful example of a reclaimed-water system for crop irrigation is a system that was initiated in 1986 as a collaborative effort between the City of Orlando and Orange County, Florida (http://www.waterconservii.com/). In response to a need to expand wastewater treatment services and eliminate discharge to surface waters, the project has been operating free of charge by providing treated wastewater to irrigate 2,737 acres of citrus annually. The project collaborates with the University of Florida to monitor the potential impacts of reclaimed water on food safety and the environment. As a result, the city of Orlando and Orange County guarantee in a tour brochure (http://www.waterconservii.com/wp-content/themes/divi-child/dls/Tour_Pack.pdf) that their product is a "highly treated reclaimed water that is free of virus and fecal coliform and meets all the requirements of Citrus Irrigation Reclaimed Water Constituent Concentrations."

A large number of other examples of reclaimed water projects exist in the United States, beyond those in California and Florida, and several of these are detailed as case studies in the EPA document entitled "Guidelines for Water Reuse" (6). In addition, many countries, such as Israel, Spain, Italy, Cyprus, and Australia, that are found in arid and semiarid regions of the world use reclaimed water for irrigation of food crops extensively.

Despite the advantages promoted for reclaimed water, there are studies that suggest that irrigation of crops with reclaimed water could lead to contamination of those crops with pathogens. In those cases, some risk to human health from consumption could occur if the crop is not thermally treated. For example, in an Italian field study, both surface and subsurface irrigation with wastewater subjected to tertiary treatment

resulted in contamination of tomatoes and eggplants with fecal coliforms and fecal streptococci (103). The worst contamination occurred when the vegetables came into direct contact with the soil or plastic mulch. In a similar field study in Spain using wastewater subjected to secondary or tertiary treatment, lettuce, parsley, and tomato plants were positive for the opportunistic pathogen *Aeromonas* spp. following irrigation (104). Nevertheless, other studies of irrigation with reclaimed water have failed to detect pathogens in the harvested crop or have detected a substantial decrease in the prevalence of contamination of the crop. For example, solar disinfection reduced *E. coli* concentrations in wastewater effluents from $>10^3$ to 10^4 CFU/ml to <2 CFU/ml, and in turn, 26 of 28 lettuce samples were negative for the indicator after being irrigated with the treated water (105). In another study, Lopez-Galvez et al. (106) examined the prevalence of *E. coli* and enteric viruses in wastewater that had been subjected to secondary and tertiary treatments and was then used for zucchini production in a commercial hydroponic system in Spain. Despite the presence of *E. coli* and enteric viruses (norovirus and hepatitis A virus) in the reclaimed water, these contaminants were not detected on zucchini. Likewise, in a Cyprus field study, irrigation of tomato plants with water that had undergone tertiary treatment did not result in microbial contamination (107). Meanwhile, field studies in Israel also failed to identify irrigation of tomatoes with wastewater subjected to secondary or tertiary treatment as the source of produce contamination with several bacterial, viral, or protozoan pathogens (108).

The lack of detection of pathogens or indicator organisms on crops does not necessarily indicate an absence of contamination, since, as discussed above, different methods have different limits of detection. Moreover, many studies do not address the possibility that pathogens may be internalized either by uptake through roots or by migration into wounds (i.e., cut tissue), stomates, or hydathodes (109). These limitations are particularly troublesome when low levels of pathogens persist, as there is a danger of regrowth of those pathogens (104). Additional discussion on the issue of pathogen regrowth is found in “Pathogen Regrowth” below.

In general, surface or subsurface drip irrigation systems that minimize contact between reclaimed water and the edible part of the crop are assumed to be safer than spray or sprinkler irrigation systems (110). Greenhouse or hydroponics-based production systems might also be considered safer than open-field operations, as they afford better control to minimize cross-contamination (110). However, hydroponically grown crops have a greater propensity to internalize pathogens from contaminated water via their root system than plants grown in soil-based systems (109). Hence, due to this multitude of factors that could affect contamination of crops following application of treated wastewater, risk-based analysis is recommended to provide some perspective of the overall risk to public health. Additional discussion on this topic is found in “Risk Assessment” below, along with a table describing risk assessment outcomes when reclaimed water is used as the irrigation source.

Direct consumption of reclaimed water by livestock is not common in the United States (6). However, *de facto* (incidental and unintended) consumption is possible

when treated wastewater is introduced to surface waters upstream of areas where domestic animals drink (111). Indirect exposure also occurs when the animals graze on land irrigated with treated wastewater. Furthermore, the use of treated wastewater to grow animal feed is a common practice (112, 113). In this case, the EPA's guidelines still recommend that the wastewater undergo some form of secondary treatment and disinfection. However, the guidelines and regulations for use of reclaimed water on such crops are less strict than those for crops that are for human consumption. The main concern associated with use of reclaimed water for animal feed crops or pastures is the potential that farm workers or the public may have direct or indirect exposure. Hence, some setback distances between an irrigated field and either publicly accessible areas or potable-water supplies are also recommended. Higher microbial standards also exist for land irrigated with reclaimed water and used for grazing by milking animals than for non-milking animals. In those situations, there is often also a requirement that there be a 15-day delay between grazing and application of the reclaimed water.

Processing Systems

Water plays a valuable role in the food and beverage industry. For example, in addition to the potable water that may be incorporated into a product, other operations utilizing water include (i) cleaning and sanitation; (ii) steam and hot-water generation for processing, transport, and cleaning of food products; (iii) equipment cleaning; (iv) package container (bottles, cans, cartons, etc.) cleaning; (v) bottle conveyor belt lubrication; and (vi) processed-product warming and cooling. Different food processing sectors require different amounts of water to function, but in general, to minimize the amount of water used and wastewater generated, the first order of business should be to critically evaluate each operation as to whether water is required at the level at which it is being used. For example, plant complexity, scale of the factory, the age and type of processing, utilization of batch or continuous processes, the efficiency and simplicity of methods used for cleaning of equipment, and water management have all been cited as contributing to the amount of water used in the dairy industry (114). However, as cleaning operations are the major activity consuming water at milk processors (28%), water conservation efforts would have an impact. For example, instead of using water to dislodge materials from the floor, they could be vacuumed or scraped off the floor.

Once conservation measures have been implemented, reconditioning treatments are the next option for consideration to minimize levels of water used in a food processing operation. Fortunately, the knowledge of water reuse principles by both the public and industry has grown and in turn has precipitated the growth in the food and beverage processing industry's reuse of highly treated process water that meets water quality criteria for a specific operation and addresses public health concerns. Furthermore, implementation of reused water in food processing operations generates both social and economic benefits. More specifically, reuse of water leads to water conservation, and hence, a manufacturing site may be classified as "green." In addition, although there are costs associated with treatment, the overall operating costs are generally

reduced in that less potable water needs to be purchased from an outside source and there are reduced expenses incurred for wastewater disposal.

The quality of the water demanded for food processing operations will vary with each specific operation, and therefore, determining whether reused water is suitable for that operation will depend on the quality of the used water, the recovery and distribution method, and the treatments applied. Given that the wastewater from different operations likely has different levels of organic and microbial contamination, keeping these streams of wastewater separated is beneficial from the perspective of efficiency, in that each wastewater stream needs to be subjected only to treatments that would achieve the minimum standards for the use for which it is intended (115).

As expected, application of reused water in food processing facilities has primarily been directed at non-food related and cleaning uses, cooling functions, and fire extinguisher purposes, as these processes would not require that the applied treatments achieve potable-water quality. However, within the dairy, poultry, and vegetable/fruit industries, the use of reconditioned water in their manufacturing practices is now being allowed (116–118). In the case of poultry processing wastewater, regulations require that the treatment processes reduce microorganism concentrations (coliforms, *E. coli*, *Salmonella*, and total aerobic microbes) by at least 60%. The regulations also stipulate that the treated water have a light transmission at 500 nm of at least 60% of that of fresh water used in the process. After those standards are met or exceeded, reconditioned water is allowed to replace water in the chilling step in certain predetermined ratios based on the level of treatment efficacy. The reconditioned water may also be used for moving heavy solids in eviscerating troughs, scalders, tanks, feather flow-aways, and picker aprons and for washing the picking room floors (119). However, reused water that came into contact with raw product prior to treatment should not be allowed to come into contact with ready-to-eat product, on the assumption that pathogens residing in the used water survive the treatment.

As for published case studies investigating reused water in food processing operations, Casani et al. (120) present multiple examples in their review. More recent research studies are summarized in Table 41.6; however, only about half of the studies that are listed examined the efficacy of the treatment(s) with regard to the microbial safety of the water. In any event, regardless of the application of reused water, the principles of HACCP should be adhered to in order to control any potential hazards and prevent them from entering the food processing environment. In addition, continuous monitoring, audits, and frequent sampling of the reused water are required (3, 120).

LIMITATIONS TO REUSED/RECONDITIONED WATER BEING INTRODUCED INTO FOOD SYSTEMS

Aerosols

Another exposure mode by which farm workers and nearby residents can potentially be introduced to health hazards associated with irrigation of wastewater or reclaimed water is via inhalation of or skin contact with aerosolized pathogens (121). For the most part, incidences of diarrheal diseases and other health problems that are attributed to aerosols are associated with irrigation using untreated or inadequately treated wastewater, a practice that is common in many developing countries (101, 121). In those cases, exposure to aerosolized pathogens can be minimized by using nonspray irrigation systems (i.e., subsurface, drip, or furrow irrigation). However, several studies have demonstrated that when wastewater is properly treated, aerosolized pathogens do not appear to pose a significant health risk to farmers or nearby communities. For example, both dermal and nasal swabs from farm workers were negative for *Staphylococcus aureus* and *Enterococcus* after the workers were exposed to wastewater that had undergone tertiary treatment and had been spray-irrigated onto a field (122). Another observation from that study to indicate that there was minimal risk from aerosolized pathogens was that the farm workers exposed on those spray-irrigated properties had the same odds of infection with the two target pathogens as did office workers who had no exposure to the irrigation water.

The degree of risk associated with aerosolized pathogens is likely dependent on a pathogen's size and, hence, its ability to be aerosolized. For example, Courault et al. (123) detected low levels of enteric viruses in air above agricultural fields that received wastewater that had undergone tertiary treatment; however, higher levels were observed in cooler months. Despite these observations, the risk of norovirus exposure for the employees who were most exposed at the treatment plant generating the reclaimed water was judged to be acceptable. Based on this assessment, the risk of exposure at the farm that received the reclaimed water from the treatment plant would also have to be considered minimal.

Cropland Runoff

The largest non-farm-related use of reclaimed water in the United States is urban use (e.g., golf course and landscape irrigation) (6). In Florida and California, urban use accounts for 55% and 19% of the total share of reclaimed water use, respectively. This form of utilization can lead to cross-contamination of croplands through runoff after irrigation or rainfall. Part of the strategy to control urban runoff is the design and implementation of best management practices that address several factors, ranging from the selection of irrigation systems to better control water delivery to the use of physical barriers to slow and filter out pollutants (124, 125). The use of vegetative buffer strips, for example, has been shown to be effective in reducing microbial loadings from runoff to water bodies (126, 127).

Table 41.6. Selected research studies addressing processes and treatments applied to food processing wastewater for the purposes of water conservation

Water source	Treatment(s)	Targeted reused-water application	Results and observations	Reference
Poultry chiller water	Electroflotation (electrolytic gas generation)	Chiller water	Aerobic bacteria and coliforms were reduced by 6 and 5 log CFU/ml, respectively	171
	Membrane bioreactor (1st tank is an aerobic bioreactor, 2nd tank is an anoxic tank for settling particles, 3rd tank has tubular module membranes for ultrafiltration); emphasis on backflushing to decrease fouling	Chiller water	Aerobic microbes were reduced by 4 log CFU/ml	172
	Hollow fiber or spiral ultrafiltration using polymeric membranes	Chiller water	Aerobic microbial levels were reduced by more than 5 log CFU/ml	173
Beverage bottle-washing wastewater	Filtration and/or nanofiltration	Washing bottles	Reduction of 98% in chemical oxygen demand	77
Dairy whey	Combined ultrafiltration and reverse osmosis unit	Clean-in-place systems	47% of water can be recovered; generates protein and lactose by-products	3
	Combined ultrafiltration, reverse osmosis unit, and a reverse osmosis polisher unit	Combined ultrafiltration, reverse osmosis unit, and a reverse osmosis polisher unit	Near-infrared spectroscopy monitors urea in reused water so it may be stored for more than 24 h before application	174
Malting wastewater	Microfiltration	Reused in steeping	Treated water has acceptable	77

from barley soaking		operations	microbiological populations	
Produce wash water	Ultrasound (20 kHz, 0.28 kW/liter) in combination with peroxyacetic acid (3.2 mg/liter)	Washing produce	Log reductions of 6, 6, and 1.7 for *E. coli* O157:H7, *Salmonella*, and *L. monocytogenes* after 11, 11, and 20 min, respectively	175
	Ultrasound (26 kHz, 41.85 kW/liter) in combination with UV-C light (1.64 kJ/m2)	Washing produce	Log reductions of 3.6 for total aerobic bacteria and 30% and 79% reduction in suspended particles and chemical oxygen demand, respectively	176
Beet sugar wash water, condensate; barometric condenser discharge	Mechanical cleaning to remove soil organic matter	Beet washing, transport and cleaning, juice extraction, cooling towers, cleaning operations	Demand for potable water during production has decreased to nearly zero	77

Disruption to Indigenous Soil Microflora

Irrigation with treated wastewater can disrupt the indigenous soil microbial communities directly through introduction of microorganisms that are not common in the soil. In a comparison of diversity between treated wastewater and agricultural soil, bacteria in three phyla and 15 orders were found to be unique to treated wastewater (128). Application of this treated wastewater can therefore introduce exogenous microorganisms, including pathogens resistant to the treatment, to those soils. However, it is not clear how many of the microorganisms introduced in this manner persist in the soil system to impart long-term disruptions to the indigenous microorganism composition. To date, studies to address the fate of microorganisms present in the reclaimed water have primarily ignored nonpathogenic microorganisms and instead have focused on only pathogens because of their potential impact on food safety and human health. Based on those studies, pathogen survival in soils varies widely but is dependent on soil properties that include texture, pH, temperature, moisture, organic matter, and interactions with the indigenous microbial

communities (129, 130). Hence, it is likely that many of the same factors influence the survival of newly introduced nonpathogenic microorganisms, which in turn impacts the previous dynamic status of the soil microbial community.

Irrigation with treated wastewater can also disrupt the indigenous soil microbial communities indirectly through the addition of organic matter and nutrients. Such disruptions to the microbial community status occur when introduction of the supplements causes growth of copiotrophic microorganisms (131). For example, Bastida et al. (132) noted that the abundance of *Proteobacteria* and *Bacteroidetes* increased with application of treated wastewater. Similarly, in a study where an orchard soil was irrigated with treated wastewater for 6 years, the relative abundance of *Actinobacteria* decreased, with a corresponding increase in the relative abundance of *Gammaproteobacteria* (133). Interestingly, the change was temporary, as the relative abundance of the microorganisms reverted to the original proportion after the irrigation was stopped, highlighting the resilience of the indigenous microbial communities to the disruption. However, extended durations of irrigation with treated wastewater appear to continue to exert their effect on the microbial community. For instance, in Spain, irrigation with treated wastewater spanned 43 years and resulted throughout that time in a lower diversity of arbuscular mycorrhizal fungi (AMF) than irrigation with freshwater (134). This response was not unexpected, as enrichment of the soil environment with wastewater-derived nutrients and organic matter would be to the benefit of copiotrophic microorganisms. AMF, on the other hand, are adapted to living in environments where nutrient levels are relatively low. The proliferating copiotrophic group would therefore have competed with the AMF and reduced their diversity.

Disruption of the indigenous soil microflora may also occur upon long-term application of reclaimed water due to soil's accumulation of heavy metals (e.g., Cu, Zn, Pb, and Ni) and salt (128, 135) found in the water source. Buildup of either of these constituents has been shown to cause a decrease in microbial abundance, activity, and diversity (136, 137). Another disadvantage to the accumulation of heavy metals in soils is that they have been implicated in coselection of antibiotic-resistant microorganisms in soils (138). The drawbacks to that situation are discussed in more detail in the next section.

Antibiotic Resistance

The extensive use of antibiotics in humans has led to the prevalence of antibiotic-resistant bacteria (ARB) and antibiotic resistance genes (ARGs) in wastewater (139). As a result, this prevalence is a major concern due to the potential for the transfer in the environment of ARGs from nonpathogenic microbes to pathogenic microbes that can cause disease in humans. Unfortunately, treatment of wastewater does not eliminate ARB and ARGs, and significant amounts are still present. To illustrate this point, Carey et al. (140) reported the prevalence of *Enterococcus* spp. that were resistant to multiple antibiotics in treated wastewater that was being used for irrigation at three sites in the United States. Moreover, significant amounts of

tetracycline resistance genes were also present in the chlorinated effluent. In other cases, chlorination and UV light have been shown to exacerbate the problem by increasing the relative proportions of bacterial isolates that were resistant to multiple antibiotics (141, 142). Such exacerbation was also demonstrated in a laboratory study by Zhang et al. (143). In that study, sublethal levels of commonly used disinfectants (free chlorine, chloramine, and hydrogen peroxide) enhanced the conjugative transfer of ARGs between *E. coli* strains and between *E. coli* and *Salmonella enterica* serovar Typhimurium, highlighting the potential role of chemical disinfectants in the spread and prevalence of ARGs. The investigators in that study speculated that the residual amounts of disinfectants led to formation of reactive oxygen species that caused increased membrane permeability, thereby facilitating the conjugative transfer of ARGs. In any event, given that there is the potential for bacterial regrowth (see the next subsection) as well as continued transfer of ARGs during distribution and storage prior to irrigation, monitoring treated wastewater at the point of use is imperative (140).

Based on the data demonstrating that treated wastewater can act as a reservoir of ARB and ARGs, it is reasonable to assume that they would be transferred to soils during irrigation. However, once transferred, selection of certain types of ARGs may occur, creating a soil with its own resistome (collection of ARGs). As an example, irrigation of six urban parks with treated wastewater in Australia significantly increased the abundance and diversity of selected ARGs in the soils (144). However, the creation of a different soil resistome upon application of reclaimed water is not certain, as was demonstrated when Israeli agricultural soils were irrigated for up to 16 years with freshwater or treated wastewater (145). During that time, no significant differences in ARB and ARGs were noted for soils irrigated with the two different water sources, and those results highlight the probability that the resistome is dependent on the ARB and ARGs that are introduced to the soil system and their stability in that system.

Pathogen Regrowth

When processes applied to wastewater fail to remove most or all of the organic material, such material can serve as a nutrient source for microbial and pathogen growth if the treated water is stored for any length of time. Hence, to measure the concentration of nutrients that could support bacterial growth, reused water samples are typically subjected to the assimilable organic carbon (AOC) bioassay. In the original assay, the water sample was heated to kill the indigenous bacterial population before inoculation of the sample with *Pseudomonas fluorescens* and then incubation of the mixture at 15°C to achieve maximum growth. Using an empirically derived yield coefficient, the results were then converted into acetate equivalents (146). Generally, water can be defined as biologically stable if its AOC value is less than 10 to 20 □g of acetate C/liter without disinfectant, or less than 50 to 100 □g of acetate C/liter if it was disinfected (147). When values are higher, bacterial regrowth is likely during distribution and storage. As confirmation that AOC supports microbial regrowth, AOC reductions were observed simultaneously with regrowth in reused water and distribution systems (148).

One of the drawbacks to the original AOC assay protocol was the long incubation periods that were necessary before maximum growth was achieved (1 week for high AOCs and up to 1 month for low AOCs) (146). Consequently, an ATP luciferin-luciferase method was adopted as a rapid AOC method which incorporated higher incubation temperatures and greater inoculation levels (149). Another recent extension to the assay has been to expand from evaluating the growth response of just one bacterial strain to inclusion of nine bacterial strains, as these strains exhibited unique substrate utilization patterns that offered a better assessment of differences in biodegradable organic matter that could be present in different reused water samples (150).

Although differences in the initial levels of nutrients present in the wastewater source may affect the subsequent AOC levels observed in treated water, the type of treatment also has an impact. For example, wastewater that had been treated with ozone resulted in reused water with AOC concentrations higher than those in reused water that had been treated with reverse osmosis (148). The potential for microorganisms to grow in nutrientfortified reused water systems also varies with the organism. For example, waterborne indicators such as *E. coli* and *Enterococcus* were infrequently detected and only at low concentrations, whereas opportunistic pathogens, such as *Aeromonas*, *Legionella*, *Mycobacterium*, and *Pseudomonas*, occurred more frequently (151, 152). Several variables may impact the regrowth potential of enteric and opportunistic pathogens, including (i) differential reactivation of viable but not culturable populations (153); (ii) differential response to residual disinfectant (i.e., chlorine) levels (154); (iii) selection of chlorine-resistant pathogenic bacteria, such as *Salmonella* (154); (iv) level of movement of reclaimed water during distribution or storage (high potential for generation of cyanobacteria blooms and subsequent generation of toxins); and (v) levels of indigenous competitive bacteria present in the water system. With regard to the latter variable, reactivation and regrowth of indigenous microflora were most likely to occur when the organisms were exposed to lower chlorine doses during treatment and decreased as the chlorine concentration increased (154).

Public Opinion

It is important to recognize that public acceptance of reused water is vital to utilization of this resource. More than 20 years ago, a survey of 500 respondents in Manama, Bahrain, was conducted and found strong opposition to using reused water regardless of the conditions. In fact, the respondents were willing to pay more to avoid using it (155). However, in that survey as well as ones conducted more recently with 400 participants in Arizona (156) and 2,800 participants across the United States (157), support increased as the intended application became less personal (i.e., less chance for bodily contact with the reused water). Acceptance of reused water was also greater with the segment of the population that had a higher level of education (155–157). Sex and age, on the other hand, showed no significant effect on the acceptance of water reuse (157). Surprisingly, drought conditions did not have a statistically significant effect on the number of reused-water supporters but did increase the

number of respondents who identified water shortages as an environmental problem (157).

In Australia, studies have found that the degree of acceptability is dependent on the type of water to be reclaimed. Rainwater harvested from one's household roof was considered more acceptable than gray water, which in turn was more acceptable than wastewater. Factoring into the acceptance of any one source, however, was the level of treatment that was to be applied to that source (158).

One of the most important factors that influence public acceptance is the perceived health risk of reused waters (159). In addition to concerns regarding the presence of pathogens and the unknown impact of chemicals used to treat the water, the public has also targeted the potential presence of endocrine-disrupting compounds in wastewater. Although these risks are real, the public's perception as to the degree of risk associated with each concern does not necessarily coincide with scientists' judgments on the matter. In fact, the public views the risks in more abstract terms, incorporating attributes such as uncertainty, dread, catastrophic potential, controllability, and equity into their risk equation (160). Moreover, when the public does not fully understand the situation, they also use their social and moral values, otherwise known as outrage factors, to evaluate the situation (161). In the end, water reuse surveys have documented that people are more trusting of their own intuition than of the authorities that monitor and regulate the process and product or the results of peer-reviewed scientific research (158, 162).

On many occasions, communities have acknowledged that there was a psychological barrier derived from the thought of using reclaimed water; hence, terminology is critical in the success in promotions of reused water. For example, survey respondents who totally rejected "reclaimed water" associated it with the terms "filthy" and "unclean," despite the fact that reclaimed water has been treated to high standards for removal of pathogens. People still perceive the water to be disgusting because it has been in contact with disgusting stimuli, in this case, human waste. Opponents of the reuse concept, particularly in relation to applications requiring potable water, have also capitalized on terminology to promote their viewpoint, using the phrase "toilet to tap" (156). Consequently, acknowledging the importance of terminology, projects that have investigated applications of reused water have attempt to avoid terms that imply treated wastewater. In Singapore, reused water was called NEWater, and in San Diego, it was referred to as repurified water. However, Rock et al. (156) reported that even the terms "recycled water" and "repurified water" were still judged negatively by a small percentage of those surveyed, as these terms still implied that the water had already been in use (163).

As noted above, the level of acceptance by the public varies and depends on the type of reuse advocated. Opposition is often fueled by unfounded fears, and to alleviate those fears, it has been advocated that an emphasis be placed on keeping the public fully informed and providing deliberative consultation (163). For example, a task force in Elsinore, CA, conducted 16 meetings with the public over a 7-month period before supplementing Lake Elsinore with recycled water. Similarly, the success of a water

recycling program at Irvine Ranch, CA, was attributed to a commitment to inform and educate the local community through public tours, in-school education, and outreach and community education that reused water is a means to protect the environment and save money and energy. However, public outreach and education have not always led to favorable outcomes; sometimes, they polarize the public even further (162). Furthermore, when implemented after the project's conception, education and outreach programs are generally considered inadequate. When reclaimed-water projects have been implemented in spite of unsuccessful education and outreach programs (e.g., Singapore's NEWater project, implemented in early 2003), the governmental systems tend to be more authoritarian (163).

Beyond efforts to educate the consumer about the technology used to reclaim used water, the extensive oversight of the industry, and the benefits of reused water, other implementation strategies have been presented to consumers for their views on whether the public would receive them favorably. In response to these inquiries, financial incentives (i.e., rebate programs and reduced water rates) were considered likely to increase the public's support for reused-water applications (156, 157). Increasing the costs to treat water to higher standards was also considered a strategy that municipalities should pursue (156). In contrast, there was divided support for mandatory programs (156), illustrating the common behavioral tendency that people will support and believe in what should be done, but opposition arises once the intended change is mandated (164). As support and acceptance of reused water varied with the intended use, it was suggested that implementation within communities should focus on applications with greater social acceptability (157). It is anticipated that when the public becomes more familiar with the technology and the general benefits of reused water, acceptance of reused water for other end uses (e.g., crop irrigation) will increase.

RISK ASSESSMENT

To estimate the likely burden of illness associated with ingestion of a specific waterborne pathogen in a specific reuse capacity, quantitative microbial risk assessments (QMRAs) are conducted, wherein experimental data are combined with mathematical models and statistical probabilities. As multiple hazards (pathogens or microbial toxins) may be present in a source water or wastewater system, one of the first considerations is to define representative organisms whose control is believed to represent control of all pathogens of concern. In some cases, consideration should also be given to the pathogen serotype present. For example, the risk of using water in a manner that creates aerosols (e.g., irrigation) is generally higher when the water is contaminated with adenovirus 2 than when adenovirus 41, a pathogen associated with gastroenteritis, is present (97).

Ideally, at least one bacterium, virus, protozoan, or helminth should be included in a QMRA to account for the wide array of potential pathogens that could be present in the water system. However, in actual practice, it has been more common to measure indicator organisms, as discussed in "Monitoring of Pathogens and Indicators in

Reused Water" above. This distinction in target organisms is important, as QMRAs using indicator organisms have been misleading due in large part to the differences encountered between the responses of indicator organisms and those of pathogens to treatments and environmental stresses before ingestion (165). Notwithstanding this limitation, some of the other parameters that serve as components in a QMRA include (i) pathogen populations within the water source, (ii) volume of water deposited on food, (iii) potential for regrowth in stored water systems, (iv) assessment of exposure levels by different segments of the population (quantities of food ingested at one time or over a period of time), and (v) susceptibility of the population segment to the waterborne pathogen (dose-response assessment). Additional information on these parameters as well as the systematic steps that should be taken in developing a QMRA are found in documents published by the USDA/EPA (166) and WHO (13).

Once QMRAs of water systems are conducted, collected data are translated into a probability of infection per year and then into an estimated disease burden per case, for which the metric disability-adjusted life year (DALY) is used. This metric takes into consideration not only the risk of illness but also the differential burden that illness entails in low-versus high-income regions. Therefore, to put everybody on the same footing, WHO has identified a health outcome target of 10^{-6} DALY per person per year (13). Another benefit of conducting QMRAs is the ability to understand the effects that various operational parameters may have on overall risk and thus enable the establishment of performance targets. For example, a risk-based goal of 10^{-4} infections per person per year is frequently used as the basis for developing pathogen removal targets. However, the determination as to whether a water quality intervention will be implemented will also likely depend on the relative level of improvement that could be expected (e.g., a decrease in disease burden of 5% or more would be considered extremely worthwhile) (13).

One scenario where QMRA is starting to be applied more routinely is for assessing the safety of irrigating vegetables with treated and untreated wastewater (Table 41.7). Comparison of the annualized risks of infection in the reported studies to the acceptable WHO target of 10^{-6} suggests that the public's risk of infection is dependent on the target pathogen as well as the level of treatment applied to the wastewater. Hence, in cases where the recommended risk level is exceeded, additional treatment of the water is advised to further reduce pathogen levels. Alternatively, management practices may also be modified such that interactions between the water and the edible portion of the crop would be minimized.

CONCLUDING REMARKS

Treatment of wastewater and applications of reclaimed/reused/reconditioned water in food operations on a global scale are relatively small. The main factor driving the adoption of reclaimed water has been water shortages in arid regions. Many other operations are attempting to implement the application of reused water to avoid the impending strain on our water resources. However, as discussed in this chapter,

microbiological safety risks are associated with the use of reclaimed waters treated to different extents. Future adoption of reclaimed water in food systems will be dependent on public opinion, which in turn will likely be dependent on the success or failure of education and marketing efforts to inform the population of the benefits and risks of this product. Assisting in those efforts will be the use of risk assessment tools (i.e., QMRA) that will ultimately relate specific treatments, costs, and applications to the risk of illness.

Table 41.7. Selected examples of QMRAs conducted to assess the microbial risk from consumption of ready-to-eat food crops that were overhead-spray irrigated with wastewater or reclaimed water

Location	Target crop(s)	Water treatment(s)	Target pathogen(s)	Annualized risk of infection (DALY/person/year)	Reference
California	Lettuce	Chlorine disinfection followed by filtration	Multiple	10^{-7} (enterovirus) 10^{-5} (*Giardia*) 10^{-4} (*Cryptosporidium*) 10^{-8} (*E. coli* O157)	177
Spain	Lettuce	Sedimentation and activated sludge (secondary); flocculation with iron chloride followed by filtration, UV treatment, and chlorination (tertiary)	Norovirus	10^{-4}(secondary) 10^{-4} (tertiary)	178
United ArabEmirates	Lettuce, cabbage, cucumbers	Chlorine disinfection	*Salmonella*	$>10^{-6}$	179
Beijing, China	Chinese chard, broccoli, flowering cabbage, lettuce	None	Rotavirus	$>10^{-6}$	180
Shepparton, Australia	Lettuce, broccoli, cabbage, Asian vegetables, cucumbers	Wastewater stabilization ponds	Norovirus	$>10^{-6}$	181

42
Relevance of Food Microbiology Issues to Current Trends (2008–2018) in Food Production and Imported Foods

Tremendous strides have been made over the past 3 decades to improve the microbiological safety of the United States food supply. Through the efforts of our scientific, industrial, and regulatory communities, these improvements have occurred in part because of increased fundamental knowledge of foodborne pathogens and an increased ability to detect and control these pathogens. However, we live in a world that is never static, and as part of that dynamic, a number of current factors will undoubtedly influence the continuing evolution of the safety of foods. One such factor is the application of whole-genome sequencing (WGS) by the public health community for detection of foodborne-illness outbreaks and identification of the causative food and its source of contamination. Another consideration is the dynamic change of consumer attitudes for the types of foods that are preferred, which will influence the manufacture and marketing of foods, some of which may be at increased risk of pathogen contamination and growth. An additional contributor will be the recent regulatory changes that are providing rules on approaches needed to produce safe foods but with minimal adverse consequences in providing a sustainable and affordable food supply.

ADVANCES IN TOOLS FOR FOODBORNEDISEASE SURVEILLANCE AND RISK ASSESSMENT

Advances in WGS and Other Epidemiologic Tools on the Horizon

Approximately 2 decades ago, pulsed-field gel electrophoresis and multilocus sequence subtyping methods were introduced to identify foodborne-illness outbreaks and to link clinical isolates from outbreaks with sources of the implicated pathogens. However, these molecular profiling techniques are laborious, time-consuming, and difficult to standardize among laboratories. Moreover, they rely on pure cultures and are therefore challenged by the increasing use of culture-independent diagnostics in clinical laboratories (1). The adoption of WGS, which reveals the complete DNA composition of an organism, is revolutionizing the public health and food safety fields. This revolution is occurring because WGS, in contrast to traditional molecular typing methods, provides much greater resolution in differentiating temporal and spatial clusters of genetically related pathogens (2).

As more researchers and public health agencies have adopted the technology of WGS, sequencing speed has increased, and the acquisition and operational costs of high-throughput sequencing have decreased. Consequently, PulseNet at the U.S. Centers for Disease Control and Prevention (CDC) and public health agencies in other countries (e.g., Canada and Australia, as well as the continent of Europe) are transitioning from PFGE to WGS typing for foodborne-illness outbreak surveillance. Facilitating these efforts are multiple databases that house the gene sequences of thousands of foodborne bacterial pathogens. Examples of these databases include the U.S. GenomeTrakr database (3), the Canadian Syst-OMICS database (4), the European Microbial Identifier database (5), and the Advanced Research Infrastructure for Experimentation in Genomics database. Given that WGS has permeated major public health agencies throughout the world, these efforts are coordinated through steering committees that seek to harmonize data collection and develop policy decisions regarding how the data will be shared. Moreover, to facilitate the adoption of this technology by developing countries, such as Brazil, those countries are forming partnerships with the World Health Organization and the United Nations' Food and Agriculture Organization. In such collaborations, guidance is offered to those countries to enable them to use WGS technology and the available databases.

The U.S. Food and Drug Administration (FDA) has initiated a process (informally described as a "swab-athon") whereby, during its food facility

inspections, approximately 150 to 200 environmental samples are obtained and tested for pathogens such as *Listeria monocytogenes* and *Salmonella*. The pathogens that are obtained are then subjected to WGS, and their sequences are entered into the GenomeTrakr database. Not only can this information help to identify which preventive or sanitary controls may have failed and need to be corrected, but also, it may reveal the route by which contamination occurred. In addition, when cases or outbreaks of foodborne illness are detected, comparisons are made with sequences in the GenomeTrakr database to determine if there are matches that could be linked to the source, such as a food processing facility. Hence, WGS data are being used to aid in foodborne outbreak investigations (6).

Examples of active and retroactive epidemiologic investigations of illness outbreaks in which WGS has been useful are listed in Table 42.1. Additional examples of WGS's role in epidemiologic investigations of foodborne outbreaks involving atypical vehicles are described by Kase et al. (7). They describe how WGS was instrumental in identifying sources (e.g., pistachios and flour) of outbreaks that had long epidemic curves and likely would not have been detected if other molecular techniques had been used. In addition to determining the source of an outbreak of foodborne illness with greater speed and precision, WGS technology can help differentiate illnesses that are part of an outbreak from those that are not, identify which ingredient in a multi-ingredient food is the cause of the outbreak, and differentiate the sources of contamination within the same outbreak, and it can link small numbers of illnesses, including those distributed widely across several states, that would not likely be detected as an outbreak.

With the large amount of molecular data obtained from WGS analyses, additional uses of this information are being applied. For example, WGS genomic data may be able to predict whether a bacterium is resistant to antibiotics and, in so doing, help us to better understand how bacteria become resistant to antibiotics and how resistance spreads (8). However, Ellington et al. (9) noted that, to date, accurate inference of antimicrobial susceptibility from WGS data has been either poor or nonexistent and suggested that more research and data sets will be needed before it can replace phenotypic antimicrobial susceptibility testing.

Another application for WGS data is the detection of phylogenetic relationships between outbreak strains; such phylogenies may then be used to establish evolutionary relationships and spatial spread or geographic associations among different strains (10, 11). Furthermore, geographical information systems and geospatial mapping of illnesses could complement this application of WGS data (12–14). For example, Wang et al. (13) suggested that by automatically uploading WGS data for clinical isolates from hospitals and clinics throughout the world with "geotagged" metadata, there is the potential to revolutionize diagnostics and characterization of foodborne disease agents at the patient level. Another benefit of WGS is to use specific genomic regions of foodborne disease agents identified by WGS to develop rapid and cost-effective PCR assays (15).

WGS data may also be used to characterize bacteria beyond the species and/or subspecies level. For example, the White-Kauffmann-Le Minor scheme has been the gold standard for serotyping of *Salmonella* isolates and is based on serological detection of expressed O (somatic) and H (flagellar) antigens. Alternatively, *Salmonella* serovars may be identified through WGS by focusing on genetic differences in the somatic and flagellar genes and subjecting the data to analysis by one of several software programs (16, 17). This approach has been adopted by Public Health England, which uses multilocus sequence typing as a replacement for traditional serotyping of *Salmonella* (18). Moreover, this approach to serotyping is not limited to *Salmonella*, as serotyping of *Escherichia coli* using WGS data has been shown to be a superior alternative to the conventional typing method (19).

Table 42.1. Use of whole-genome sequencing to analyze foodborne-illness outbreaks[a]

Pathogen	Vehicle(s)	Results
E. coli STEC	Flour	WGS analysis conducted by FDA demonstrated that *E. coli* O121 isolates obtained from open flour product samples in multiple states were closely related to outbreak strains obtained in 2016. Subsequent testing by a third-party laboratory on nonrecalled flour samples at the behest of the implicated company revealed three STEC strains (O103, O26, and O111), of which one (O26) was subsequently identified as closely related genetically to a clinical isolate. WGS characterization of the remaining isolates obtained from the flour samples did not lead to identification of any additional clinical cases (119).
Salmonella Typhimurium	Multiple	Retrospective evaluation of five distinct foodborne-illness outbreaks in Australia. In four of the outbreaks, WGS confirmed that the human and environmental isolates epidemiologically linked by MLVA typing either were identical or differed by one or two SNPs. Moreover, additional isolates initially not considered to be linked with the outbreaks were determined to belong to the outbreaks, increasing the total outbreak size by 107%. In the fifth outbreak, isolates differed by up to 12 SNPs and thus suggested that the outbreak was caused by more than one strain (120).
L. monocytogenes	Caramel apples	Using WGS, environmental testing revealed contamination with *L. monocytogenes* at the implicated firm's apple-packing facility, and these isolates were highly related to the outbreak strains (121).

	Soft cheese	Five PFGE patterns of *L. monocytogenes* were initially included in the investigation; however, WGS revealed that these strains were closely related genetically (122).
	Ice cream	Outbreak-associated isolates with multiple PFGE profiles were determined to cluster together by WGS, and these were differentiated from epidemiologically unrelated isolates that exhibited outbreak PFGE profiles (123).

[a] Examples of recent outbreaks where whole-genome sequencing has been used as a tool to link an outbreak to a food source either during an investigation or to retrospectively evaluate its efficacy compared to traditional epidemiologic tools used in the investigation. STEC, Shiga toxin-producing *E. coli*; WGS, whole-genome sequencing; MLVA, multilocus variable-number tandem-repeat analysis; SNP, single nucleotide polymorphism; PFGE, pulsed-field gel electrophoresis.

Virulotyping is yet another opportunity to apply WGS data. Through the identification of a pathogen's genes that contribute to varying degrees of virulence and hence illness, virulotyping may provide a system to differentiate those isolates. Such a typing system would avoid the overly conservative approach that currently exists, in which all members of a particular bacterial genus (e.g., *Salmonella*) or species (e.g., *L. monocytogenes* and *Cronobacter sakazakii*) are considered equally pathogenic by public health and regulatory agencies.

Tools complementary to WGS are also being used to enhance the safety of foods. Examples include metagenomic and metatranscriptomic approaches, whereby either the entire DNA or the cDNA (created from RNA extracted from an entire community) is sequenced and used to identify and characterize baseline microbial communities along the food supply chain for the purposes of detecting safety and quality anomalies (20). It is also envisioned that meta-analysis (statistical combination of results from multiple studies, including those based on WSG) will be a common application in the near future (13).

Current Limitations of WGS and the Need for International Data Harmonization

Despite the wide appeal of employing WGS in research and epidemiologic food safety investigations, there are two fundamental challenges to

routine application of WGS: sensitivity and the determination of viability (21). Pathogen contamination of foods is often characterized by variability in the type of the target organism present, heterogeneity in distribution of the microorganisms within the matrix, and the presence of low levels of the target microbe. As a result, platforms developed for health care systems that rely on large numbers of pathogens often cannot be easily adopted for foods unless the microbial contaminants are grown to large populations to produce sufficient DNA for analysis (20).

Widespread adoption of WGS is also currently restricted by limited resources, e.g., financial resources and the availability of skilled personnel. These restrictions include not only the relatively high costs of WGS assays but also insufficient expertise in bioinformatics analysis as well as inadequate levels of computational power needed to process and analyze the large sets of sequenced data (22). Different groups employing different platforms, data analysis pipelines, and terminology of contextual data (23) have also contributed to the lack of harmonization and restrictions in the sharing of data. Hence, international efforts to address this issue are under way (2, 20, 23).

CONSUMER TRENDS THAT CAN AFFECT THE MICROBIOLOGICAL SAFETY OF FOODS

The scientific, industrial, and regulatory communities as well as consumers believe that under ideal conditions and given enough resources, the food supply could be made completely safe. However, available resources are not the only factor influencing the safety of foods. Rather, consumer preferences are another very important factor that can directly influence the microbiological safety of foods. From the perspective of food production, consumers through their food preferences largely dictate what foods are produced and manufactured, since the industry focuses much of its food manufacturing on the foods which most people prefer. However, there are niche markets in part due to fringe population groups interested in unique foods because of health, cultural, or religious heritage reasons or because they avoid certain traditional foods, such as meat. Some of the foods they desire, especially those with no antimicrobial preservatives or pathogen inhibitors, are challenging, if not impossible, to make microbiologically safe, as

extended shelf lives and some degree of consumer temperature abuse are factors that are likely to complicate safe food production.

Consumer Response to Food Recalls

Although everyone's goal is to always produce safe foods, the occurrence of human errors and the limitations of many food safety technologies make it impossible to produce a food supply that is completely safe. Hence, food recalls often occur and may arise in response to an outbreak or because of contamination in samples that are tested for pathogens. Food recalls result not only in extra costs to the food industry related to recovering, disposing of, or reconditioning the contaminated food product already in the market pipeline but also in additional economic repercussions when concerned consumers respond by avoiding the product. Pozo and Schroeder (24) determined that the degree of media coverage and whether a company has an orchestrated plan to promptly offset any negative publicity will often determine the magnitude by which consumers' responses affect sales. As an example, it was reported that the American Egg Board's $1 million media campaign designed to restore the image of eggs in consumers' minds was successful, as consumers' response by consuming eggs occurred more quickly than in other markets associated with similar food recalls (25). In addition to media coverage, other factors, including prior experiences and overall concern for food safety, influence how individuals respond to food recalls (26, 27).

A survey conducted 10 years ago revealed that 80% of responding consumers thought that food recalls were increasing, yet over 50% of the respondents greatly underestimated the actual number of recalls that were occurring annually (26). Despite these concerns, 12% of those responding also reported they knowingly ate a recalled food, with 57% of them indicating they ate the food because they did not believe it would harm them. An explanation for this behavior was that these consumers were suffering from optimistic bias and underestimated their own vulnerability.

Although consumers may be lackadaisical about recalled product they have already purchased (i.e., they do not want to throw it away or do not want to be bothered to return it to the store), consumers are more apt to not purchase the recalled branded product in the near future. For example, sales of recalled frankfurter brands declined roughly 22% 2 to 3

months after the recall and did not return to near pre-recall levels until 4 to 5 months later (28). Consumers are also known to adjust their purchase habits beyond the recalled brand or commodities to nonrecalled brands or other closely related commodities (27). This has occurred for both meat and poultry products (29). However, these trends in consumer responses to recalls may shift as different age groups become the dominant force in the marketplace. For example, it was observed in a survey that millennials remembered on average two or fewer recalls in the previous year than the older generation, which remembered two to five recalls (27). This disparity may relate to the different sources by which the two groups learn about that recall information (i.e., nonmillennials generally rely on television and newspapers, whereas millennials obtain their news primarily through social media networks, instant messaging, and texting). Moreover, even when presented with the same information, the different population groups can have different interpretations. For example, in the Peake et al. (27) survey, approximately 30% and 10% of millennials and nonmillennials, respectively, indicated that they would react in a way which would be considered unexpected given the warnings that they had just read regarding a peanut butter recall.

Consumers' Response to Foodborne Illness Outbreaks

Studies have revealed that consumers' purchasing response to outbreaks associated with contaminated food products is more negative than that for recalled product that was not associated with any illnesses. Using Nielsen Homescan data, Bakhtavoryan et al. (30) determined that there was a decrease in the demand for peanut butter following the 2007 *Salmonella* outbreak associated with peanut butter, but within 27 weeks following the crisis, peanut butter sales for the implicated company had recovered. The 2006 outbreak of *E. coli* O157:H7 in spinach had an even greater influence on consumer demand for spinach. In this case, consumers substituted lettuce for spinach but also avoided bagged salads that did not contain spinach. More specifically, over a period of 68 weeks, retail sales decreased by 20% for bagged spinach and by 1% for bulk spinach (31).

As shifts in consumer demand for products vary in response to outbreaks caused by different types of contaminated products, consumers'

purchasing habits also differ depending on the type of pathogen contaminating a food. For example, two outbreaks associated with cantaloupes occurred in successive years, 2011 and 2012. In the 2011 outbreak, the contaminating pathogen was *L. monocytogenes*, which caused 33 deaths (32). In contrast, in the 2012 outbreak, the contaminating pathogen was *Salmonella*, which caused only three deaths (33). When consumers learned of the 2011 cantaloupe outbreak with its high fatality rate, the demand for cantaloupes decreased and consumers substituted other melons. In contrast, the consumer response to the 2012 cantaloupe outbreak, with the lower fatality rate, exhibited no shift in demand for cantaloupes (34).

Foods Consumers Prefer That Pose a High Microbiological Food Safety Risk

Consumers' food preferences largely determine the types of foods that the industry produces and that are sold at retail. The food industry has relied in the past largely on product sales to influence its product development and production focus. However, in this digital age, industry is also listening to the conversations on social media where consumers voice their viewpoints and concerns. In response, the industry is making changes such as product reformulation by providing more "natural-like" foods that do not contain many of the food additives that have been commonly used to preserve freshness, flavor, and texture, enhance color, and reduce spoilage to extend shelf life. Consumers, especially the younger generation, want foods that not only look and taste good but are also healthful. In some cases, these choices reflect the advice given by nutritionists and the medical field. However, in other cases, consumers are basing their decisions on misguided, nonfactual information and can be increasing their risk of acquiring a foodborne illness. In the following sections, some of the food groups that have recently been surging in the marketplace due to consumer demand are discussed with regard to their microbiological safety risk.

Fresh Produce

Many public health organizations both in the United States and globally promote the consumption of fruits and vegetables as important components of a healthy diet to help prevent major diseases (35). As a

result of these advisements, the U.S. per-capita consumption of fruits and vegetables has had moderate growth. In the period between 1998 and 2008, the per-capita consumption increased 6% and 5% for fruits and vegetables, respectively (36). However, during that same period, produce accounted for 47% of reported foodborneillness outbreaks in the United States (37). Their percapita consumption has continued to increase since that period (increases of 8% and 1% occurred between 2008 and 2016 for fruits and vegetables, respectively), and outbreaks attributed to fresh produce have likewise continued to occur. Of concern is that many fruits and vegetables are ready to eat and do not receive an adequate antimicrobial intervention treatment to reduce or eliminate enteric pathogens.

A number of other challenges encountered by the produce industry that are of concern include the following: (i) the majority of fruits and vegetables are grown in fields, where they are exposed to the natural elements (i.e., precipitation runoff, wild animals, and bioaerosols) that could potentially introduce pathogens to the crops, and (ii) surveys monitoring the prevalence of pathogens on fresh produce have revealed very low levels of contamination, so detecting and removing contaminated fruits and vegetables through routine product testing are very difficult. The produce industry has attempted to address the issue of produce having a high microbiological risk of contamination by focusing on prevention, with water, soil amendments, and field workers' sanitation practices being the primary points of intervention for minimizing introduction of pathogens into the fields.

Initial prevention efforts were guidelines known as good agricultural practices, but these were not mandatory in the United States. Then, as part of the Food Safety Modernization Act (FSMA), the produce safety rule, finalized in 2015, established for the first time science based minimum standards for the safe growing, harvesting, packing, and holding of fruits and vegetables for human consumption. However, to avoid the excessive economic burden that implementation of these measures would impose on small farmers, exemptions based on the farm's income from its produce sales were specified in the rule. Therefore, a large portion of the locally grown produce purchased at farmer's markets is not likely to be subjected to the standards established in the produce safety rule. These exemptions do not mean that on-farm

food safety measures are completely absent from these market sources. In many cases, they are subject to local and state requirements, but the degree of rigor of those requirements varies from location to location (38). To date, studies comparing the prevalence of pathogen contamination in produce from farmers' markets versus other retail sources have been inconclusive. More specifically, Young et al. (39) identified two studies in their scoping review where a higher prevalence of either *Campylobacter* or *Salmonella* was found in produce from farmers' markets than in produce from other sources, whereas in another two studies that they identified, no difference in the prevalence of *E. coli* was found in produce from these different sources. However, these results may change if the food safety standards applied by most of the produce industry are more effective in reducing the levels of contamination. Consumers should be advised that when purchasing or consuming locally grown produce, they should determine that the vendor is both knowledgeable and diligent in applying safe food production and handling practices in their operations.

Ethnic Foods

Immigration brings cultural diversity to countries, and as part of the immigrants' heritage, traditional foods from their homeland are often desired and are imported to meet the demand (40). Moreover, many of these new residents open restaurants featuring their unique cuisine. The popularity and growth of ethnic foods worldwide are well documented (41, 42). However, along with the increased popularity of ethnic cuisines, there has been an increasing number of foodborne illnesses in the United States (41, 42). At least one factor contributing to this finding is that food code violations for ethnic restaurants are substantially more numerous than those for nonethnic restaurants (43). Several reasons have been proposed to explain the higher microbiological risk of eating ethnic foods, including the following: (i) a large proportion of ethnic restaurants use unfamiliar ethnic ingredients (44); (ii) some types of ethnic restaurants use a large portion of ingredients that are considered to have a higher microbiological risk, such as fresh vegetables in Mexican food or raw fish in Japanese food (41); (iii) employees may lack the knowledge of how to prepare safe ethnic foods (e.g., fried rice prepared from kernels contaminated with *Bacillus cereus*) (44); and (iv) language barriers may

prevent effective communication of safe food preparation practices to owners and employees of ethnic restaurants (44, 45).

Raw Milk and Products Made from Raw Milk

Raw milk contains a diverse microflora which can include pathogens transmissible to humans. In the United States, interstate retail sales and distribution are not allowed, and within many states, raw milk retail sales of any kind are prohibited. Despite these strict regulations, a perception has persisted for many years that a heat treatment used to pasteurize milk destroys some of its nutritional and health benefits (46) and has likely been a major factor contributing to the fact that 3.4% of Americans drink unpasteurized milk (47). A closer examination of the basis for these nutritional claims reveals that they are largely based on anecdotal evidence, and when scientific studies have been conducted, the experimental design was either weak or questionable (48). In fact, many of the beneficial properties attributed to drinking raw milk, such as having a greater nutritional value than pasteurized milk, have been determined to be minimal when milk is stored at refrigeration temperature.

The nutritional benefits of drinking raw milk stored above refrigeration temperatures, when growth of lactic acid bacteria produces health-benefiting antimicrobials, is negated by the simultaneous acidification and coagulation of milk, reactions which render the product spoiled and unsuitable for consumption. Moreover, there is in fact an increased risk associated with consumption of unpasteurized milk products compared to that of pasteurized milk products, as evidenced by the nearly 3-fold-higher incidences of outbreaks with the former than the latter during the period from 1993 to 2006 (49). A comparison of more recent data shows that the number of U.S. foodborne-illness outbreaks caused by unpasteurized milk increased from 30 during 2007–2009 to 51 during 2010–2012 (50). Considering all of these factors, most food safety professionals consider drinking raw milk to be a substantially greater public health risk than drinking pasteurized milk (51). However, some consumer groups, not trusting health officials' recommendations regarding consumption of raw milk (46), continue to promote raw milk as a product that is superior to pasteurized milk. Moreover, these raw-milk proponents have used the Internet and social media channels to

disseminate their message, resulting in a surge in the popularity of drinking raw milk.

As with raw milk, consumer interest in consuming dairy products made from raw milk (cheese, butter, cream, and buttermilk) has also increased. One of the main drivers for the popularity of raw-milk cheese is that it is considered to have more intense and varied flavors than cheese made from pasteurized milk. Several recently published review articles have addressed the microbial benefits and risks of dairy products made from raw milk (52, 53). The overall consensus is that the microbiological risks associated with cheese made from raw milk are reduced when the cheese is aged (cured) for sufficient time at temperatures that minimize the growth of pathogens (53). Thus, U.S. federal guidelines mandate that raw-milk cheese be held at a temperature of not less than 35°F (1.7°C) for at least 60 days (54) based on information indicating that pathogenic microbes should be inactivated by the low pH, low water activity, high salt, and competitive bacteria dominant in the ripening cheese (55). Several studies have revealed that when cheese is manufactured under such conditions, there is a very low prevalence of pathogens in these products (55, 56). Furthermore, outbreak data from the United States between 1993 and 2006 suggest that raw-milk cheeses do not appear to present a greater microbiological safety risk than cheeses made from pasteurized milk, as 38 (42%) and 44 (49%) of the 90 foodborne outbreaks were attributed to these dairy products, respectively (57). However, closer examination revealed that the outbreaks involving cheese made from pasteurized milk occurred in venues where cross-contamination was a likely vehicle (57). In addition, studies have revealed that a 60-day aging period did not guarantee complete control of *E. coli* O157:H7 in cheeses manufactured from raw milk contaminated with initial population levels as low as 33 CFU/ml (58, 59). Moreover, in light of the 2013 *E. coli* O157:H7 outbreak in Canada that was linked to aged (60-day) raw-milk Gouda cheese (60), the contribution of other potential factors (e.g., cheese type, composition of the raw-milk microbiota, and type and level of the pathogen isolate) needs to be more thoroughly investigated. Thus, aging of raw-milk cheese may not be regarded as a fail-safe solution to produce a risk-free product (53), and appropriate warnings should be provided to consumers.

Antimicrobial Preservative-Free Foods

A reason that consumers desire raw milk is that they perceive it as "natural." Also included in this natural food group are non-genetically modified foods (61) and foods where chemical additives are absent or processing of the foods has been minimized (62). Many surveys have confirmed the popularity of this movement (63). In reality, naturalness is difficult to quantify or measure, especially since the term is not regulated and the aspects that are considered essential in perceiving a food item as natural vary among consumers and different stakeholder groups (63). However, three categories have emerged as components of a food to be classified as natural: (i) the origin of the food or the way the food has been grown; (ii) the extent to which technology and ingredients have been applied to the food (in other words, how the food has been produced); and (iii) the properties that constitute the final product (63).

The food industry has responded to consumers' food preferences as they have evolved. Three major approaches have been taken to address consumers' concerns regarding the inclusion of synthetic food additives, specifically antimicrobials, in their products. The first was to change on the package label the terminology used to describe the antimicrobial (62). For example, in the European Union, an added chemical is listed by its name rather than by its "E" number, given that consumers perceive E numbers as being artificial. Another labeling change has been to use a "clean label" version of the chemical being added (i.e., the label contains recognizable ingredients) rather than identifying the active agent itself (e.g., using the term "vinegar" or "egg white" instead of "acetic acid" or "lysozyme," respectively) (62).

The second approach to addressing consumers' concerns regarding synthetic additives in foods involves removing antimicrobials from product formulations; however, most consumers are not aware of the functions of these ingredients (62). More specifically, antimicrobials serve a useful purpose not only in controlling harmful microbes that may be in foods but also in preventing the growth and metabolic activity of spoilage organisms. The repercussions of eliminating antimicrobials from food product formulations include (i) shorter shelf lives resulting from spoilage occurring sooner, (ii) increased risk of survival and growth of pathogens, (iii) increased risk for mycotoxin production, (iv) more consumer complaints as consumers fail to recognize changes to expiration dates, (v) higher prices as changes in formulations and

distribution practices need to be implemented, and (vi) increased food waste due to microbial spoilage (62).

A third approach to addressing consumers' concerns regarding synthetic additives in foods is to replace the synthetic chemical with natural sources of antimicrobials (e.g., essential oils) or bioprotective cultures (e.g., lactic acid bacteria). However, there are shortcomings to using this approach (62). First, these natural sources of antimicrobials can contain multiple antimicrobials, some of which are more effective than others (64). Furthermore, given that these natural sources are derived from biological systems and may be subject to variations in environmental conditions and other factors affecting biological variability, the proportion of the active antimicrobial constituents within the natural source may vary considerably, leading to variable antimicrobial efficacies. Another challenge is that many of these natural antimicrobial sources often have low concentrations of the antimicrobials and have potent aromatic or flavor compounds associated with them. Hence, to achieve antimicrobial activities comparable to those of the synthetic chemicals, large amounts of the natural preservative must be added but may simultaneously introduce undesirable aromatics or flavors into the product. An example is the use of cranberry concentrate to serve as a natural source of benzoate to control mold and pathogen growth. The relatively large amount of cranberry concentrate needed to provide the level of benzoate to control the microbes would add undesirable flavor to the finished product. Another example is cured meats. Instead of adding nitrites directly to cured meats to control pathogens such as *Clostridium botulinum* and *Clostridium perfringens*, celery juice concentrate, which is a natural source of nitrate that is converted to nitrite in the meat by microbial activity, is added. However, to avoid compromising the flavor with the celery concentrates, lower levels of nitrite were added from the celery concentrates. As a result, there was a greater potential for *C. perfringens* to grow when the meats were cooled, thereby increasing the microbiological risk in these cured meats relative to the risk in products that had synthetic nitrite added (65).

Innovative Approaches Needed To Provide Consumers Credible Food Safety Information

Over the past 2 decades, social media communication has evolved such that consumers often obtain unreliable information regarding the safety of their foods. To enable consumers to make informed decisions, food safety professionals need to challenge unsubstantiated claims and provide credible, science-based information. However, an underlying complication is that safe food handling behaviors and perceptions occur as part of a complex interaction of everyday consumer practices and habits. Moreover, most consumers are not concerned about food safety practices in the home and are generally not motivated to change their behavior based on new knowledge about food safety risks (66). Hence, to overcome these barriers, innovative approaches are needed to educate the younger generation, although traditional approaches may be sufficient for educating the older generation. Both stakeholders and experts agree that social media could be an effective tool in crisis communication and issue awareness, as they offer speed, accessibility, and the potential for changing food habits through social pressures (66–69). However, to minimize information overload and to overcome the low levels of trust associated with many Internet and social media sites (70), it is important for educators to not only capture the initial attention of visitors to the site but also instill trust and confidence with information presented within that site. An example is an approach used by Sillence et al. (71), focused on unpasteurized raw milk, which revealed that good website design was only one component to an effective Internet site. Another important element is its content, which should be of personal and social relevance in describing the risks and benefits of the food product being addressed.

IMPORTED FOODS

Globalization of the world's food supply has been beneficial to both importing and exporting countries, with a variety of supply- and demand-side factors driving the marketplace. Many of the importing countries in this global marketplace are developed countries, whereas many of the exporting countries are developing nations. Consumers in developed countries desire a year-round supply of seasonal fruits, vegetables, and nuts, as well as ethnic foods. Hence, these items are largely supplied by many developing countries where these foods are available. Developing nations are also able to provide these foods at reasonable costs, as they have low land values, water availability where needed, appropriate

climate conditions, and cheap labor. The book *Imported Foods: Microbiological Issues and Challenges* (72) describes the trends of foods imported into the United States during the early 2000s, as well as the weaknesses inherent in the food safety net and programs designed to mitigate those deficiencies (72). The remainder of this section updates the trends relating to food imported into the United States and the continued deficiencies that exist with this part of the U.S. food supply.

Food Groups Representing the Greatest Microbiological Risk

Thirty-two food groups are used by the FDA's OASIS (Operational and Administrative System for Import Support) to categorize foods imported into the United States. The food groups that represent the greatest microbiological safety risk are often those that have the greatest number of total shipments refused. On that premise and based upon the recent summary prepared by Bovay (73), the top four groups and the percentages of the total food shipments refused by the FDA between 2005 and 2013 that they constituted were (i) fishery and seafood products (20.5%), (ii) vegetables and vegetable products (16.1%), (iii) fruit and fruit products (10.5%), and (iv) spices (7.7%). However, refusals may not always be attributed to the microbiological violation codes, which include the following: (i) *Salmonella*, (ii) filthy, (iii) insanitary, (iv) *Listeria*, (v) histamine, and (vi) "imptrhaccp" (described as failure to provide verification of compliance of sanitary conditions during preparation, packing, or holding). In any case, among these four food groups, 83% of the total violations were attributed to a pathogen or toxin (73). Despite this association, refusal statistics may not be used as conclusive evidence that these food groups have a greater microbiological safety risk due to the preferential sampling that is assigned to specific food groups. The FDA has not had the resources to physically inspect all food import shipments, and in fact, they physically inspect less than 1% of all regulated food imports into the United States (74). Hence, to obtain the maximum benefit from the inspections that are conducted, the FDA uses a risk-based prediction algorithm to target shipments posing what is considered a greater risk to human health or that are more likely to be in violation of U.S. laws.

Another approach to identifying specific imported food groups that are of greater microbiological risk than other food groups is to consider foodborne-illness outbreak data collected by the CDC between 1996 and 2014 (75). The food groups that accounted for the greatest percentage of outbreaks and illnesses within the United States using this data set are listed in Table 42.2.

Magnitude of U.S. Imports of Selected Food Groups

Focusing on the food group that accounts for more than half of the outbreaks listed in Table 42.2 (i.e., seafood and fish), it is noteworthy that more than 90% of the seafood and fish consumed in the United States in 2017 was imported (76). Moreover, the major countries of origin for most farmed seafood and fish products, such as shrimp and tilapia, are developing countries (Table 42.3), with the U.S. per-capita consumption of shrimp and tilapia being 2.0 and 0.5 kg/year, respectively, in 2017 (77). Of concern is that these countries are known to employ sanitary practices in production and processing that are inferior to those employed in developed countries (78). Food safety hazards that may be potentially encountered in these countries are addressed in greater detail in the following section.

Table 42.2. Imported food groups that have accounted for the greatest percentage of foodborne outbreaks and illnesses within the United States between 1996 and 2014[a]

	% of imported food-related:	
Imported food group	Outbreaks	Illnesses
Fish, mollusks, crustaceans, other seafood	55	11
Fruit	12	32
Vegetables (row and seeded)	10	29
Spices	2	5
Nuts/seeds	3	1
Other	18	22

[a] Adapted from table in reference 75.

Three other major food groups from which one-quarter to over one-half of the U.S. imported food supply came in 2016 were fruit, fruit juices, and vegetables. However, within each group, the import share of individual commodities varied greatly. For example, in 2016, the import share (percentage of the total) of head and leafy lettuce was only 6% and 4%, respectively, whereas for the vegetables listed in Table 42.4, they ranged from 14% to 90% (36). Per-capita consumption of the commodities is also provided in a column in Table 42.4 to illustrate the amount of each imported commodity that Americans consume. Of the major countries exporting these fruits and vegetables to the United States, more than 65% of the total imports are from developing countries (Table 42.5).

Table 42.3. Source countries of U.S. shrimp and tilapia in 2018 based on volume[a]

Shrimp		Tilapia	
Country	% of total imported[b]	Country	% of total imported[c]
India	36	China (mainland)	75
Indonesia	20	China (Taiwan)	6
Vietnam	10	Honduras	4

[b] Domestic and imported.

[c] Values obtained by multiplying total per capita consumption by the % imported of total supply.

Spices are another food group that has had many shipment refusals. In addition, several outbreaks of foodborne illness have been traced to imported spice contamination (Table 42.2). As with the food groups described above, a large percentage of spices consumed in the United States are imported (79), with developing countries being the primary sources (Table 42.5). Since the U.S. per-capita consumption of spices in 2012 of 1.5 kg/year (80) is likely to increase as consumers demand more preservative-free food, pathogen contamination could be amplified because of the many additional foods that will contain spices as an ingredient. An additional complication is that spices are often a "stealth ingredient" in foods, in that they are not known to be added to a food associated with an outbreak and, hence, are not identified as the source of an outbreak. Therefore, spices are more likely to be frequent sources of foodborne illnesses than is being recognized.

Table 42.5. Top six sources and their percentage of total U.S. imports (based on U.S. dollar value) for selected food groups in 2017[a]

	Fruit and preparations[b]		Vegetables (fresh)		Fish/shellfish		Spices	
Rank	Country	% of total	Country	% of total	Country	% of total	Country	% of total

[b] Includes fresh, frozen, dried, preserved, and prepared fruit and fruit juices.

Production and Sanitation Practices within Developing Countries

Developing countries represent most of the major exporters to the United States of the types of imported foods most often associated with foodborne illnesses and outbreaks (Tables 42.2 and 42.5). Similarly, across all food groups imported into the United States and using value (in U.S. dollars) as the measure of ranking, 11 of the top 15 sources were from developing countries in 2016 (Table 42.6). However, developed countries may export more highly valued items than developing countries. For example, one of the major foods exported into the United States from Canada is salmon, whereas tilapia, which is a less expensive fish, originates mainly from China. Hence, although Canada ranks higher than China for value of imported fish and shellfish (Table 42.5), China must have a larger proportion of the import volume, which translates to greater product exposure and potential adverse public health risks.

Several factors contribute to concerns regarding the microbiological safety of imported foods from developing countries. These concerns are based on two major sources of information: (i) outbreaks that have been epidemiologically linked to foods imported from these countries and (ii) surveys of both imported and domestically produced foods from these countries as well as surveys of practices and knowledge associated with producers of these foods. Selected examples of various microbiological food safety risks associated with specific imported food groups are listed in Table 42.7.

Table 42.6. Major source countries of U.S. food imports in 2017 based on U.S. dollar value[a]

Country	% of total food imports
Mexico	23.0
Canada	18.4
European Union	18.2
China	3.7
Indonesia	3.1
Brazil	2.7
Australia	2.7
Chile	2.4
Colombia	2.2
India	2.2
New Zealand	2.1
Thailand	2.0
Vietnam	2.0
Guatemala	1.7
Peru	1.6

[a] Information extracted from spreadsheets in reference 36.

One of the common deficiencies contributing to an increased likelihood that the food produced or processed in developing countries will be contaminated is the absence of adequate regulatory oversight and enforcement of good hygienic practices (81). Under such conditions, food producers and processors often do not have an adequate incentive to obtain the necessary knowledge and resources to implement sanitation and good agricultural practices that would reduce the likelihood of contamination.

Another major limitation for many developing countries is the use during production of water that is contaminated with pathogens, which is a result of those countries lacking the basic infrastructure to treat the wastewater used in food production and processing (82–84). In other cases, the use of animal waste-contaminated water in agriculture is

recommended by some sustainability-conscious advocates as beneficial from a sustainability perspective, while the potential associated food safety risks are not recognized (85). For example, in one type of integrated multitrophic aquaculture system, animal wastes are dumped into ponds, where the farmed fish may directly feed on the feces or the feces may serve as a nutrient source for algae and plankton, which the fish then consume. In either case, those fecal wastes may introduce enteric pathogens into the pond environment if the animals are carriers of human pathogens such as *Salmonella* and enterohemorrhagic *E. coli*. The extent to which the addition of fecal wastes leads to an increased prevalence of contaminated fish appears to be dependent on the type of pathogen or indicator microbe and the potential for the pathogens to survive in the environment or be introduced from other environmental sources (Table 42.7). The increased interest in integrated multitrophic aquaculture systems among countries within the European Union has led to the realization that in order to utilize products produced in these systems, substantial regulatory reform and oversight are needed (86).

Another common practice of many aquaculture producers in developing countries is the indiscriminate use of antibiotics to prevent disease in fish and shrimp. For example, Vietnamese shrimp farming has been adversely affected by several diseases, which has led to extensive use of antibiotics as a prophylactic. In addition to the potential for antibiotic residues to be present in the exported seafood (87), incomplete assimilation of the antibiotics by fish leads to high levels remaining in ponds, sediments, and the surrounding environment (88). Such residues, whether in fish or the environment, at subtherapeutic levels pose a major risk for the proliferation of antibiotic-resistant bacteria, including foodborne pathogens such as *Salmonella* (89, 90).

Table 42.7. Reported instances of microbial contamination of imported foods or food raised or grown in developing countries being documented or being a subject of concern

Food item(s)	Key points of survey, incident, or study
Fish, aquacultured	Similar levels of *E. coli* were found in the muscle of fish raised in integrated pig-fish ponds and nonintegrated fish ponds. In contrast, *E. coli* levels in the intestines were 100 times higher in fish from integrated than nonintegrated ponds (125).
Tilapia	No significant difference in the occurrence of *Salmonella* spp. was found in fish raised in traditional nonintegrated and integrated tilapia-pig aquaculture systems (manure from pigs serves as fertilizer in the ponds). In the integrated systems, *Salmonella* spp. were found in 20.0%, 40.0%, and 11.1% of fish mucus, fish intestine, and pig feces, respectively, whereas in nonintegrated systems, the pathogen was found in 40.0% and 40.0% of fish mucus and intestines, respectively. Commercial feed could not be linked to the common genotype of *Salmonella* found in both systems and suggested that *Salmonella* may be able to survive and possibly multiply in tropical aquatic environments (126).
Shrimp	Use of antimicrobials to treat diseases, most commonly due to *Vibrio parahaemolyticus*, can lead to development of antimicrobial-resistant microbes. In addition, when the antimicrobial treatment is not effective to stop the outbreak, many shrimp farmers harvest the shrimp early (127).
Seafood	Intermediate resistance to ampicillin was exhibited in 63% of *V. parahaemolyticus* isolates recovered from 21% of shrimp samples (n = 38) imported into the U.S. Resistance to nitrofuran was found in 75% of *L. monocytogenes* isolates recovered from 42% of salmon, shrimp, and tilapia samples (n = 171) imported into the U.S. (128).
Lettuce	Prevalence of norovirus, rotavirus species A, or human adenovirus collected from irrigation waters and lettuce at

	three to five sites in Brazil ranged from 17 to 50% and 25 to 42%, respectively (84).
Snap peas	An outbreak in 2005 of *Cyclospora cayetanensis* in Ontario, Canada, was linked to the consumption of snap peas imported from Guatemala (129).
Berries, frozen	A prolonged outbreak (2013-2014) occurring primarily in Italy was epidemiologically linked to imported frozen berries (130).
Produce, fresh	A review documents the numerous outbreaks associated with the consumption of fresh produce that was imported from developing regions and contaminated with the protozoan parasites *Cryptosporidium*, *Giardia*, and *Cyclospora*. The possible sources of contamination and control measures are discussed (131).
Spices	The U.S. FDA conducted a survey on the prevalence of *Salmonella* in 11 spices with □1% found in product offered for sale at retail establishments but ranging from 1.7 to 18% in products entering the U.S. (132).

Efforts To Improve the Safety of Foods Exported from Developing Countries

Although food produced and processed in developing countries and exported to global markets is advantageous for many factors driving the supply chain (e.g., low land values, water availability for some locations, appropriate climate conditions, and cheap labor), unsuitable production and processing practices that do not comply with the food safety standards established by an importing country can prevent an industry from exporting products to other countries. Multiple factors contribute to this situation, including outdated laws, lack of knowledge in the industry due to limited or inadequate coordination and communication with organizations handling food safety issues, underfunding of national research institutes that can provide practical solutions to food safety-related deficiencies, and lack of awareness of food standards and quality criteria (91).

Many approaches are being taken to improve the microbiological safety of foods being exported by developing countries. Historically, private

enterprise has been an external driving force that has successfully incorporated safe food production and handling practices into the food production and processing operations of developing countries, but the level of involvement and enforcement of internal policies varies (92). At one end of the spectrum, there can be complete involvement at all phases of the food continuum (production, processing, and transportation) in applying preventive controls to prevent hazards from occurring, but at the other end of the spectrum, where the smallest amount of control over safety of imported foods occurs, the private enterprise selects their suppliers and routinely monitors by inspecting and testing the safety of the incoming foods. Because only a small percentage of the imported food can be adequately inspected and tested, unacceptable products can enter the food supply.

Another approach to improving a developing country's food safety practices is for the country to develop and implement regulations that specifically address food safety practices. Examples of countries where this approach has been successively applied are Malaysia (93) and Thailand (94).

Governments and private enterprises are not the only organizations involved in setting food safety-related criteria for food exports from developing countries. Many nongovernmental organizations (NGOs) have developed certification criteria (95, 96). An example is the Global Good Agricultural Practices (GLOBALG.A.P.) program in Germany that is a certification process for many agricultural products, including those from aquaculture. Another NGO, the Global Aquaculture Alliance (a U.S. organization representing aquaculture producers, seafood traders, and major restaurant chains) created the Aquaculture Certification Council to certify that aquaculture facilities throughout the world were applying responsible and established social, environmental, and food safety standards. However, it is important to recognize that not all NGOs address food safety issues. For example, the Aquaculture Stewardship Council's certification standards primarily address environmental stewardship and working conditions for producers (96). Nevertheless, to encourage food retail corporations to address food safety as well as social and environmental responsibility, the criteria of many NGOs include required third-party audits and certification rather than self-reporting or certification by business partners (96). However, to meet these

requirements, access to these certification bodies is critical. For example, Mohammed and Zheng (97) determined that distance between the food producer and the certifying organization negatively affected the number of certified sites in a country. Thus, developing countries in Africa and Asia would be at a disadvantage in adopting food safety standards, as they would likely be faced with higher certification costs due to this disparity.

In many developing countries, it is recognized that advances to their food safety system will require a multifaceted approach (98). For example, to encourage farmers in China to comply with higher product safety and quality standards, a survey revealed that a small price increase would be a sufficient incentive to change their practices (99). In other cases, countries may need to obtain sufficient capital before they can provide the basic infrastructure to establish and maintain basic clean water and sanitation practices (98). In countries such as Vietnam, where more than 330,000 small-scale shrimp producers contribute to a very fragmented supply chain (96), it is currently difficult to provide adequate tracking documentation regarding compliance with certification, and addressing this deficiency will require an innovative approach.

For foreign suppliers of food products to the United States, restrictions that are included within the Foreign Supplier Verification Program (FSVP) of the FSMA are now mandated. The compliance date for this rule was 30 May 2017, and it requires that importers perform certain risk-based activities to verify that food imported into the United States has been produced in a manner that meets applicable U.S. safety standards. Moreover, to reflect modern supply and distribution chains, the rule offers importers flexibility in meeting key FSVP obligations in that they may rely on certified third parties to provide the required analyses, evaluations, and activities as long as those importers review and assess the corresponding documentation (100). Additional information on the FSVP is provided in Table 42.8 and in “Current Outlook and Impact” below.

RECENTLY ENACTED REGULATORY AND POLICY CHANGES TO IMPROVE FOOD SAFETY

U.S. Food Safety Modernization Act

In 2011, the FSMA was signed into law with the purpose of improving public health within the United States by strengthening the country's food safety system. In particular, it sought to provide the FDA, who has oversight of more than 80% of the U.S. food supply, with new enforcement authorities. With these new powers, the FDA would then be able to proactively protect the food supply rather than continuing to react to problems after they occur. In response to the FSMA's mandate, seven foundational rules have been written that encompass different aspects of the food supply chain. They are (i) current good manufacturing practices and hazard analysis and risk-based preventive controls for food for animals; (ii) current good manufacturing practices and hazard analysis and risk-based preventive controls for human food; (iii) standards for the growing, harvesting, packing, and holding of produce for human consumption (produce safety rule); (iv) foreign supplier verification programs; (v) sanitary transportation of human and animal food; (vi) accredited third-party certification; and (vii) mitigation strategies to protect food against intentional adulteration (101). Specific areas covered within several of these rules are provided in Table 42.8, whereas summaries and access to the complete documents published in the *Federal Register* can be found on the FDA FSMA website (101).

Table 42.8. Major sections and provisions specified in three of the seven rules that were mandated in the FSMA (100, 102, 133)

- HARPC for human food rule (reassessment every three years)
  - Updates to the current good manufacturing practices
    - Employee hygiene training required
    - Confirmation that employees qualified for assigned duties
  - Food safety plan (prepared by qualified individual)
    - Hazard analysis
    - Written preventive controls (process, allergen, sanitation, and other controls)
    - Oversight and management of preventive controls (monitoring, corrections, documented corrective actions, documented verification of controls—e.g., scientifically validating preventive process controls)
    - Supply chain program to address hazards
    - Written recall plan if hazard identified
- Produce safety rule
  - Agricultural water for produce (other than sprouts)
    - Microbial water quality (target organism and numerical criteria)
    - Indicate options for corrective actions
    - Microbiological testing
  - Biological soil amendments
    - Raw manure
    - Stabilized compost
  - Domesticated and wild animals
  - Worker training and health and hygiene
  - Equipment, tools, and buildings

    - Sprouts
        - Prevention of microbial seed contamination
        - Testing of spent irrigation water
        - Testing sprout environment for *Listeria monocytogenes*
        - Corrective actions if out of compliance
- Foreign supplier verification program rule
    - Scope
        - Overview of who is covered
        - General responsibilities of food importers
    - Hazard analysis (identify potential hazards [biological, chemical, physical] based on experience and database of food item)
    - Evaluation of food risk and supplier performance by importer or certified third party
    - Supplier verification either by importer or certified third party (e.g., on-site audits, review of supplier records, sampling and testing)
    - Corrective actions
    - Exemptions and modified standards
    - Unique facility identifier

Before the FSMA foundational rules were drafted, extensive input was obtained from the industry, the public, and other stakeholders through public meetings, webinars, and listening sessions with the intent that the final rule be practical and flexible but effective. As a result, dates of implementation have been staggered depending on when the final rule was published and to give sufficient time for different segments of the industry to implement changes (i.e., smaller companies were given more time to adapt, as it would likely impose a greater financial burden on them). However, one of the overarching themes encompassed within these rules is that whenever possible, science-based preventive controls

should be used to minimize hazards in the production, processing, transport, and storage of food. However, in some cases, such as the produce safety rule, insufficient data were available to make a risk-based recommendation on application times of raw manure relative to harvest of the produce. Hence, it was decided that adherence to the USDA's National Organic Program standards could be used until sufficient data were collected to evaluate whether to continue with those metrics or adopt more stringent metrics (102).

Other common components within the seven foundational rules are delineation of the tools that will be used by the FDA to ensure compliance by commercial entities within the food chain. Examples include mandated inspections by the FDA of food facilities, expanded requirements for industry to have available written documentation of their preventive plans and activities, and authorization for the FDA to issue mandatory recalls when unsafe food is not recalled by companies voluntarily as well as to suspend a company's registration, prohibiting it from distributing food.

Although all FSMA foundational rules are anticipated to lead to substantial improvements in the safety of the U.S. food supply, the use of hazard and risk-based preventive controls (HARPC) for human food is among the most important of the FSMA rules. This rule is a successor to the hazard analysis and critical control points (HACCP) system that the U.S. food industry had been observing and emphasizes prevention of hazards before they occur rather than their remediation after they occur. To illustrate this point, some of the differences that exist between HACCP and FSMA-HARPC include the following: (i) FSMA-HARPC places a much greater emphasis on science, research, and prior occurrences of outbreaks than does HACCP; (ii) an FSMA-compliant food safety plan must be prepared and overseen by a qualified employee at each facility; (iii) good manufacturing practices, allergen controls, integrated pest management, and vetting suppliers are expected to be integral components in FSMA-compliant food safety plans to a greater extent than they were in HACCP plans; (iv) in place of corrective actions, corrections that involve minor improvements and require less documentation to the food safety plan are allowed; (v) a food defense component must be a part of the plan and must address both terrorism and economically motivated adulteration; (vi) in addition to chemical, biological, and physical hazards

that were covered in HACCP systems, radiological hazards must also be addressed within the food safety plan; and (vii) preventive controls include all control points appropriate for food safety but do not require critical limits, as they did in HACCP systems.

Another FMSA foundational rule that is anticipated to have a major impact on reducing food safety risk is for the produce industry. More specifically, the produce safety rule provides enforceable standards for the production of minimally processed fresh produce, whereas, prior to the adoption of this rule, such criteria did not exist. Instead, only nonenforceable good agricultural practices and good manufacturing practices guidelines and guidelines developed by trade associations were being followed by much, but not all, of the produce industry. Within the specifications of the new produce safety rule, there are several concerns. One concern is the costs of complying with the new rule, as it could disproportionately burden small farms and drive them out of business. Hence, multiple studies have been conducted to address the cost that has been or will be incurred as a result of implementing either the food safety criteria of the California Leafy Greens Marketing Agreement (LGMA) or the standards of the produce safety rule. Major findings of those studies are listed in Table 42.9, but in general, compliance costs were determined to be marginal, although there were economies of scale (i.e., expenditures per acre decreased with increased farm size).

For this reason, the FDA chose to exclude from compliance farms whose annual produce sales were less than $25,000 for the three preceding years. Included in this category would be many local operations that engage in sustainable practices, community engagement, and direct farm-to-table networks (farmers' markets and roadside stands). Although these farms represent a small portion of total acres devoted to growing produce, they are growing in popularity each year (103). Unfortunately, many of these growers do not have a food safety plan, not because of financial constraints, but because they are not required to do so under the FSMA (104). Moreover, the growers selling their produce in direct market channels may not have the requisite knowledge to engage in practices that would ensure the safety of their products (39). Although the number of individuals made ill from consuming contaminated produce from these sources may be small compared to the number affected by outbreaks associated with commercial retail brands, negative publicity from a

produce-associated outbreak from a small farm may spread to include other types of produce grown in the area or even to other areas of the country, thereby adversely affecting produce sales in general.

Table 42.9. Costs associated with implementation of on-farm food safety standards within the LGMA or the FSMA produce safety rule

Location	Produce item(s)	Major findings	Reference
California	Muskmelon, spinach, tomatoes	Costs incurred by produce due to food safety outbreaks are much greater than LGMA compliance costs. Third-party audits, staffing, and water testing were the most significant compliance costs.	134
Florida	Cabbage	When attempting to meet LGMA standards, the probability of operating at a net loss over a 2-year period (based on values on year in which study was conducted) increased by 17%.	135
California, Florida, and Texas	Cabbage, cantaloupe, citrus, onion, spinach, tomato, watermelon	The cost of complying with the FSMA produce rule was not size neutral and could have negative impacts on the profitability of small farms.	136
Mid-Atlantic	Leafy greens, tomatoes	Based on a survey, adoption of food safety practices similar to those required under the FSMA would impose a fairly modest cost burden on farms of all sizes, but there would be substantial economies of scale.	137
California	Leafy greens	Distribution of costs associated with food safety practices being conducted to meet the requirements of the LGMA were 38% for food safety and clerical staff involved in food safety tasks,	138

		32% for time expended by harvest foreman, 17% for time and other expenditures involved with audits, 11% for product unharvested due to animal intrusion, and 2% for testing of water.	
National, but more farms representing the South and Northeast than West	Vegetables, berries, fruits, and tree nuts	Expenditures per acre decreased with farm size as a result of complying with FSMA produce rule. In addition, growers using sustainable farming practices spent more than conventional growers on many food safety practices.	139

Another concern associated with the produce safety rule is the metrics and frequency of sampling required for the microbial quality of agricultural surface water used for irrigation. These criteria are based on the EPA standards for recreational water, as there are otherwise insufficient data available for establishing standards that would be relevant to surface water, streams, and ponds used for irrigation. Therefore, to address this deficiency, Havelaar et al. (105) sampled six agricultural ponds in west central Florida to evaluate the empirical and theoretical basis of the microbial water quality parameters within the produce safety rule. Their findings revealed that 20 samples were insufficient to determine the bacteriological quality of irrigation ponds and the specified rolling data set included in the rule led to delays in detecting a shift in water quality. Although increasing the number of samples was postulated as a possible solution to this problem, it increased the costs of monitoring. Hence, these researchers advocated that further data collection and analysis be conducted to better understand the factors influencing the variability of the bacteriological quality in irrigation ponds.

Projected Evolution of Regulatory and Policy Initiatives

Current Outlook and Impact

Currently, the FDA does not recognize any food safety program as an alternative to FSMA's produce safety rule. However, in the future, partnerships between industry and government are expected and could pave the way for recognition of alternative compliance and verification programs that will be accepted by the FDA (106). One of the strengths of the FSMA is that it aligns with many regulatory programs adopted in developed nations. In addition, it is compatible with binding international trade rules as well as nonbinding internationally recognized standards set forth by institutions such as the World Health Organization, the World Trade Organization, the Codex Alimentarius Commission, and the Global Food Safety Initiative (GFSI). However, in many cases, industry-driven criteria may be more stringent than governmental regulations (106). Under those circumstances, individual food manufacturers often select a third-party food safety auditing scheme (e.g., GLOBALG.A.P., Primus GFS, Global Aquaculture Alliance, Global Red Meat Standard, etc.) that is recognized by the GFSI. Once the company has passed the audit, the company is then certified against the benchmarked scheme.

There are many advantages to companies going through a GFSI certification process, including the following: (i) it is currently required by many of their current retail customers; (ii) it is an asset that can be used for bringing in new customers; (iii) it reduces the number of third-party food safety audits; and (iv) it facilitates continuing improvement of the company's food safety program (107). However, to date, most companies do not use these third-party certification programs as a marketing strategy to convince consumers that their products are safe. Moreover, in contrast to the newly required foreign supplier verification program and the accompanying program established for accreditation of third-party auditors, the United States does not currently provide any oversight for audits performed on domestic food operations (106). However, if such a system were to be implemented in the future, it would be one more layer of bureaucracy but it would ensure that when deficiencies are identified, corrections are automatically implemented. Another outcome of incorporating into the U.S. federal regulations a mechanism to oversee audits or auditors would be the opportunity to include this on the package label, similar to the USDA label of inspection. Support for implementing such a strategy is based on studies conducted in China and Thailand, where safety claims were viewed as an important

factor by consumers with regard to purchasing the product or a willingness to pay more for the product (108, 109).

One of the challenges confronting the implementation of FSMA concerns its FSVP rule. In contrast to the previous policy regarding imported foods that relied on testing product as it came into the country, the current rule places the responsibility for safety of the food products on the importers who are introducing food products into the United States, and it is those entities that will be held responsible should any food safety problems arise. The justification for the FDA's major departure in their approach to ensuring the safety of imported foods was the increasing volume of food products being imported from foreign countries, limited official capacity to inspect foreign suppliers' sites and imported food at ports of entry, complexity of the food supply chain, and the alarming number of cases of food adulteration by foreign countries supplying food products to U.S. markets, for which China has been the most notorious.

The number of serious incidents of compromised food safety that China has experienced has had an economic ripple effect on its international trade. Hence, in addition to executing violators, China has been engaged in its own changes to its regulatory system to alleviate concerns by countries receiving their food products (110). More specifically, it revamped in 2015 its 2009 Food Safety Law (111). Unfortunately, expectations for several of its goals have not been met. For example, the 2015 amendment aimed to establish a national traceability mechanism for food safety; however, Lin (110) reported that a supply chain approach to food safety regulations, not to mention full traceability, had yet to be adopted. Furthermore, most loopholes present in the 2009 law (i.e., a thin rule of law [discrepancy between laws and enforcement], coordination between central and local governments, and a lack of supply chain approach) continue to be present in the 2015 amendment (110). However, two other mechanisms have played an increasingly important role in improving the regulatory effectiveness of China's food export system: (i) public-private partnerships such as those adopted by the European Union's food safety regulatory system (112) and (ii) the adoption of bilateral agreements between China and multiple World Trade Organization countries, including the United States (110).

In the case of the U.S.-China Food Safety Agreement, and in line with the mandates of the FSMA's FSVP rule, the FDA is now theoretically able to

expand its regulatory boundaries to suppliers in China. More specifically, the U.S.-China Food Safety Agreement incorporates three major components: (i) it provides for confidential exchange of foodborne-illness information as a means to contain and remedy the problem and to minimize the harm that could be inflicted on companies not involved in the incident; (ii) companies within China that export foods to the United States must be registered and be inspected on an annual basis by the Chinese government; and (iii) through offices established in Beijing, Shanghai, and Guangzhou, the FDA is empowered to conduct their own on-site inspections of Chinese companies exporting food to the United States (110). However, criticisms of the agreement are that the framework is based more on economic interests than on public health and that it applies only to specific products rather than all foods (110). Moreover, because of the decision to incorporate outsourcing of its regulatory authority to third parties as a major component of its policy, there is uncertainty as to its effectiveness and accountability. At issue is the structural mismatch between the broad scope of power granted to the FDA and the long chain of power out-sourcing to governments or private companies (i.e., FDA first delegates regulatory authority to accreditation bodies, which in turn accredit third-party auditors, who then certify that producers' food products are safe) (110). Hence, if these concerns materialize, they will likely be addressed in the future as food safety regulations and policies evolve.

Evolution of Food Safety Regulations and Policies

Quantitative microbiological risk assessment (QMRA), a structured probabilistic process for assigning a public health risk to a foodborne pathogen in a food product, has been and will continue to be an integral component in the development of regulations and policies addressing the safety of the world's food supply. Although the individual components within a QMRA have been identified, the degree of the contribution of some of the components may only be estimated. For example, current models are still only in their infancy in addressing the considerable biological variability and uncertainty that exist in food systems. Recent developments in "-omics" technologies (genomics and transcriptomics) may fill the knowledge gaps on pathogen strain diversity, virulence, and physiological variability. As these data gaps are filled and statistical techniques are refined to translate genome-level multidimensional

information into the single dimension associated with the measure of risk (113), QMRAs will become more robust. In turn, there will be greater assurance that the projected outcomes are realistic and could serve as the impetus to change policies if current management strategies are considered either of negligible effect or insufficient to enhance the safety of foods.

At present, the designated standards for the presence of foodborne pathogens within a food are often not consistent between countries, and this highlights the lack of harmonization that exists worldwide. For example, one standard that is not consistently applied between countries, because it is being used in many cases as a trade barrier, is zero tolerance (i.e., the pathogen must be absent from the food). Primarily intended to convey a level of concern in safeguarding the public from consumption of foods contaminated with pathogens, zero tolerance emerged as a target goal in the absence of being able to establish specific thresholds for highly infectious and toxico-infectious pathogens (114). Moreover, in instances when zero tolerance is being used, it is important to understand that it is an operational standard wherein the zero is being defined relative to a sampling plan and testing protocol (114). Otherwise, in the absence of these defining criteria, zero could be a moving target as different groups use different assays with different sensitivities. Zero tolerance will likely continue to be used as a target standard for the immediate future, despite some critics' argument that it is more realistic to reduce to a level that is as low as reasonably possible the prevalence of pathogens in ready-to-eat foods that do not receive a treatment to kill pathogens (115).

Regardless of the current or future criteria that are used to determine which food safety regulations and policies are developed and applied, there must be some measure(s) by which the standards contained within them can be judged to be effective. Presently, there are two main measures: (i) the prevalence of foodborne pathogens in foods or in the environments in which the foods are grown or processed and (ii) the prevalence of reported foodborne illnesses and outbreaks. In the absence of improvements in these measures, critics of the policies may have a valid argument that the costs for implementation of the standards do not provide sufficient public health benefits. As an example of the vulnerability of food safety regulations to such scrutiny, the current U.S.

administration, in line with the view that regulations stifle the economic growth of the country, indefinitely delayed implementation of several key provisions within the FSMA rules (116).

Economic considerations are not the only external force that may determine the type of regulations and their degree of stringency. Other competing priorities, including nutritional and sustainability issues (117), could also influence the type of regulations that would be enacted to protect the food supply. To assist in making decisions as to practices that could affect multiple outcomes (i.e., food safety, operational costs, environmental sustainability, and nutritional food value), a valuable new tool known as multidimensional criterion analysis was recently developed to address such multidimensional issues (118).

CONCLUDING REMARKS

Approaches to enhancing the safety of foods have been evolving over the past decade. As part of that evolution, the implementation of the FSMA is likely to lead to reductions in the microbiological risk associated with foods; however, consumers' desire for foods that carry a high microbiological risk has made it more difficult to achieve that goal. The adoption of WGS as a tool to identify and track pathogens through the food chain has led to the identification of outbreaks that would not otherwise have been detected; however, it is envisioned that over the long term, this tool will ultimately decrease both the number and size of outbreaks. Further advances in food safety are coming, but the degree to which they will be adopted will likely have to be weighed against how they affect other factors that the consumer or industry considers important (e.g., sustainability, nutritional components of the food, costs, convenience, and taste).

Web resources, whole-genome sequencing databasing and subtyping, 976–977
Weissella spp.
genomes, 808
meat fermentations, 891
primary applications, 791
vegetable fermentations, 875–876
White, Bruce, 226

Whole-genome sequencing, 209, 211–212, 215–216, 928, 965, 1049
advances in, 1049–1051
analyzing foodborne-illness outbreaks, 1051
Campylobacter spp., 266, 267–268
Cronobacter spp., 398–399, 400, 401
current limitations of, 1051–1052
laboratory advances, 217–218
Listeria monocytogenes, 980
Salmonella, 978–979
Shiga toxin-producing *E. coli* (STEC), 293–295, 979
Shigella detection, 320
strain characterization, 1019
subtyping methods, 975
use in foodborne surveillance, 930–932
wgMLST, 976
Williams, Jesse, 790
Wine. *See* Cereal wines, spirits, and vinegar
Working Group on Civilian Biodefense, 498

World Health Organization (WHO), 67, 220, 226, 348, 372, 590, 613, 997, 1050
Aeromonas spp., 422
foodborne illnesses, 1007
Global Foodborne Infections Network, 981
growth-promoting antibiotics, 911
Listeria monocytogenes assessment, 467
risk assessment of viruses, 632
Shigella spp., 317, 326
sorbates in food products, 711
trichinellosis, 647
uncertainty guidelines, 998
water guidelines, 1030
World Organisation for Animal Health, 651
Wound and soft-tissue infections, *Aeromonas* spp., 418
Xanthomonas campestris, 331
Yak milk, fermented, 117
Yeast(s)
contaminating crops and processed foods, 182
fermentation, 860–861
formation of flavor volatiles by, 861, 862
meat fermentations, 891
red smear cheese, 884
Yelp!, 216

Yersinia enterocolitica, 437, 446–447
association with foods, 438, 440
cell metabolism, 437
current findings, 446
detection of pathogenic, 439
epidemiologic studies, 442
factors influencing survival and growth, 440–441
foodborne yersiniosis, 441
genome structure, 437–438
methods for epidemiological studies, 443
mode of transmission, 446
outbreaks and transmission, 441–444
outcome of phage biocontrol of, on foods, 771, 774
pH, 440
phage biocontrol in milk and dairy products, 776
preservatives and growth inhibitors, 440–441
sources of, 438
temperature, 440
virulence factors, 444–446
water activity, 440
yersiniosis, 441–444
Yersinia pestis, 437, 444–445
Yersinia pseudotuberculosis, 332, 437, 444–445, 446–447

Yersiniosis, 441–444
foodborne, 441
outbreaks and transmission, 441–444
Yogurt, 116
fermentation processes, 876–877
microbiota and role in quality, 877–879
Zearalenone. *See also* Mycotoxin(s)
analysis of, 601–602
chemical characterization, 601
chemical structure, 597
control, 602
evaluation in humans, 588
fungal sources, 601
occurrence and regulation, 602
toxicology, 601
Zebrafish model, *Cronobacter* spp., 407–408
Zygosaccharomyces rouxii, 874, 889
