

FOOD

MICROBIOLOGY

FUNDAMENTALS AND FRONTIERS
5TH EDITION

EDITED BY Michael P. Doyle,
Francisco Diez-Gonzalez, and Colin Hill

Table of Contents

- Cover
- Contributors
- Preface
- About the Editors
- I Factors of Special Significance to Food Microbiology
  - 1 Behavior of Microorganisms in Food: Growth, Survival, and Death
    - GROWTH BEHAVIOR IN FOOD
    - SURVIVAL BEHAVIOR IN FOOD
    - CELL DEATH BEHAVIOR IN FOOD
    - CONCLUDING REMARKS
    - References
  - 2 Spores and Their Significance
    - SPOREFORMER PHYLOGENY AND SPORULATION AND GERMINATION OVERVEWS
    - SPORULATION
    - THE SPORE
    - SPORE RESISTANCE
    - SPORE ACTIVATION, GERMINATION, AND OUTGROWTH
    - PRACTICAL PROBLEMS OF SPORES IN THE FOOD INDUSTRY
    - DISCOVERY OF PATHOGENIC AND SPOILAGE SPORE-FORMING BACTERIA AND DEVELOPMENT OF EARLY CONTROL PROCESSES
    - MICROBIOLOGY OF SPOREFORMERS IN FOODS
    - CONTROL OF SPOREFORMERS IN FOODS

TECHNOLOGIES FOR INACTIVATION OF SPOREFORMERS IN FOODS
IMPORTANCE OF BIOFILMS IN CONTROL OF SPOREFORMERS IN FOODS AND MANUFACTURING
SPOILAGE OF FOODS BY SPOREFORMERS
SPOILAGE OF SPECIFIC FOOD CLASSES BY SPOREFORMERS
SPORES AS PROBIOTIC AGENTS
MODELING OF SPOREFORMER GROWTH IN FOODS AND ASSESSMENT OF SAFETY
References
3 Microbiological Criteria and Indicator Microorganisms
MRM METRICS
INTRODUCTION TO MC AND SAMPLING PLANS
PERFORMANCE OF SAMPLING PLANS
MICROBIOLOGICAL PROFILE OF A FOOD PRODUCT
PERFORMANCE OF CONTROL MEASURES
INDEX AND INDICATOR MICROORGANISMS
References
4 Responses in Foodborne Bacteria
GLOBAL STRESS RESPONSES
ACID STRESS
OSMOTIC STRESS
OXIDATIVE STRESS
HIGH-TEMPERATURE STRESS
LOW-TEMPERATURE STRESS
HHP SURVIVAL
STRESS RESPONSES AND VIRULENCE

SUMMARY
References
II Microbial Spoilage and Public Health Concerns
5 Milk and Dairy Products
MILK MICROBIAL DIVERSITY AND ABUNDANCE
CHEESE
KEFIR
OTHER FERMENTED MILK BEVERAGES
CONCLUSIONS
References
6 Meat and Poultry
FRESH MEAT
PROCESSED MEAT PRODUCTS
DETECTION AND ANALYSIS OF SPOILAGE, PATHOGENIC, AND RESIDENT MICROBES IN MEAT AND POULTRY
ANTIBIOTIC RESISTANCE
PACKAGING SYSTEMS
MEAT TRACEABILITY
CONCLUDING REMARKS
References
7 Microbiological Issues Associated with Fruits, Vegetables, Nuts, and Grains
PRODUCT TYPES ASSOCIATED WITH EACH FOOD GROUP
TYPES OF MICROBIAL CONTAMINATION ASSOCIATED WITH EACH FOOD GROUP
QUALITY AND SAFETY OF FOOD CROPS ASSOCIATED WITH MICROBIAL CONTAMINATION

ENUMERATION AND DETECTION OF MICROBIAL CONTAMINANTS AND INHERENT LIMITATIONS
SOURCES OF MICROBIAL CONTAMINATION
FACTORS THAT CONTRIBUTE TO THE FATE OF MICROBIAL CONTAMINANTS
INTERVENTIONS
RISK ASSESSMENT
CONCLUDING REMARKS
References
III Foodborne Pathogenic Bacteria
8 Epidemiology of Foodborne Illnesses
EPIDEMIOLOGY
AGENTS AND TRANSMISSION
FOODBORNE ILLNESS SURVEILLANCE
SURVEILLANCE FOR FOOD HAZARDS
FOODBORNE DISEASE SURVEILLANCE AND ATTRIBUTION
SUMMARY OF MAJOR ADVANCES IN THE EPIDEMIOLOGY OF FOODBORNE ILLNESS
References
9 Salmonella
CHARACTERISTICS OF THE ORGANISM
CLASSIFICATION AND TAXONOMY
PHYSIOLOGY
PATHOGENICITY AND VIRULENCE FACTORS
CHARACTERISTICS OF DISEASE
References
10 Eleven Campylobacter Species
THE GENUS CAMPYLOBACTER

BACTERIOLOGICAL ASPECTS OF CAMPYLOBACTER
CAMPYLOBACTER DIVERSITY AND SUBTYPING
CAMPYLOBACTER ASSOCIATION WITH FOODS
CLINICAL ASPECTS OF HUMAN ILLNESSES
ANTIMICROBIAL-RESISTANT CAMPYLOBACTER
DETECTION OF CAMPYLOBACTER IN FOODS
CAMPYLOBACTER CONTROL IN THE FOOD CHAIN
CONCLUSIONS

Preface

Microbiologists are using an ever rapidly expanding tool chest of new and extraordinary molecular methods to address many of the challenges associated with the microbial world of foods. Methods involving "-omics," whole-genome sequencing, CRISPR-Cas9, and the microbiome, to name a few, are revolutionizing the field of food microbiology by helping us better understand how microbes behave in foods. Such methods will also facilitate the development of innovative approaches (i) to reduce and control contamination of foods by harmful and spoilage microbes, (ii) to better detect outbreaks of microbe-associated foodborne illnesses, (iii) to deliver microbially produced foods of higher nutritional and functional quality, (iv) to detect and characterize undesirable microbes in foods more quickly and accurately, (v) to enhance the overall microbiological safety of foods, and much more.

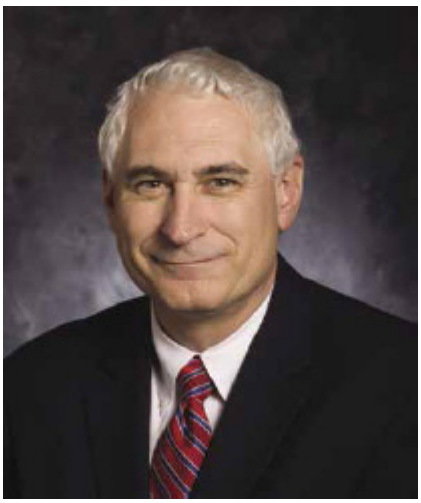
The 5th edition of *Food Microbiology: Fundamentals and Frontiers* (*FMFF*) addresses these and many more topics focused on the microbes associated with foods. Those chapters that have long been fundamental to the field of food microbiology have been updated with new research findings and related information, and new chapters on recent topics in food microbiology have been included. Since its introduction in 1997, the purpose of *FMFF* has been to serve as an advanced reference that explores the breadth and depth of food microbiology. Hence, for most chapters, there is only a minimal review of the basic principles and techniques of food microbiology, as this book is written at a level that presumes a general background in microbiology and biochemistry that is needed to understand the principles of food microbiology at a basic scientific level.

The book is composed of seven primary sections that address major areas of the field based on the roles that microorganisms play in the production, preservation, safety, and quality of foods. The first

section, “Factors of Special Significance to Food Microbiology,” addresses the growth, survival, and inactivation characteristics of foodborne microbes, the significance of spore-forming microbes in foods, proper use of microbiological criteria and indicator microorganisms, and the importance of stress response mechanisms in microbes that enable them to persist in foods under adverse conditions. The second section, “Microbial Spoilage and Public Health Concerns,” focuses on the quality and safety issues associated with three primary food groups, i.e., dairy, meats, and produce. These commodity-oriented chapters address the types of microbial spoilage associated with foods and innovative approaches for prevention and control. In addition, the types of harmful microbes that have been associated with these commodities and their adverse consequences on public health are described.

The book’s third and fourth sections, “Foodborne Pathogenic Bacteria” and “Nonbacterial Pathogens and Toxins,” cover the major harmful microbial agents associated with foods. Each chapter addresses the diseases caused by each agent, its epidemiology and etiology, the virulence determinants of pathogens, and control measures to prevent foodborne illnesses. Considerable molecular information regarding virulence and toxicity has been added to the pathogenic bacteria section, as has new information on control measures to reduce contamination along the food chain.

The fifth section, “Preservatives and Preservation Methods,” provides state-of-the-science information on the three approaches to preserve foods, namely physical, chemical, and biological methods. With special interest by consumers and the food industry in reducing the use of manufactured chemicals in foods, the chemical chapter includes coverage of natural antimicrobials that may be applicable to foods. In addition, a chapter on bacteriophages, which is another “natural” approach to controlling foodborne pathogens, has been added to this section. Each chapter addresses traditional and emerging preservation techniques including their mechanisms of microbial inactivation or suppression.



The sixth section, “Fermentations and Beneficial Microbes,” addresses microbes and microbial substrates and end products that promote human health. Studies of the human intestinal microbiome have revealed exciting information regarding the significance of diet to the gut microbiota and the effects of these microbes on health. This is opening new avenues to defining approaches for more healthy eating. In addition, major advances have been made to perfect the use and control of microbes used as starter cultures to produce fermented foods such as cheese and sausages. This section covers these topics and more.

The final section, “Current Issues and Advances in Food Microbiology,” covers a variety of “front and center” topics of special interest to food microbiologists. These include antimicrobial resistance and its relationship to gut microbes and human health; the application of genomics and metagenomics to food microbiology; the influence of food production environments on food microbiomes; the use of whole-genome sequencing in molecular source tracking of foodborne illness outbreaks and molecular subtyping of foodborne pathogens; advances in the application of predictive microbiology and risk assessment models for food safety; modern food management systems in the food industry that are used to mitigate contamination by undesirable microbes; the microbiological constraints for the use of reclaimed and reconditioned water in food production and processing operations; and the relevance of food microbiology issues to current trends in food production and imported foods. These chapters provide scientific and technical insights that may not otherwise be readily available in one convenient source.

We thank our coauthors for their diligence and commitment to developing timely and informative chapters to broaden our knowledge of the rapidly expanding field of food microbiology. It is their contributions that are the foundation for this book. We also thank our reviewers for their critical evaluations which enabled us to fine-tune each chapter.

About the Editors

Michael P. Doyle is a retired Regent's Professor of Food Microbiology and founding Director of the Center for Food Safety at the University of Georgia. He was a Wisconsin Distinguished Professor of Food Microbiology at the Food Research Institute, University of Wisconsin–Madison. Dr. Doyle has published more than 600 scientific papers and has given more than 900 invited presentations at national and international scientific meetings on food microbiology and food safety topics. He is a fellow of the American Academy of Microbiology, the American Association for the Advancement of Science, the Institute of Food Technologists, the International Association for Food Protection, and the National Academy of Inventors, and is a member of the National Academy of Medicine.

Francisco Diez-Gonzalez is the Director of the Center for Food Safety at the University of Georgia. He earned his MS and PhD in Food Science from Cornell University. In 1999, he joined the Department of Food Science and Nutrition at the University of Minnesota, where he was professor for 17 years and served as department head from 2014 to 2016. He has taught courses on food safety and food microbiology, has authored more than 90 peer-reviewed articles, and serves on the editorial board of several journals. His research interests center on the control and detection of foodborne bacteria in different food commodities.

Colin Hill, PhD DSc, is Professor of Microbial Food Safety at University College Cork, Ireland. He is also a Principal Investigator at APC Microbiome Ireland in Cork, a research center devoted to the study of the role of the gut microbiota in health and disease. In 2009 he was elected to the Royal Irish Academy and in 2010 he

received the Metchnikoff Prize in Microbiology and was elected to the American Academy of Microbiology. He has published more than 540 papers and holds 18 patents. His main interests are in the role of the gut microbiome in protecting against microbial infections.

I

Factors of Special Significance to Food Microbiology

Ahmed E. Yousef

1
Behavior of Microorganisms in Food: Growth, Survival, and Death

Monitoring microbial population density in any environment (including food) over time generally reveals one of three states or behavioral modes: growth, survival, or death (Fig. 1.1). If the monitoring period is extended, more than one state may be observed. Growth involves replicating the microbial genome, which is often followed by replication of other cell constituents and culminates in cell division, i.e., multiplication. Growth is measured empirically by the increase in biomass, as is the case for molds, or by cell count, as is the case for bacteria and yeasts; other means of monitoring growth are discussed below. A microorganism in food may enter a state of arrested growth (described here as survival), and the density of its viable population remains constant or fluctuates minimally (e.g., a ±0.25 log change in cell count) during the experimental monitoring period. Therefore, the "surviving" microorganism temporarily loses its ability to multiply, which can be regained if environmental conditions (e.g., medium composition) change during the period of observation. In contrast, death occurs when a cell loses its ability to multiply regardless of how favorable the growth conditions are. Experimentally, death becomes evident when the microorganism fails to reproduce upon subculturing.

GROWTH BEHAVIOR IN FOOD

Beneficial microorganisms can grow during food fermentation; hence, monitoring their growth can provide valuable information about the progress of the fermentation process. Microbial

populations may increase during the storage of food, causing its spoilage or rendering it unsafe for human consumption. Hence, monitoring growth of undesirable microorganisms also is important for ensuring food quality and safety. Growth can occur when an inoculum of a microbe is introduced into a new medium (e.g., food), and both the medium composition and environmental factors influence its growth. The presence of available water and essential nutrients (e.g., carbon and nitrogen sources, growth factors, and micronutrients) and the lack of hostile components (e.g., antimicrobials) or unfavorable pH are important characteristics of food that influence microbial growth. Factors providing a growth-supporting environment include suitable temperatures and gaseous environments. Different microorganisms grow over different temperature ranges. Psychrophiles, psychrotrophs, mesophiles, thermophiles, and extremophiles are categories of microorganisms that grow at temperatures ranging from subfreezing to higher than that of boiling water. Food microbiologists are mostly concerned about psychrotrophs, mesophiles, and thermophiles. Gaseous requirements for growth depend on the specific microorganism. Oxygen is toxic to strict anaerobes (e.g., some *Clostridium* spp.), but it is essential for the growth of aerobes, such as *Bacillus* spp. and fungi. In addition to growth media and environmental conditions, exposure time is also an important factor influencing microbial growth. A bacterium divides and doubles its population under a set of conditions, during a defined time interval called generation time or doubling time. Generation times are affected by different conditions; hence, the time required to complete a growth cycle can vary.

Growth recognition requires the measurement of microbial population density repeatedly on a time scale. Demonstrating the changes in microbial population density over time is used to determine if growth occurred. There should be a clear distinction between growth in food, as just described, and growth on a microbiological counting medium. The two events are interrelated, and both involve genome multiplication and cell division; however,

the latter is done merely to determine the population density in food at a given time point. Additionally, multiplication of a cell into a colony on an agar medium is described qualitatively as growth, whereas the increase in the population of a microorganism or microbiota in food over time quantifies that growth.

Measuring Microbial Populations in Food

The plate count method is one of the oldest and most commonly used methods to determine the viable microbial population in a food sample (1). The method may involve placing the food directly in a plate (petri dish) containing a suitable growth medium with agar (direct plating) or preparing dilutions of the food before selected dilutions are plated (dilution plating). The inoculated agar plates are incubated, and the resulting microbial colonies are counted. Colony counts on plates are used to determine the population count in food, which may be expressed as colony-forming units (CFU) per unit volume (e.g., milliliters) or weight (e.g., grams) of food. Considering that the population density under optimum growth conditions can increase by several orders of magnitude, the population is often presented in scientific notation (e.g., 2.7×10^6 CFU/g) or the logarithm to base 10 ($\log_{10}$ or simply log) of that number. In the example just described, the microbial population will be 6.4 log CFU/g. When the population, expressed as a log value, is plotted against time, it is relatively easy to determine if the microbial behavior in food is growth, survival, or death (Fig. 1.1). The plate count method is most suitable for counting sizable populations of single-celled, easyto-culture microorganisms. The method fails to produce satisfactory results when the foodborne microorganism is present in a small population (e.g., most pathogenic bacteria), has a tendency to produce cell clumps (e.g., staphylococci), or requires host cells to grow (e.g., parasites). The method also is inherently labor-intensive, costly, and slow. It requires 24 hours or more before colonies on plates are countable and the microbial population is measurable.

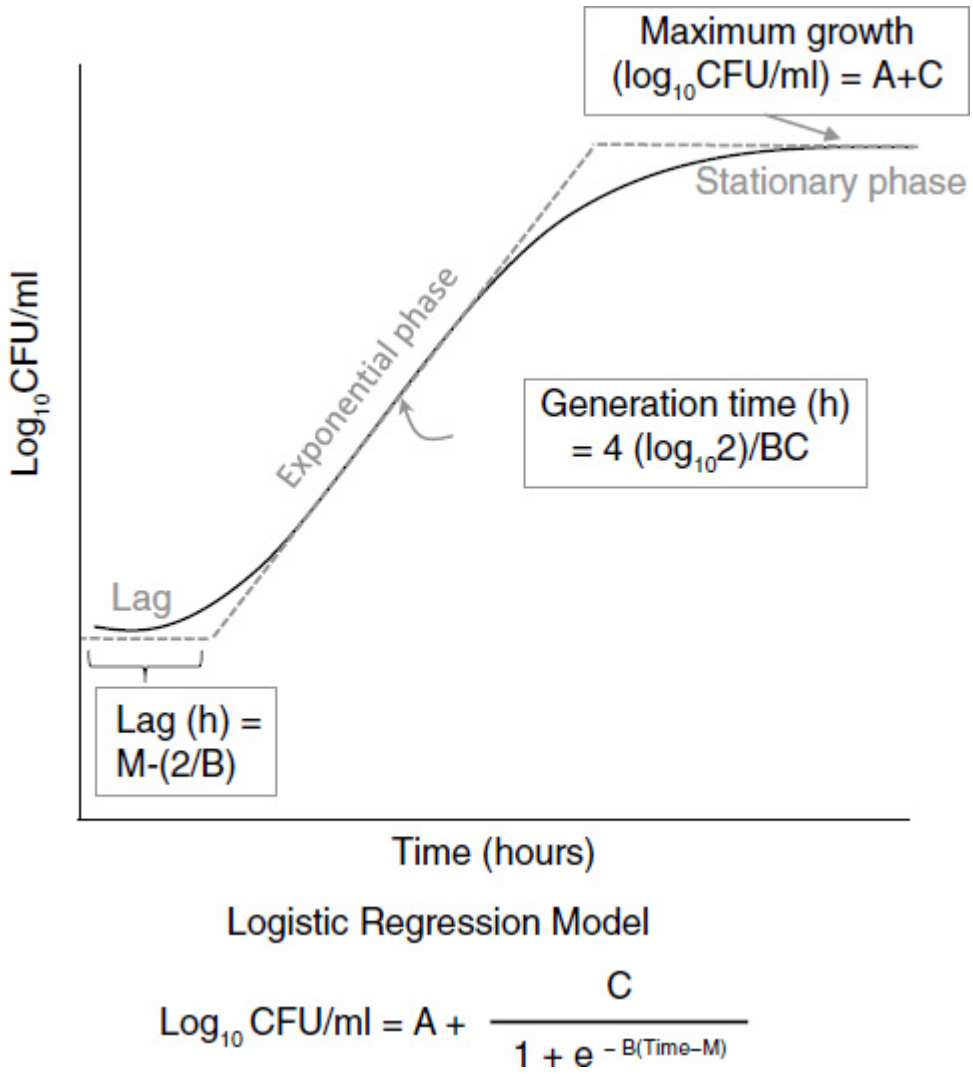

Figure 1.1 Conceptual behavior of microorganisms in various environments. The scale of the *y* axis symbolizes populations of single-celled foodborne microorganisms.

The most-probable-number technique was introduced to overcome some of the deficiencies of the plate count method, particularly the inability to enumerate small microbial populations. The technique involves making dilutions of food in a number of tubes containing a suitable broth and incubating the tubes of diluted food to enable growth of the small microbial population. After incubation, the numbers of positive and negative tubes (i.e., with detectable and undetectable growth, respectively) are compared to numbers in standard tables and used to estimate the population size. Results

are reported as the most probable number per unit of food. The method has been used for enumerating pathogen populations (e.g., *Listeria monocytogenes*) in food (1, 2).

Spiral plating relies on colony counting but reduces labor, cost, and time compared with the plate count method (3). A spiral plater uses a robotic arm to dispense a sample aliquot in an Archimedean spiral onto the surface of a rotating agar plate. The volume of the sample decreases from the center to the periphery of the plate so that a concentration range is established on a single plate. Counting of colonies is achieved using a specialized counting grid. The use of fewer dilution bottles or tubes and less agar medium and the ability to process a large number of samples in one batch are the main advantages. Some of the drawbacks of this method are the high limit of detection and the great variation in counts observed when small populations are counted, particularly in samples of solid foods.

Speedy measurement of microbial populations in food has been attempted using different methods. The direct microscopic count method involves using a specially designed glass slide having a small chamber and a microruler. A small measured volume of the sample, entrapped in the chamber, is examined with a microscope, cells are counted within a ruled area (e.g., 1 mm^2), and the estimated population per unit volume of the sample is calculated. A commonly used slide is the Petroff-Hausser counting chamber, which is suitable for counting prokaryotes in food. The method can be conducted easily, quickly, and inexpensively, but live and dead cells cannot be differentiated unless a vital-staining technique is included in the procedure. The method is well suited for rapid cell counting in liquid foods such as milk but less well suited for cell counting in solid foods.

Flow cytometry uses an optical system which enables rapid and highly sensitive estimation of cell numbers in a given suspension. Cells are stained with fluorescent dyes to allow the analysis of functional cell properties. Flow-cytometric methods have been used

to determine total bacterial counts in food (4). The high cost of flow cytometry equipment and the management of instrumental data are some limitations of this method.

A biosensor-based approach for real-time counting of microbial populations in food has been investigated. Biosensors are analytical devices that convert a biological response into electrical signals. Many of these devices consist of two main components: (i) a biorecognition element or a bioreceptor, which recognizes the analyte, and (ii) a transducer, which converts recognition events into measurable electric signals. Optical biosensors were tested successfully to quantify *Escherichia coli* O157:H7 in ground beef (5) and *L. monocytogenes* and *Salmonella enterica* serovar Enteritidis in frankfurters (6, 7). Electrochemical sensors were tested to monitor *E. coli* O157:H7 in milk (8) and to quantify *Campylobacter jejuni* in chicken carcasses (9). These assays have a short sample-to-answer time (10). Efforts continue to develop reliable, sensitive, rapid, accurate, selective, and cost-effective biosensor-based techniques. Such a technique could offer a commercial advantage to the food manufacturing and processing sectors by facilitating the rapid detection of foodborne pathogens and the release of uncontaminated foodstuff in hours, rather than the several days required for culture-based methods.

The methods described above were developed with the assumption that bacteria represent the majority of the food microbiota. Although some of these methods have been adapted for counting molds and yeasts, monitoring the growth of these eukaryotic organisms, particularly molds, in food may produce unsatisfactory results. When molds grow on food, they form a multicellular structure (mycelium) that is not quantifiable in terms of cell count or CFU. When mold hyphae are chopped during homogenization of a food sample, resulting pieces (propagules) may produce colonies whose number depends on the degree of chopping/homogenization. Growth of mold also results in the production of a large number of spores (e.g., conidiospores and sporangiospores), each of which is potentially capable of producing a colony on agar medium.

Therefore, it is likely that the count monitored over time is underestimated before spores are formed and overestimated as the spores are released from mycelia.

Phases of Microbial Growth in Food

Similar to a batch culture, microbial growth in an inoculated food can be described by the classical growth curve. When the log population count is plotted against time, four distinct phases can be discerned: lag phase, exponential phase, stationary phase, and death. Microorganisms dividing by binary fission (i.e., bacteria) in a liquid food (e.g., milk) produce growth curves with four recognizable phases. Careful consideration of the growth of other microorganisms in various food matrices can reveal the phases of a classic growth curve. The following discussion addresses the first three phases of growth; the death phase is addressed later.

Lag Phase and Shelf Life Extension

When a microorganism is introduced into a fresh environment, a period of growth cessation (lag phase) is observed. During this lag in growth, it is presumed that the microorganism is adapting to the new environment through retooling and synthesizing new components prior to resumption of cell division. For example, expression of a new set of enzymes may be needed if the microorganism is introduced into a medium different from the one in which it was growing previously. Once adaptation is successful, DNA replication resumes and cell division ensues. The length of the lag phase varies with the nature of the medium and the stress condition of the microorganism. If the inoculum is old (e.g., the stock culture was preserved at −80°C) or is transferred into a chemically different medium, the lag phase will be long. In contrast, the lag phase will be short or even absent when a vigorously growing young culture is transferred into a fresh medium having the same composition.

Bacterial growth in a laboratory setting starts with inoculation of a microorganism into a microbiological medium. Growth in most foods starts with an accidental contaminant gaining access to the food. When a microorganism enters a food, the nutritional and inhibitory characteristics of this new environment dictate the length of lag imposed on the microorganism. Availability of water and nutrients and favorability of the temperature, pH, oxygen level, and other environment factors are important determinants of duration of the lag phase. The presence of antimicrobial agents in food could suppress cell multiplication, thus extending the lag period. Food processors design processes to extend the lag period of food microbial contaminants; in essence, this approach extends the shelf life of the newly prepared food. Processing food (e.g., pasteurization) may render modifications in food composition and its environment, whereby even resident microorganisms that survived the process may undergo a lag to adapt to the new conditions.

Exponential Phase

A microorganism transitions from the lag to the exponential growth phase when cells start to multiply at measurable rates. Under favorable conditions, a microorganism multiplies at an increasing pace until a state of balanced growth is reached. During this state, the microorganism doubles its population at equal time intervals, called the generation time or doubling time (t_d). Therefore, the growth at this balanced-growth stage can be described by the following equation:

$$N_t = N_0 \times 2^n$$

where N_0 is the initial population at this stage, N_t is the population at time t, and n is the number of generations in time t. This equation can be used to derive the doubling time, which can be calculated as follows:

$$t_d = \frac{0.301t}{\log N_t - \log N_0}$$

In addition to the generation time, the specific growth rate is another way of expressing growth during the exponential phase. This is based on the assumption that the rate at which the cell population increases at a given time (t) depends on the population size (N) at that time.

$$\frac{dN}{dt} = \mu N$$

where μ is the specific growth rate, which is species and environment dependent. Integration of the above equation gives the following exponential function:

$$N_t = N_0\, e^{\mu t}$$

These equations can be used to derive μ as follows:

$$\mu = \frac{d\ln\, N}{dt}$$

Therefore, μ equals the slope of the line representing the exponential phase when the natural logarithm of population density (ln CFU per milliliter) is plotted against incubation time (typically in hours). The following is a more conventional way to calculate μ using Commonly plotted growth curves, i.e., $\log_{10}$ CFU per milliliter versus incubation hours.

$$\mu = \frac{\log N_t - \log N_0}{0.434\ t}$$

Comparing the above equations, for t_d and μ, results in the following relationship between these two exponentialgrowth-phase parameters:

$$\mu = \frac{0.693}{t_d}$$

At the exponential phase, the cell population is relatively uniform in terms of physiological and biochemical characteristics; therefore, microbial cultures in the exponential phase are used often in microbiological studies.

Exponential microbial growth in food

Knowledge of growth kinetics during the exponential phase is indispensable to food microbiologists. Understanding growth kinetics also helps processors quantify the behavior of beneficial bacteria and alleviate the harm of spoilage and pathogenic microorganisms. Fermentation, spoilage, and toxin accumulation in food are the result of vigorous microbial growth activities. During food fermentation, growth of beneficial microorganisms results in a wide range of changes in food components that lead to nutritional enrichment, improved safety, and promotion of health. Rapid growth of a starter culture during fermentation often inhibits the growth of foodborne pathogens. A microorganism may exhibit metabolic activities that differ with the phase of growth. For example, the proteome and transcriptome of *Lactobacillus rhamnosus* GG change significantly during the transition from the exponential to the stationary phase. This transition is accompanied with a shift from glucose fermentation to galactose utilization and from homolactic to mixed-acid fermentation end products (11). In a strain of wine yeast, the number of proteins involved in ethanol production and sulfur metabolism during alcoholic fermentation is different during the exponential and stationary phases (12).

Food spoilage is an outcome of microbial growth and metabolism. These activities can result in changes in the pH of food, release of off odors, generation of undesirable flavors, formation of gas and slime, and product discoloration (13). Accumulation of toxins in food also is the outcome of active growth of toxigenic microorganisms. For example, production of staphylococcal enterotoxins occurs during the exponential and stationary growth phases of *Staphylococcus aureus* (14). Toxigenic molds also grow on

stored food, including fruits, with the production of mycotoxins during the mold's growth cycle (15).

Stationary Phase

The exponential growth phase ends with a stage of growth deceleration due to the depletion of critical nutritional components or the development of unfavorable environmental conditions, such as low pH, low redox potential, or the release of inhibitory metabolites. During the transition to the stationary phase, the pace of growth decreases to a negligible rate and population density reaches an asymptote. Despite the lack of noticeable multiplication during the stationary phase, the cell population may remain metabolically active. Prokaryotes have evolved several strategies to survive a starvation similar to that encountered during the stationary phase. Under this condition, cells frequently produce starvation proteins (chaperones) which increase peptidoglycan cross-linking, protect DNA, and prevent protein denaturation (16). These chaperones make starved cells difficult to kill and resistant to further starvation or other stresses. Moreover, starvation-resistant cells may become more virulent (17), an observation which has major implications for the safety of foods. The following are stationary phase-associated phenomena of great significance in food microbiology.

Quorum sensing

Bacterial behavior during the stationary phase is linked to the quorum-sensing phenomenon. At the onset of this phase, bacteria reach a high cell density and experience physiological stress due to nutrient limitation and other unfavorable conditions. Quorum sensing is a process by which bacteria cope with stationary-phase stress and shift their central metabolism toward production of components that benefit the population as a whole (18). For example, quorum sensing modulates the cellular metabolism of *Burkholderia* spp. to produce oxalate, which enables their survival during the stationary phase. In *Burkholderia glumae*, quorum

sensing serves as a metabolic brake to halt multiplication but maintain the cells' primary metabolism.

The term "quorum sensing" was first suggested to describe how bacteria communicate with each other through signaling molecules released into the environment during growth. Several cellular processes are triggered when the density of bacterial cells and the concentration of the signaling molecules reach a threshold. The signaling molecules required for communication can be divided into four categories: (i) *N*-acyl homoserine lactones (AHLs), which are generally known as autoinducer 1 molecules and are used by Gram-negative bacteria for facintraspecies communication (19); (ii) furanosyl borate diester, known as autoinducer 2, which serves as a universal signal and is used for interspecies and intraspecies communication by Gram-positive and Gram-negative bacteria (20); (iii) autoinducer 3, which is used by enterohemorrhagic *E. coli* for expression of virulence genes and cross talk with mammalian host cell signaling (21); and (iv) autoinducing peptides, which are produced by Gram-positive bacteria (22). However, other molecules similar to those of quorum-sensing systems have been described in the published literature. Quorum sensing occurs when there is a high cell density. Microbial spoilage of food also is a high-celldensity event. Hence, researchers have investigated the potential role of quorum sensing in spoilage. Additionally, quorum sensing has been investigated in the context of how it regulates food spoilage (23), how production of signaling molecules by pathogens is impacted by food system conditions (24), and how quorum sensing affects expression of survival and virulence genes of foodborne pathogenic bacteria (25). Understanding quorum sensing may help in disrupting cellto-cell communication and thereby preventing food spoilage. This may be achieved by targeting the synthesis of cell-signaling molecules or blocking these signaling systems. An alternative approach, referred to as quorum quenching or quorum sensing inhibition, involves using quorum-sensing molecules to generate false sensing and confuse bacteria, leading to the arrest of their growth or metabolic activity (26). Plants have

received considerable interest for their ability to produce compounds capable of interfering with quorum sensing in bacteria. Plant extracts may contain AHLdegrading enzymes which are capable of disrupting quorum sensing and are potentially useful in extending food's shelf life.

Biofilm formation

Bacteria in the planktonic state in an aqueous environment may form biofilms by residing on surfaces and undergoing sessile growth. Once a biofilm is formed on a surface, bacteria become more difficult to remove, and their susceptibility to antimicrobial agents or adverse environmental changes decreases relative to that of planktonic cells. It is not surprising that the formation of biofilms in food processing environments is difficult to control. Biofilm formation includes four stages: (i) initial attachment, which may occur to moist food or pipeline surfaces; (ii) microcolony formation; (iii) biofilm maturation; and (iv) dispersion. A cyclic increase and decrease in the population of a contaminant may occur in the processing environment, such as that which may be observed in effluents collected during the cleaning of pipes. During this cycle, the decrease in population may correspond to the initial stages of biofilm formation and the increase may coincide with the dispersion phase.

Biofilm formation is influenced by environmental factors (e.g., pH and temperature), surface characteristics (electrostatic forces, roughness, and hydrophobicity), bacterial factors (e.g., flagella and pili), and genetic factors (e.g., the polysaccharide intercellular adhesion gene). Biofilm formation may be regulated by quorum sensing, which activates several genes that are necessary for expression of extracellular polymeric substances. Control of bacterial biofilms in food processing facilities is vital to mitigate the occurrence of pathogens in food. Disinfection, cleaning, enzymatic treatment, and application of bacteriophages have been reported as effective treatments in controlling biofilms (27). Microbial metabolites, such as surfactin from *Bacillus subtilis*, prevented

biofilm formation by *Salmonella* Typhimurium (28). In addition to chemical and biological control strategies, new physical treatments, such as laser decontamination and antimicrobial coating of surfaces, have been proposed.

Predictive Modeling of Microbial Growth

When growth of a microorganism is monitored experimentally, plotting the lag, exponential, and stationary phases against incubation time typically produces a classic sigmoid curve (Fig. 1.2). Mathematical modeling of such a curve helps researchers and processors predict the growth behavior of the microbe in food under various processing and storage conditions. This predictability has important food safety and quality implications. A predictive growth model developed for a specific microorganism in a given food should be reevaluated if the food composition or storage environment is changed.

There are generally two types of models used in predictive microbiology: stochastic (probabilistic) and deterministic models. The latter type is often used for modeling growth curves, and it includes empirical analytical expressions and rate equations (29, 30). In order to build a deterministic model, growth has to be measured first; then growth data (e.g., measurements of CFU per milliliter for 24 hours) are fitted mathematically with the selected model using nonlinear regression statistical software, and the goodness of the model's fit is determined statistically. Data fitting involves determining model constants, i.e., the model's mathematical parameters. These parameters vary with the species, medium characteristics (e.g., pH and aw), and environmental Factors (e.g., temperature). Gompertz and logistic models are some of the most commonly used models for microbial growth. The following are equations representing these models.

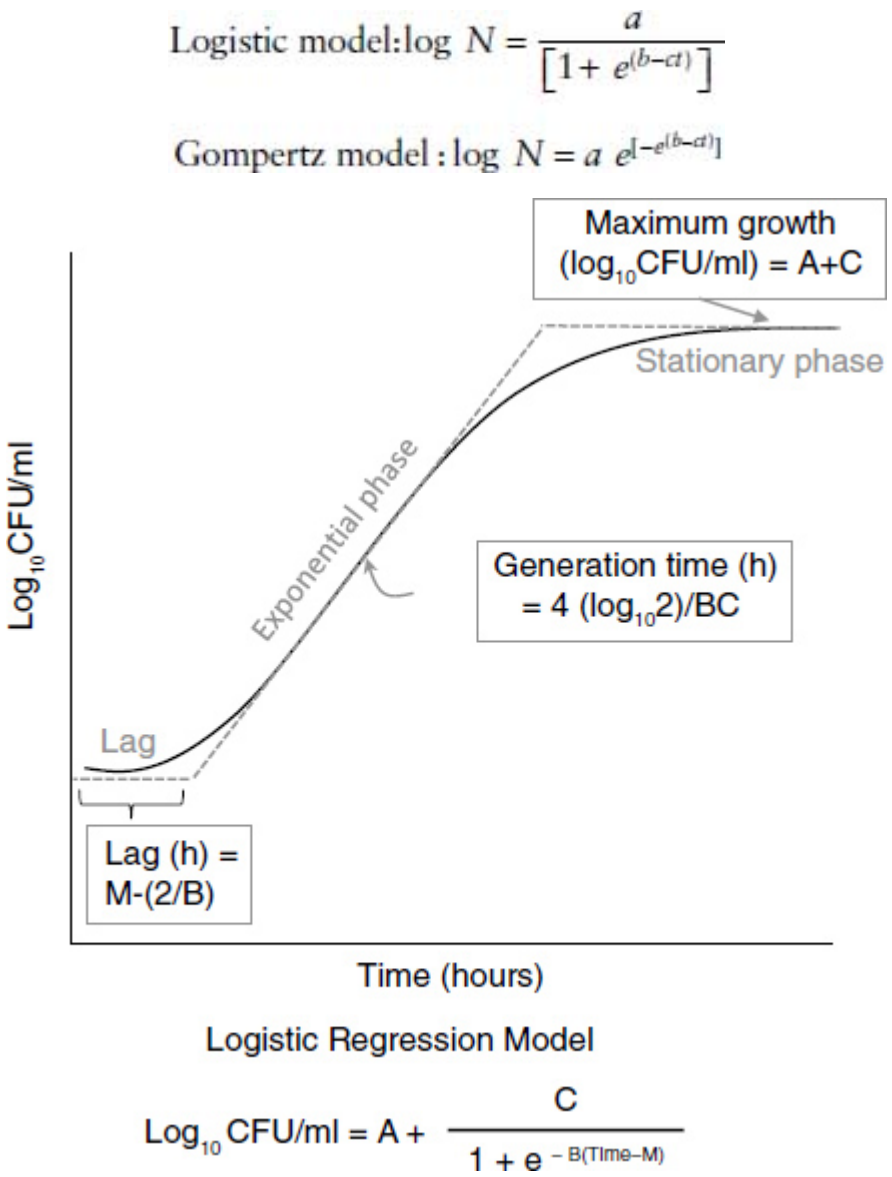

Figure 1.2 Typical bacterial growth curve, fitted with a logistic model.

where t is incubation time, N is population density, and a, b, and c are model parameters. Biologically meaningful parameters, such as lag phase, specific growth rate, and generation time, are calculated from the mathematical parameters. An implementation of the logistic model is illustrated graphically in Fig. 1.2 (31).

Microbial Metabolism in Food

Microbial growth per se is not the direct cause of food fermentation or spoilage; enzymes and metabolites released from the growing biomass are responsible for these changes. Covering the large number of metabolic pathways and the overwhelming number of metabolites produced by foodborne microorganisms is beyond the scope of this introductory chapter. Therefore, metabolism is addressed at the fundamental level only.

Microbial metabolism can be arranged into two categories based on how microorganisms obtain carbon for the synthesis of their biomass: (i) autotrophic (carbon is obtained by fixing CO_2) and (ii) heterotrophic (carbon is obtained from metabolized organic compounds). Utilization of carbon, regardless of its source, requires energy. Based on the source of energy that microbes use, both autotrophic and heterotrophic microorganisms can be photosynthetic (using light energy) or chemotrophic (energy derived from oxidation of chemical compounds). The chemicals providing energy could be from an organic (organotrophic) or inorganic (lithotrophic) source. Most microorganisms of importance to food are chemo-organoheterotrophs. These microorganisms use organic compounds as both carbon and energy sources. They also may derive their organic nutrients from dead matter or living hosts; these are termed saprophytes and parasites, respectively.

Aerobic Respiration

For many foodborne microorganisms, carbohydrate metabolism is the primary source of energy that drives vital cell reactions and the source of building blocks needed for cell growth. Different microorganisms metabolize carbohydrates (typically glucose) differently depending on the functionality or dysfunctionality of their metabolic pathways. Utilization of glucose by microorganisms capable of cellular respiration is accomplished through glycolysis, which is also called the Embden-Meyerhof-Parnas pathway, and the citric acid cycle, which is known as the Krebs cycle (Fig. 1.3). The

outcome of these metabolic activities is formation of energy-rich ATP and a reducing power in the form of NADH and $FADH_2$. These reduced molecules are used to produce more ATP at the electron transport chain, which is embedded in the cytoplasmic membrane of prokaryotic cells or the inner membrane of mitochondria in the case of eukaryotic cells. The reduced products (particularly NADH) are oxidized, becoming positively charged and releasing electrons to the electron transport chain.

$$NADH \rightarrow NAD^+ + H^+ + 2e^-$$

This chain is composed of a series of membrane-embedded protein complexes as well as mobile carriers (e.g., cytochrome *c*). Along the chain, the released electrons undergo a series of redox reactions, losing energy that is used to pump protons from the cell cytosol side (or mitochondrial matrix) to the outside of the membrane. The energy gradient generated across the membrane is used by ATP synthetase, which is also embedded in the membrane, to phosphorylate ADP (in the presence of inorganic phosphate) to ATP in a process called oxidative phosphorylation. At the end of the chain, electrons are passed to oxygen, the final electron acceptor, producing water.

$$2e^- + \tfrac{1}{2}O_2 \rightarrow H_2O$$

The metabolism of one glucose molecule by aerobic cellular respiration (glycolysis + citric acid cycle + electron transport) yields 30 to 32 ATP molecules, but some references report larger numbers. Most of these ATPs are the result of oxidative phosphorylation. The aerobic respiration pathways are fairly highly conserved in both prokaryotic and eukaryotic cells. In bacteria, glycolysis and the citric acid cycle occur in the cell cytosol and the electron transport takes place at the cytoplasmic membrane. In fungi and other eukaryotes, glycolysis occurs in the cell cytosol, and the citric acid cycle takes place in the mitochondrial matrix, with electron transport occurring in the inner membrane of mitochondria. Some bacteria use

alternative pathways for glycolysis and the citric acid cycle. *Pseudomonas fluorescens*, for example, metabolizes sugar using the keto-deoxy-phosphogluconate pathway, instead of the Embden-Meyerhof-Parnas pathway, which is partially defective in this species (32).

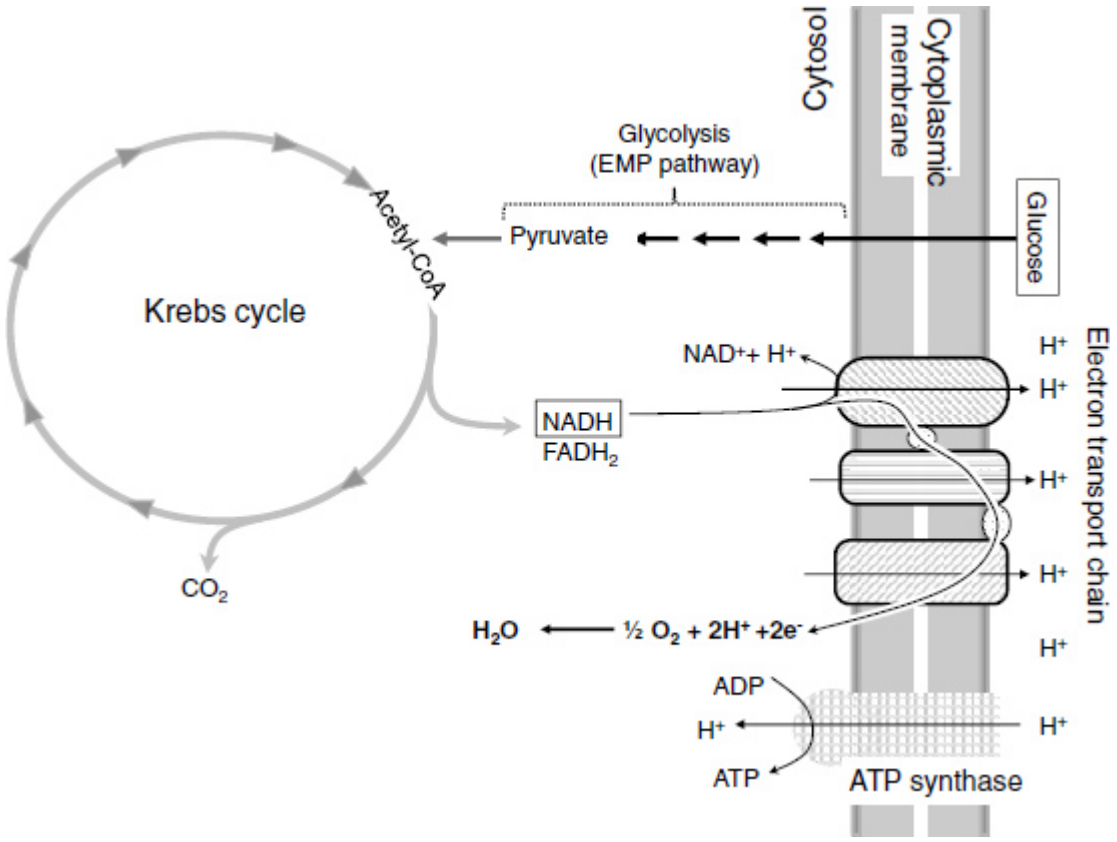

Figure 1.3 Glucose metabolism through aerobic respiration. In the absence of oxygen, the presence of an alternative oxygen acceptor results in anaerobic respiration. EMP, Embden-Meyerhof-Parnas.

Aerobic microorganisms such as *Bacillus* spp. and most molds are rapid growers and often cause food spoilage. Beneficial molds, however, are useful in making moldripened cheeses and other fermented products. These molds are grown on the cheese surface (e.g., Camembert cheese) or inside the cheese matrix (e.g., blue and Roquefort cheeses) (33). In the latter case, cheese blocks are spiked with needle-like rods to allow the air to contact the mold inside the block.

Anaerobic Respiration

The respiratory pathways just described can occur in the absence of molecular oxygen when alternative electron acceptors are reduced at the end of the electron transport chain. Alternative electron acceptors include nitrate, sulfate, fumarate, tetrathionate, and dimethyl sulfoxide. These alternatives have less oxidizing power than oxygen; thus, less energy is produced than in aerobic respiration. Utilization of nitrate during anaerobic respiration can be a multistep denitrification process that involves more than one cellular enzyme. The enzymes needed for complete denitrification, in conjunction with electron transport, are nitrate reductase, nitrite reductase, nitric oxide reductase, and nitrous oxide reductase (Fig. 1.4). Some foodborne bacteria (e.g., members of the *Enterobacteriaceae*) are capable of completing the first step only, i.e., the reduction of nitrate to nitrite in the presence of cellular nitrate reductase (34). *Staphylococcus carnosus*, a starter culture for naturally fermented sausages, also is capable of converting nitrate to nitrite. Considering that nitrites inhibit the growth of *Clostridium botulinum* in food, this denitrification step can be significant for the safety of food. Additionally, the products of denitrification can affect the color of raw red meat and some processed meats.

Intriguingly, anaerobic respiratory metabolism can be linked to microbial pathogenesis and virulence. *Salmonella* pathogenicity islands which carry virulence genes can harbor genes encoding specific metabolic pathways that are important for the successful infection of a host. Inflammation of the intestine caused by *Salmonella* Typhimurium infection results in the release of reactive oxygen species, which oxidize intestinal thiosulfate into tetrathionate. Considering that *Salmonella* Typhimurium is capable of utilizing tetrathionate as a final electron acceptor (anaerobic respiration), this permits *Salmonella* to multiply and colonize the intestinal tract, giving the pathogen a competitive advantage over the predominantly fermentative gut microbiota (35).

Fermentation and Anaerobic Bacteria

Bacteria having a dysfunctional citric acid cycle are anaerobes and produce energy through fermentation. These bacteria carry out glycolysis to produce pyruvate which is converted to other organic end products (Fig. 1.5). These products include ethanol, acetate, lactate, and butyrate. Gases such as CO_2 and H_2 may be produced as fermentation end products. Fermentative bacteria generate ATP through substrate-level phosphorylation, where phosphatecontaining high-energy organic compounds convert ADP to ATP. There are fermentative bacteria that can tolerate oxygen (e.g., many lactic acid bacteria), whereas others (e.g., some *Clostridium* spp.) have an extremely low tolerance to oxygen (i.e., strict anaerobes).

Lactic acid and propionic acid bacteria are fermentative microorganisms with great importance in food processing. Fermented dairy products, meats, and vegetables are made using lactic acid bacteria, and Swiss-type cheeses are made using propionic acid bacteria. Recent genomic analyses of lactic acid bacteria revealed novel metabolic pathways that led to the discovery of unusual phenotypic characteristics. Arginine catabolism by these bacteria was found to contribute to stationary-phase survival and acid resistance. Engineering fermentative bacteria by introducing new cellular processes at central metabolic pathways enabled the production of novel metabolites. For instance, engineering *Lactococcus lactis* subsp*cremoris* NZ9000 with a four-enzyme cascade enabled the production of guanosine diphosphate l-fucose (36). l-Fucose is a biologically important monosaccharide. Metabolic engineering of lactic acid bacteria may reduce their nutritional requirements and enable them to ferment low-cost polysaccharides.

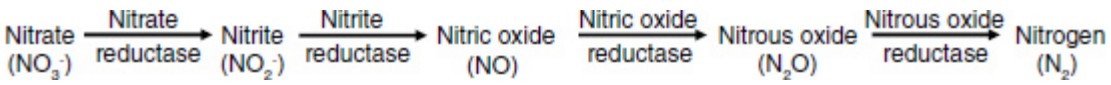

Figure 1.4 Microbial reduction of nitrate and other inorganic nitrogen during anaerobic respiration.

Facultative anaerobes

Some food microbiota are capable of metabolizing glucose using multiple pathways. In other words, these microorganisms can switch between aerobic respiration and anaerobic pathways (anaerobic respiration or fermentation) depending on oxygen availability. Members of the *Enterobacteriaceae* are facultative anaerobes; thus, they can complete aerobic respiration in the presence of oxygen (using glycolysis, the citric acid cycle, and the electron transport chain), and in the absence of oxygen, they metabolize glucose by anaerobic respiration using alternative oxygen acceptors. In the absence of any electron acceptors, *Enterobacteriaceae* are fermentative, producing a mixture of acetate, formate, lactate, and succinate. These metabolites are products of multiple pathways; hence, this mode of glucose metabolism is known as mixed-acid fermentation (Fig. 1.5). This versatility gives facultative anaerobes a competitive advantage in environments having a variety of microbiota. The persistence of coliforms in the intestine, despite the complexity of gut microbiota, illustrates their high metabolic adaptability to various environments. Some yeasts (e.g., baker's yeast) carry out aerobic respiration and anaerobic fermentation.

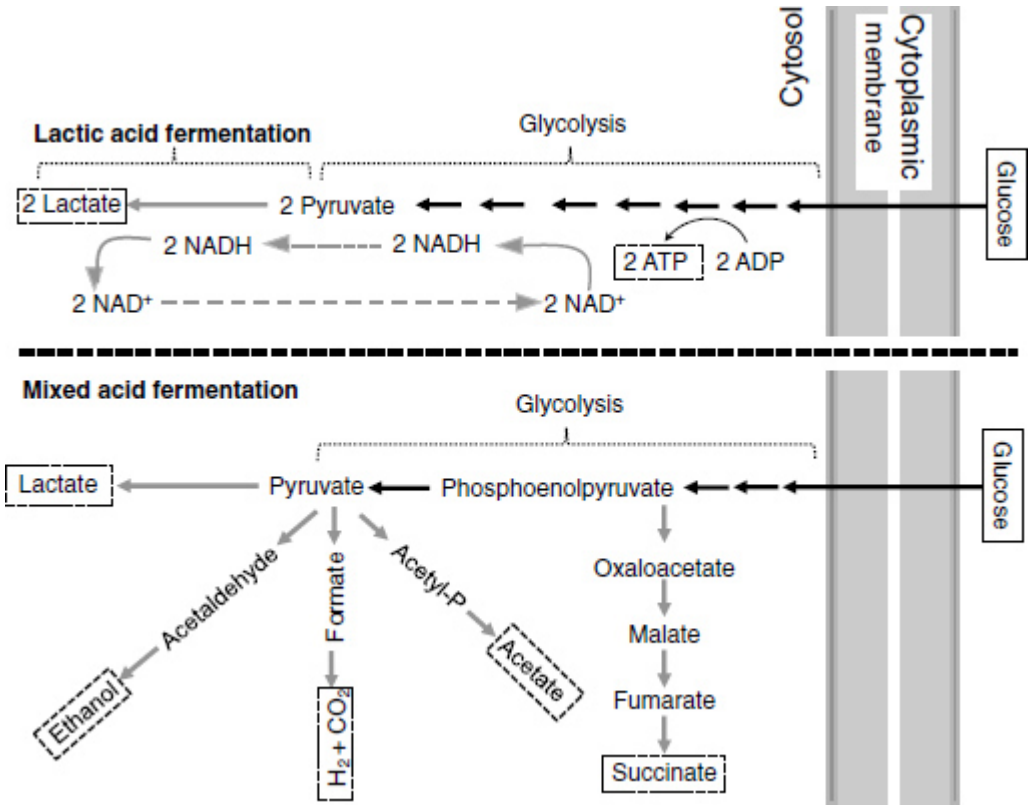

Figure 1.5 Anaerobic metabolism of glucose through fermentation. (Top) Lactate fermentation. (Bottom) Mixed-acid fermentation. Final fermentation products are in dotted boxes.

Consequences of Microbial Growth and Metabolic Activity in Food

Microbial growth in food can lead to desirable or undesirable effects. Fermentation, biocontrol, spoilage, and increased disease risk are the main outcomes of this growth.

Food fermentations are the bases for an important sector of the food industry. There should be a clear distinction between "metabolic" fermentation, which is discussed above, and industrially relevant food fermentations, which are addressed in this section. Industrially relevant fermentations use desired microorganisms to convert raw or minimally processed products into fermented foods regardless of the metabolic pathways contributing to this conversion. The source of the inoculum used in food fermentations

could be (i) microorganisms naturally present in raw food, (ii) microbe-containing food products from a previous fermentation (a process known as back slopping), or (iii) an in-house-prepared or commercial starter culture. Small inocula generally must grow to produce the desired effect, whereas large inocula may accomplish the fermentation with limited growth due to the metabolic activity of the microbial biomass. There are many desirable bacterial groups, including lactic acid bacteria, which have been used in food fermentation.

Spoilage is a result of an unintended microbial growth and its associated metabolic activities. Release of metabolites and enzymes (with or without celllysis) is the direct cause of the spoilage. Spoilage microorganisms could be part of the natural microbiota of food or may have gained access to food during handling or processing. Indications of food spoilage include changes in odor, color, or texture; accumulation of gas; slime formation; and accumulation of exudates. Certain conditions can promote the sequence of events that lead to food spoilage. These are (i) food having characteristics that support microbial growth; (ii) presence of microbial contaminants compatible with food characteristics; (iii) growth of the contaminant to high population density (commonly greater than 106 CFU/ml or CFU/g), which occurs when storage conditions favor microbial growth (e.g., temperature abuse); and (iv) food being held for a sufficient length of time under the growth-favoring conditions. Many microorganisms that are naturally present or unintentionally added to food are capable of causing its spoilage.

Increased risk of disease transmission is an important but undesirable consequence of growth of microorganisms in food. Based on the mode of causing illness, microbial foodborne diseases can be grouped into intoxications, infections, and toxicoinfections (37). Intoxication is an illness resulting from ingestion of a toxin produced during growth of the toxigenic microorganism in food. Once the toxin is produced in an active form in a food, there is no need for the microbial cells to be viable for illness to occur.

Foodborne intoxications include botulism, staphylococcal gastroenteritis, and *Bacillus cereus* gastroenteritis. Growth of molds (e.g., some *Aspergillus* and *Fusarium* species) in food may result in the accumulation of mycotoxins which cause human and animal intoxications. Infections, in contrast, require ingestion of live microorganisms which may or may not have grown in the food. Some infectious pathogens (e.g., *L. monocytogenes* and *E. coli* O157:H7) have low infectious doses, so their growth in food is not a prerequisite for illnesses to occur; however, growth of these pathogens in food increases the risk of disease transmission. Toxicoinfection results from ingestion of a live pathogenic microorganism with contaminated food, growth of the pathogen in the gastrointestinal tract, and production of a toxin in the intestine. A classic example of toxicoinfections is cholera, which is caused by *Vibrio cholerae*.

Pseudogrowth in Food

An increase in microbial populations in food cannot always be translated into microbial growth. For example, the population of *L. monocytogenes*, measured as CFU per gram, increased almost 10-fold during the manufacture of Colby cheese (38). This increase, however, was most likely due to entrapment of the pathogen in the curd while syneresis (i.e., whey expulsion) was occurring. Similar pseudogrowth may be observed in other events. Concentration of milk, whey, or juices during ultrafiltration most likely results in an increase in counts (CFU per milliliter or gram) that has nothing to do with the growth of food microbiota.

SURVIVAL BEHAVIOR IN FOOD

When conditions in food are neither conducive to growth nor hostile enough to cause death, microbial populations may remain relatively unchanged for a period of time (Fig. 1.1). This state is described in this chapter as “survival.” Conceptually, when a food known to support microbial growth is treated with a bacteriostatic

agent (i.e., a growth inhibitor), the treatment prevents contaminants from multiplying, thereby leading to a state of survival. Published literature contains many studies revealing the survival behavior as described here; however, some researchers use the word to describe subpopulations that remain viable after lethal treatments (i.e., treatment persisters). Despite the inconsistent use of this term in the published literature, microbial survival, as used in this chapter, is intended to represent a phenotypic state where neither growth nor death is noticeable. When the physiological and molecular bases for survival are further investigated, uniformity in the usage of the term is expected. Considering the difficulty of demonstrating survival, as intended here, in a complex matrix such as food, the term is used even when some changes in microbial population are observed during lengthy storage of a product.

Pathogen survival in food was demonstrated in a 1986 study on the behavior of *L. monocytogenes* in Cheddar cheese (39). Although most strains of the pathogen had died gradually during the lengthy storage of cheese, the population of *L. monocytogenes* V7 persisted relatively unchanged, or minimally decreased, in some batches held at 6°C for more than 200 days. Dry conditions are conducive to lengthy microbial survival, particularly when the contaminated product is stored at temperatures that are lower than ambient. Populations of *Salmonella* Enteritidis phage type 30 on the surfaces of raw almonds did not change considerably (~1-log reduction) during storage at 4°C or −20°C for over 550 days (40). Similarly, populations of *L. monocytogenes* and *E. coli* O157:H7 remained unchanged when inoculated almonds and pistachios were stored for 12 months at 4°C or −19°C (41). In the same study, nuts were inoculated with *E. coli* O157:H7 and *L. monocytogenes* and stored at 24°C. Populations of these two pathogens declined 0.60 and 0.71 log CFU/g/month on almonds and 0.35 and 0.86 log CFU/g/month on pistachios, respectively. *Salmonella* Enteritidis PT 30 was capable of long-term survival on the surface of in-shell walnuts (42). The population of the pathogen declined at 4°C by 0.1 log CFU/nut/month, whereas under ambient conditions, the decline

ranged from 0.55 to 2.5 log CFU/nut/month. In a study on fresh produce, *E. coli* O157:H7 persisted on lettuce and parsley after seedlings were planted in soils amended with contaminated composts or contaminated irrigation water (43).

One may presume that microorganisms in the survival mode are growing and dying in small increments, for short periods, so that the overall outcome is a population size that is relatively constant over time. In other situations, the survival state may reflect a quasi-equilibrium between cell division and death. Alternatively, cells of the surviving population may have stopped their metabolic activity, leading to growth arrest. In the latter case, it is unlikely that microorganisms maintain this survival state for a long time; they may adapt to these conditions and resume growth, or they may suffer physiological injury leading to gradual death. Physiological changes leading to the state of survival have intrigued many researchers, and phenomena contributing to this state have been investigated. Some of these phenomena are stress adaptation, persistence, dormancy, and the viable-but-nonculturable (VBNC) state; these are discussed below.

Stress Adaptation

When microorganisms sense unfavorable changes in their surroundings, they may respond by altering gene expression in a way that increases their tolerance to the perceived stresses. This stress adaptation phenomenon has greater implications than just improving the survival ability of the microorganism. Stress adaptation could alter virulence characteristics of bacterial pathogens and enhance their ability to infect a host. It is plausible that adaptation occurs more readily when microorganisms experience sublethal rather than lethal stresses (44). Mild treatments during food processing are becoming popular due to the growing demand for minimally processed foods. Microorganisms that survive these processes may respond by adapting, thus compromising the safety of food.

Various cell structures, such as proteins, DNA, RNA, cell walls, and cell membranes, undergo injury and damage as a result of exposure to stress (45). Microorganisms may respond by expressing genes for repairing such damage and aiding their survival. Stress responses Include production of proteins that maintain cellular homeostasis, repair damage, or remove the stress agent. The pre-exposure of pathogens to sublethal levels of a given stress, leading to tolerance to harsher levels of the same or different types of stress, is the basis for stressadaptive or cross-adaptive responses, respectively.

The response of bacteria to stress can be general or specific. Since many stresses have similar effects on vital cellular structures, bacteria have evolved general stress responses controlled by sigma factors. Binding of these factors to RNA polymerase core enzyme directs transcription of a set of genes to support cell survival. In Gram-negative bacteria (*Salmonella*, *Vibrio*, and *E. coli*), RpoS is a main sigma factor, whereas SigB is an alternative sigma factor with similar functions in Gram-positive bacteria (*S. aureus*, *L. monocytogenes*, and *B. subtilis*). These regulators are the key players in coordinating response to stresses such as high osmolarity, starvation, higher-than-optimum temperature for growth, and exposure to bacteriocins, antibiotics, and low pH (46). Specific stress responses involve the production of proteins that protect bacteria against specific suboptimal conditions in their environments. Examples of these proteins include heat shock proteins, cold shock proteins, acid shock proteins, systems responsible for potassium uptake and accumulation of compatible solutes, catalase, and superoxide dismutase (47–49). In foodborne pathogens, stress adaptation and virulence may be interrelated. For example, a mutation in *opuC*, a gene encoding the osmolyte transport system, reduced the ability of *L. monocytogenes* to colonize and cause infection in mice (50). Similar studies revealed a link between salt tolerance and virulence in *S. enterica* (51).

Adaptation to stress can be derived from mutations that select for phenotypes that enable microorganisms to survive under selective environments. Development of resistance to high hydrostatic

pressure (HHP) among strains of *E. coli* has been attributed to the probable acquisition of specific genetic determinants that maintained HHP resistance for 80 generations (52). After a single exposure to an HHP treatment of 400 MPa for 20 min, a piezotolerant strain of *L. monocytogenes* was isolated. This isolate had increased cell size, lacked flagella, exhibited morphological alterations, and had increased tolerance to acid, heat, and hydrogen peroxide treatments (53). This multi-stress-resistant phenotype was attributed to a deletion in the glycine-encoding repeat region of *ctsR*, a gene that encodes the class 3 stress gene repressor. Genetic analysis of 24 HHP-resistant variants of *L. monocytogenes* LO28 revealed seven variants with mutations in *ctsR* and two variants with deletions in the upstream region of the gene (54). However, HHP-resistant variants of *S. aureus* had no mutations in *ctsR*, suggesting that there are different mechanisms for acquisition of HHP resistance by different species (55).

Persistence

Persistence refers to the ability of a microorganism to remain viable for a period of prolonged time in a certain habitat. Although persistence can be an outcome of microbial growth, colonization, biofilm formation, or resistance to decontamination processes, it is discussed in this chapter under the survival mode of microbial behavior. Persistence of pathogens results in repeated contamination of foods, increased violation of the safety of foods, and elevated public health risks. At preharvest, persistence includes colonization of an animal by a particular pathogen that results in shedding of the pathogen for weeks or months. Bacterial pathogens also may persist in farm environments such as feed or stables. Persistence at processing facilities is manifested by repeated isolation of the same strain of a pathogen (e.g., *L. monocytogenes*) for months or even years from the same sites.

Several studies have revealed evidence for the persistence of foodborne pathogens in the food production environment. For cattle that persistently shed Shiga toxin-producing *E. coli* in their feces,

there was a greater prevalence of the pathogen in the farm environment than for cattle that occasionally shed the pathogen (56). Cattle that shed more than 10^4 CFU of *E. coli* O157:H7/g of fecal matter are described as supershedders (57). *Salmonella* can persist for years in feed-processing environments. The persistence of *Salmonella* has been explained by several mechanisms, including the ability to form biofilms, which enhances its resistance to disinfection and desiccation (58). The correlation between biofilm formation and persistence has been investigated extensively, and the biofilm-forming ability of *Salmonella* has been proposed to play a key role in its resistance in dry environments and persistence in food factory environments (59). *L. monocytogenes* can persist and survive disinfection and cleaning procedures, thereby causing crosscontamination of food products. Persistence of this pathogen is presumed to be attributable to desiccation and disinfection resistance, biofilm formation, and differential gene expression for utilization of carbon sources that confer a competitive advantage (60, 61). *Cronobacter sakazakii* can survive and persist in low-wateractivity matrices, such as powdered infant formula, for up to 2 years and in infant cereals for approximately 24 weeks (62). The mechanism for the persistence of *Cronobacter* is not fully understood; however, some researchers have related this behavior to the successful accumulation of ions (e.g., calcium) or compatible solutes (e.g., trehalose) which increase intracellular osmolarity (63). *Campylobacter* spp. contaminating work surfaces and equipment during the slaughter of infected poultry flocks can survive and contaminate *Campylobacter*-negative flocks. The persistence of *Campylobacter* may be associated with its resistance to disinfectants and antibiotics, biofilm formation, and interaction with protozoan cells (64, 65)

Dormancy

Bacterial sporulation, which is common in *Clostridium* and *Bacillus* species, represents a dormancy state that is considered the ultimate survival mechanism in nature. Spores retain viability due to reduced

metabolic activity and increased resistance to extreme physical and chemical conditions. Spore dormancy is thought to be associated with the dehydration of the spore core and reduced molecular movement. To end the state of dormancy, a spore undergoes a series of biochemical reactions that involve activation, germination, and outgrowth; these are described collectively as spore-to-cell transformation. Spores that need an extended length of time before this transformation are described as superdormant. If superdormant spores are present in processed food, they cannot be recovered by conventional detection or enumeration methods. When such food is stored, the superdormant spore may germinate, causing spoilage or a disease hazard.

Many researchers have evaluated different strategies to inactivate bacterial spores. A combination of pressure and heat applied sequentially or simultaneously proved effective for inactivating *Clostridium sporogenes* spores (66). Synergistic inactivation of spores of *C. botulinum* by heat and high pressure was shown to be strain dependent (67). Other researchers combined pressure, heat, low pH, and the addition of nisin to inactivate spores of *B. subtilis* and *C. sporogenes* (68). A germination-induced inactivation approach has been developed. This involves inducing spore germination using suitable germinants followed by exposure of the outgrowth to an antimicrobial chemical, physical, or biological agent. An example of this approach was the application of HHP, mild heat, and selected amino acids (added as germinants), which was found to be an effective sporicidal combination treatment (69). A combination of osmotic activation and treatment with nisin was proposed as a strategy to inactivate *Clostridioides* (formerly *Clostridium*) *difficile* spores (70). The application of the germinant asparagine followed by HHP treatment (586 MPa) at 73°C for 10 min killed *C. perfringens* spores in meat products (71).

VBNC State

Bacteria are considered VBNC when they cannot grow in conventional culture media but they maintain their viability.

Dormancy is similar to the VBNC state, but VBNC cells possess measurable metabolic activity that is not detectable in dormant cells. Being nonculturable, VBNC cells cannot be detected by conventional methods, which poses a great challenge for the detection of pathogens in this state. Recently, 85 species of bacteria, among which 67 are pathogenic, have been recognized to enter the VBNC state. Some foodborne pathogens have the ability to enter the VBNC state and maintain their virulence, but they cannot initiate disease until resuscitated (72). For example, VBNC cells of *L. monocytogenes* regained pathogenicity after resuscitation by incubation in embryonated eggs (73). Some researchers, however, reported that pathogens that enter VBNC state become nonpathogenic. For example, VBNC *Salmonella* Typhimurium could not infect mice in an *in vivo* experiment (74). In contrast, VBNC cells of enteropathogenic *E. coli* have been observed to retain their enteropathogenicity (75).

There is increasing evidence that correlates VBNC pathogens with the occurrence of foodborne-illness outbreaks. It was proposed that an outbreak of *E. coli* O157:H7 infection in Japan was caused by the VBNC state of the pathogen in salted salmon (76). Moreover, *Salmonella* Oranienburg entered the VBNC state in response to NaCl stress and caused an outbreak in dried processed squid (77). Failure to isolate the *E. coli* O104:H4 outbreak strain from food in Germany was attributed to the nonculturable state of this strain (78).

VBNC foodborne pathogens pose a safety risk because they escape conventional detection methods and recover their pathogenicity under certain conditions to present a human health threat. Within the supply chain, food is exposed to conditions that may be conducive to the entry of pathogens into the VBNC state. Foodborne pathogens have been recognized to enter the VBNC state in grape juice (79), vegetables (80), and milk products (81). The VBNC state of *E. coli* O157:H7 has been induced by UV disinfection on lettuce and spinach plants (82). Pulsed-electric-field treatment may have induced cells of *L. monocytogenes* and *B. cereus* to enter the VBNC

state (83). The mechanisms for induction into and resuscitation from the VBNC state need to be fully investigated.

CELL DEATH BEHAVIOR IN FOOD

Microorganisms may die spontaneously during food storage or be killed intentionally by processes designed to inactivate spoilage and pathogenic microbiota. Spontaneous death of pathogens in hard cheese, for example, is expected to occur with 60 days after manufacture (84) Food processors inactivate undesirable microbiota in food using physical factors such as heat, gamma radiation, and ultrahigh pressure; chemical factors such as antimicrobial gases and food preservatives; or biocontrol measures such as applying antagonistic beneficial microbial cultures. Details of these methods can be found in subsequent chapters. The following discussion addresses microbial death in food as a behavior or phenomenon that applies to a broad set of conditions.

Unmediated Microbial Death

Microorganisms may die in food during storage without the application of external lethal treatments. This behavior is described here as unmediated death. For example, a fraction of the population of lactic acid bacteria die and autolyze during the ripening of Cheddar cheese (85). Studies on *L. monocytogenes* revealed that the pathogen died more rapidly during storage in Parmesan cheese than in other cheeses (86). This rapid death in Parmesan cheese could be attributed to its hostile environment, such as its low water activity and the liberation of antimicrobial fatty acids during cheese ripening. Cell injury during processing (e.g., curd cooking during the preparation of Parmesan) combined with storage conditions that are unfavorable for cell repair may lead to such behavior. When *E. coli* was inoculated in apple juice and treated with a pulsed electric field, cell death continued to be observed during refrigerated storage of the juice (87). Death of *Salmonella* organisms was observed during the storage of dried cocoa beans for 30 days at room temperature

(88). The death, instead of survival, of *Salmonella* was attributed to the low water activity (0.68) of the product. A rapid death rate of *C. jejuni* was observed in Chinese-style sausage subjected to 50°C air blast drying, and a nondetectable level of the pathogen was reached in non-vacuum-packed sausage after 21 to 28 days of storage (89).

Competition between pathogens and other microbiota may explain the unmediated death of these pathogens in the production environment or food. Death of *L. monocytogenes* in a cheese microcosm was attributed to the microbial communities of Gram-positive and Gram-negative bacteria and yeasts present in Livarot cheese (90). The death behavior of *Salmonella* and *Campylobacter* in the ceca of poultry is regulated by the size and complexity of the microbial community inhabiting the alimentary gut (91, 92). The exclusion of invading pathogens from the intestinal tract may result from the competition for limited nutrients and adhesion sites, production of antimicrobial metabolites, and the occurrence of environmental conditions that are hostile to the pathogen. Unmediated cell death may also be explained by the programmed cell death (PCD) phenomenon, which is discussed below.

Programmed Cell Death

Certain stresses can lead to PCD in microbial communities. Death and lysis of these cells can provide nutrients that are usable by the surviving subpopulation. Several mechanisms of stress-induced PCD have been reported, and some are outlined here. One such mechanism in *E. coli* involves a toxin-antitoxin system encoded by a pair of genes, *mazF* and *mazE*, which constitute the *mazEF* module. These genes encode a stable toxin (MazF) and an unstable antitoxin (MazE) which prevents the lethal action of the toxin. Stress factors that inhibit transcription and translation of MazE allow its degradation, causing cell death by the action of MazF (93). High temperatures, DNA damage, and oxidative stresses were found to induce *mazEF*-mediated cell death. It is commonly believed that PCD under stress permits the survival of a small population that will act as a nucleus for the renewed population whenever the

conditions become conducive to growth. Hence, *mazEF*-mediated cell death is considered an altruistic mechanism of bacterial survival and is population dependent. Addressing PCD in foodborne pathogens can have significant implications for food safety, because this phenomenon could be used beneficially in food preservation.

Death Kinetics

Deliberate treatment of a microbial population with an antimicrobial agent may result in cell death to a degree that depends on the strength of the applied lethal factor and the duration of application. Similarly, when such a treatment is applied to raw food, it causes product decontamination to a level that depends on the delivered dose of the lethal factor. Heat, radiation, ultrahigh pressure, and antimicrobial gases are examples of lethal factors applied in food processing. Determining the rate of cell death (i.e., inactivation or death kinetics) in response to a lethal treatment is important for quantifying the effectiveness of that treatment.

Death kinetics can be measured accurately for a microorganism having a homogeneous population, exposed uniformly to a lethal treatment, and monitored carefully over a defined time period. Such a population often produces a death curve similar to that shown in Fig. 1.6. When the death behavior of bacteria is examined, the following phases may be observed: (i) viability depletion, (ii) logarithmic death, and (iii) persistence. These phases are more noticeable with mild, rather than aggressive, lethal treatments; the latter often cause a death behavior that is more linear than curved. The viability depletion phase is seen as a lag in death immediately after application of the antimicrobial agent at its full strength. This initial resistance to inactivation may be attributed to cells' innate ability to sustain the damage caused by the lethal factor. The reserve resistance response is eventually depleted, and cells then enter the logarithmic death phase.

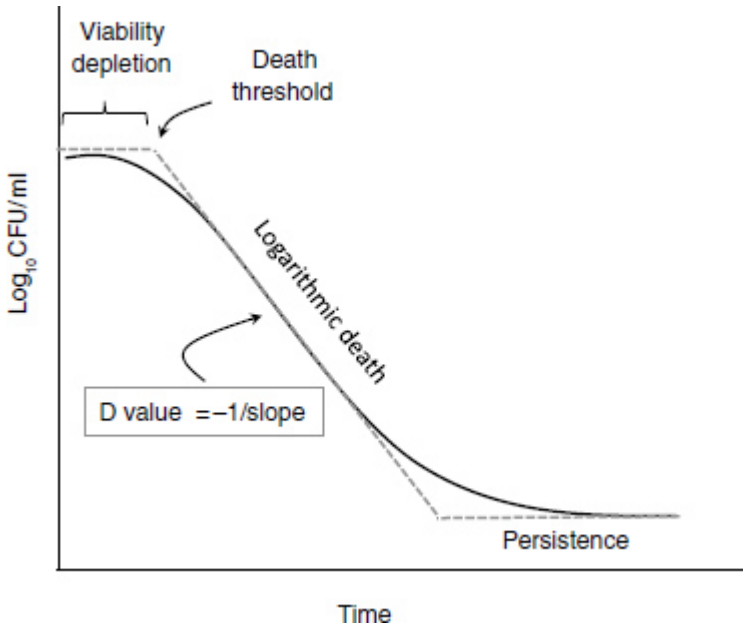

Figure 1.6 Phases of a microbial inactivation curve.

During the logarithmic death phase, the homogeneous microbial population undergoes first-order inactivation kinetics, which can be described by the following equation,

$$N_t = N_0\, e^{-kt}$$

where N_0 is the initial population, *Nt* is the population at time *t*, and *k* is the rate constant. For a population exposed to a lethal factor in a given medium, the *k* value depends on the species, the lethal factor applied, and the strength of that lethal factor. Instead of *k*, food processors use decimal reduction time (*D* value), which is a more meaningful cell inactivation parameter.

$$D = \frac{-dt}{d\log N}$$

In practical terms, the *D* value equals the negative reciprocal of the slope calculated from the linear portion of the death curve (Fig. 1.6). The linearity of death occurring during this phase (observed on a logarithmic death plot) is probably the outcome of uniform disruption of a viabilitylimiting step by the applied lethal factor.

At the end of the logarithmic phase, the rate of population death decreases, leading to the persistence phase. The size of the persistent population is often small. If the initial population is 107 CFU/ml and the persistent population is 102 CFU/ml, the latter represents only 1/105 of the original population. Many hypotheses have been suggested to explain the persistence of this subpopulation. Adaptation of members of the population to the applied lethal factor has been proposed; however, this adaptation is unlikely to develop during heating or the application of other physical lethal factors. Protection of the surviving population by lysates from inactivated cells seems plausible, but little information to support this hypothesis has been published. Genetic and phenotypic diversity within the initial population was also proposed. When a lethal factor is applied, a resistant phenotype is selected for, resulting in tailing of the curve. Some consider the persistence an outcome of flaws in techniques used to enumerate the cell population (see the discussion of these techniques above). For example, if cells of bacteria clump together, cell clumps appear to be dying at a lower rate than the rest of the population, which is made up mainly of individual cells. This observation is expected when heat is applied as a lethal factor and the viable population is counted as CFU per milliliter of food. Chemical lethal factors also may act more swiftly on planktonic cells than on cells embedded within clumps.

Persistence of a pathogen during testing and food processing minimizes the predictability of the process, which can lead to serious safety implications. If the parameters of the lethal process (e.g., temperature and time) were selected based on the *D* value for a targeted pathogen exhibiting a sigmoidal death curve, persistence of this pathogen leads to an underestimation of the processing conditions needed to make the food safe for human consumption. Understanding death kinetics of microorganisms in food, and the limitations on measuring reliable death parameters, should help processors to properly implement current and emerging

preservation technologies and to effectively mitigate disease transmission risks.

CONCLUDING REMARKS

Despite its importance, microbial behavior in food is often addressed casually in the published literature. Understanding the different patterns of this behavior is essential for promoting microbial growth when needed, inhibiting growth-associated spoilage and toxin production, and eliminating foodborne pathogens through processing. Food microbiologists, processors, and regulators need to consider the quantitative and mechanistic aspects of microbial growth, survival, and death. Behavior of microorganisms in food is intimately linked to important biological phenomena, such as quorum sensing, biofilm formation, stress adaptation, persistence, dormancy, and the VBNC state. Understanding programmed, unmediated, and induced microbial death and how these modes are interrelated could lead to new strategies in eliminating pathogenic and spoilage microorganisms in food.

2
Spores and Their Significance

Members of the Gram-positive *Bacillales* and *Clostridiales* and some closely related genera respond to slowed growth or starvation by initiating the process of sporulation, and the resultant spores can cause practical problems in food microbiology as well as human disease. The molecular biology of sporulation and spore resistance and germination in *Bacillus subtilis* has been extensively studied for many years, and there is detailed knowledge of these processes and many of the regulatory mechanisms involved (1–12). With the recent availability of many genome sequences as well as methods for genetic manipulation of clostridia of industrial and medical importance, a detailed molecular understanding of sporulation and spore germination in clostridia is also being developed (4, 9, 13–17). This chapter describes the fundamental bases of sporulation and spore germination and resistance and the problems that spores present to the food industry.

SPOREFORMER PHYLOGENY AND SPORULATION AND GERMINATION OVERVEWS

The primary sporeformers of significance in foods are *Bacillus*, *Clostridium*, *Anoxybacillus*, *Desulfotomaculum*, *Geobacillus*, *Paenibacillus*, and *Sporolactobacillus*. These members of the *Bacillales* and *Clostridiales* have undergone extensive phylogenetic analysis, largely based on genome sequencing (17–19), which provides insight into their evolution and physiological

characteristics. Overall, the sporeformers have DNA with a low G_+C content and possess a Gram-positive cell wall structure. Other systematic, species, and physiological characteristics of these organisms have been described in detail (20). It appears likely that the ability to sporulate was acquired early in evolution, and a core of ~60 genes is associated with sporulation. Interestingly, food-related bacteria classified in the *Firmicutes* include *Listeria*, *Staphylococcus*, *Streptococcus*, and *Lactobacillus*, and these genera have lost the ability to sporulate at variable times in evolution (17). Despite the ability of sporeformers to remain in a dormant state for long periods of time, their rate of evolution appears to be the same as that of non-spore-forming bacteria (21).

Sporulation in *B. subtilis* has been most extensively studied and forms the basis of most descriptions in this chapter. The first obvious morphological event in sporulation is an unequal cell division. This creates the smaller prespore or forespore compartment and the larger mother cell compartment. As sporulation proceeds, the mother cell engulfs the forespore, resulting in a single forespore (an endospore) within a mother cell, and eventually the mother cell lyses. Note that while generation of one spore in a sporulating cell is common, there are a number of examples of sporulating cells that form multiple spores in a single cell (18). Throughout sporulation, gene expression is ordered both temporally and spatially, as some genes are expressed only in the mother cell or the forespore (2, 4–7, 9, 14, 22). The pattern of gene expression during sporulation is controlled by the ordered synthesis and/or activation of five new sigma (specificity) factors for RNA polymerase and many DNA-binding proteins. As sporulation proceeds, there are striking morphological and biochemical changes in the developing spore. It becomes encased in two and sometimes three novel layers: a large layer of peptidoglycan (PG) termed the spore cortex, whose structure differs from that of growing-cell PG, a number of spore coat layers, and in some species an exosporium. Both the coats and exosporium contain proteins unique to spores (23, 24). The spore's central region, or core, accumulates a huge

depot (~10% of spore dry weight) of pyridine-2,6-dicarboxylic acid (dipicolinic acid [DPA]) (Fig. 2.1), as well as a large number of divalent cations, including Ca^{2+}chelated with DPA (CaDPA), and the core loses much water (25). In addition, the developing forespore synthesizes large amounts of novel small acid-soluble proteins (SASP), some of which coat the spore chromosome and protect the DNA from damage (8, 12, 14). As a result of these and other changes, the spore becomes metabolically dormant and resistant to harsh conditions, including heat, radiation, and chemicals.

Despite the spore's dormancy, if given the appropriate stimulus (often a sugar or amino acid), the spore can return to life via germination (4, 9–11). Within minutes of exposure to a germinant, spores lose their unique characteristics, including loss of CaDPA by excretion, loss of the cortex and SASP by degradation, much core water uptake and swelling, and loss of resistance. Completion of germination allows progression into outgrowth, when normal metabolism of endogenous and exogenous compounds begins and macromolecular synthesis is initiated. Eventually the outgrowing spore is converted back into a growing cell. Detailed study of sporulation, spores, and spore germination and outgrowth has been motivated by a number of factors, one of which is the attraction of this developmental system. Another motivating factor is the major role played by sporeformers in food spoilage and foodborne diseases; related to this factor is the recognition of the potential for the use of spores of *Bacillus anthracis* as an agent of bioterrorism. This review focuses on molecular mechanisms of sporulation, spore resistance, and germination, most of which have been examined in *B. subtilis*, the model sporeformer for mechanistic studies on sporulation, spore germination, and spore resistance. However, there is increasing knowledge of many aspects of the sporulation and spore germination in many *Clostridium* species, most notably, *Clostridium perfringens*, *Clostridium sporogenes*, and *Clostridioides difficile* (formerly *Clostridium difficile*) (4, 9–11, 13–15). The completed genome sequences of many hundreds of Gram-positive spore-forming species are now available, and comparison of

these sequences indicates that there is a tremendous degree of conservation among genes whose products are involved in sporulation, spore resistance, and spore germination, most notably a core set of ~60 conserved genes (17–19). This conservation extends to many similar mechanisms, including regulatory mechanisms, involved in sporulation, spore resistance, and spore germination in these various species, although there are important differences in both sporulation and germination in members of the *Bacillales* and *Clostridiales* (4–7, 9–11, 13–18).

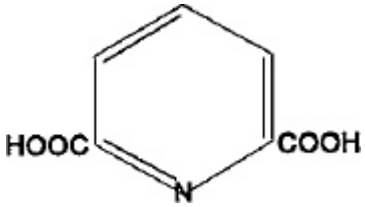

Figure 2.1 Structure of DPA. Note that at physiological pH, both carboxyl groups are ionized.

SPORULATION

Distribution of Sporeformers

The sporulating bacteria discussed in this chapter form heat-resistant endospores that contain DPA and are refractile or phase bright under phase-contrast microscopy. Most studies on sporulation, spores, and spore germination utilize species of either the aerobic bacilli or the anaerobic clostridia. However, members of many closely related genera form similar spores (17, 18).

Induction of Sporulation

Induction of sporulation in the laboratory is generally achieved by nutrient limitation, either by exhaustion of nutrients during growth or by shifting cells from a rich to a poor medium. Addition of an inhibitor (decoyinine) of guanine nucleotide biosynthesis also leads to sporulation. Although these methods cause most cells in a culture to sporulate, this may not be how sporulation is induced in

nature. Even cells in a growing culture produce a small but finite number of spores, with the percentage of spores increasing as the culture's growth rate decreases (26).

Massive sporulation of a cell population generally takes place only when cells enter stationary phase. However, sporulation is not an obligatory outcome of entry into stationary phase, and many stationary-phase events are attempts to access new sources of nutrients such that sporulation either will not take place or is at least delayed. These stationary-phase events include the following (Fig. 2.2) (1, 2, 5–7, 13, 15, 22, 27): (i) synthesis and secretion of degradative enzymes such as amylases and proteases; (ii) synthesis and secretion of antibiotics such as gramicidin and bacitracin; (iii) in some species, synthesis and release of protein toxins; (iv) development of motility; (v) killing and cannibalism of sister cells in the population; (vi) in a few species (e.g., *B. subtilis*), development of genetic competence; and (vii) biofilm development. Although these phenomena are not necessary for sporulation, they are often regulated by mechanisms that modulate gene expression during sporulation. Like sporulation, competence is also regulated in a cell density-dependent manner via the secretion of small peptides termed competence pheromones. There are also drastic changes in stationary-phase cell metabolism, with these changes extending into sporulation. Some of these changes include catabolism of polymers like poly-β-hydroxybutyrate formed in vegetative growth and initiation of oxidative metabolism due to synthesis of tricarboxylic acid (TCA) cycle enzymes. Many of these enzymes are not present in the developing forespore. Consequently, the mother cell and forespore have different metabolic capabilities.

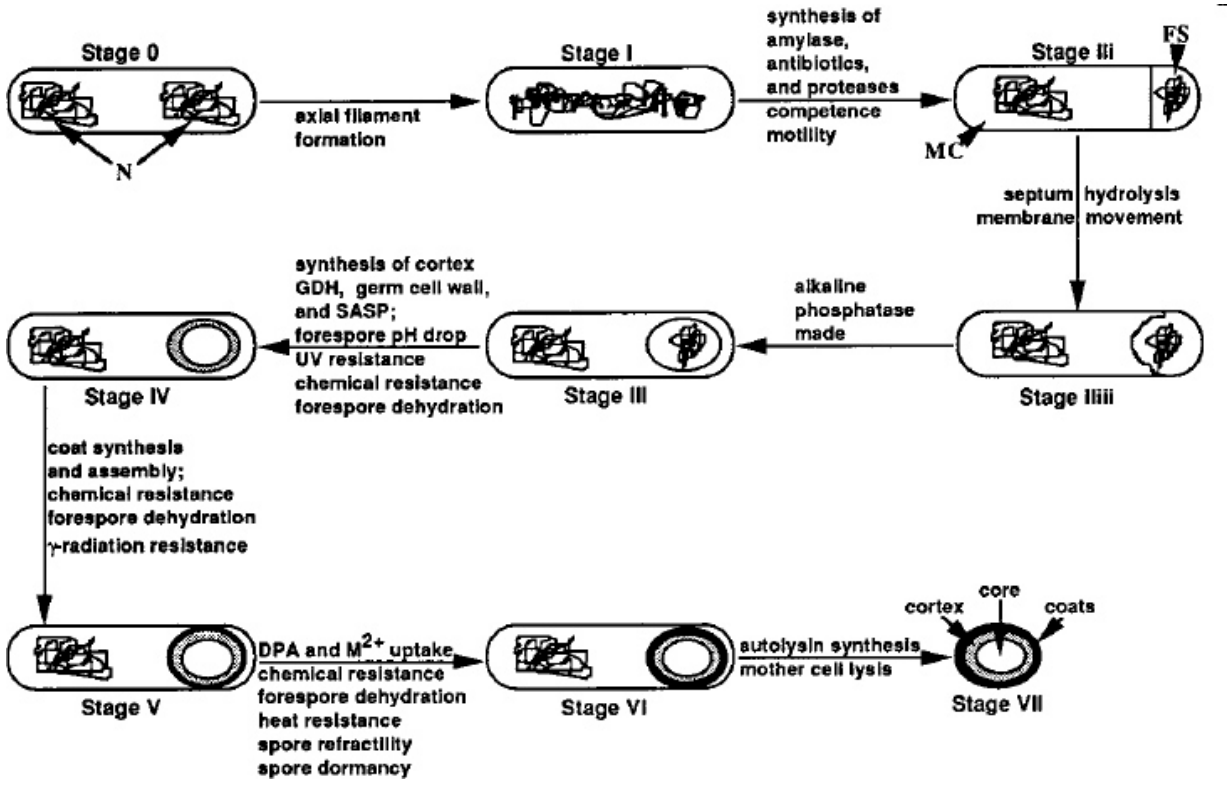

Figure 2.2 Morphological, biochemical, and physiological changes during sporulation of a rod-shaped *Bacillus* cell. In stage 0, a cell with two nucleoids (N) is shown; in stage IIi, the mother cell and forespore are designated MC and FS, respectively. Note that the forespore nucleoid is more condensed than that in the mother cell. Stage IIii is not shown in this scheme, and the forespore nucleoid is not shown after stage III for clarity. The time of some biochemical and physiological events, such as forespore dehydration and acquisition of types of resistance to different chemicals (alllumped together as "chemical resistance"), stretches over a number of stages.

Progression into sporulation generally requires regulatory signals that lead to the derepression of genes expressed only in stationary phase, although usually not the products of genes encoding degradative enzymes, antibiotics, toxins, and proteins involved in motility or competence. However, induction of sporulation in *Bacillus* species does require completion of chromosome replication, repair of DNA damage, and induction or synthesis of

TCA cycle enzymes. Entry into sporulation is also increased in cells growing at high cell density by small molecules secreted into the growth medium (28). In general, extracellular signals are extremely important in directing decisions about the immediate and ultimate fates of stationary-phase cells of sporeformers, as these cells have a variety of developmental pathways available, as noted above, and most of these pathways are not mutually exclusive (1, 5–7, 28).

Morphological, Biochemical, and Physiological Changes During Sporulation

In *B. subtilis*, sporulation can take as little as 8 h and is divided into eight stages based largely on morphological characteristics (Fig. 2.2). Growing cells are in stage 0, and in stage I, the sporulating cell's two nucleoids align in an axial filament that can be observed in electron micrographs. The first morphological feature of sporulation easily seen in the light microscope is the formation of an asymmetric septum dividing the sporulating cell into the mother cell and forespore compartments (3, 5–7). Immediately after asymmetric septation, only ca. 30% of the chromosome destined for the spore is present in the forespore; the remainder is subsequently transferred into the forespore, and then both mother cell and forespore compartments contain complete and apparently identical single chromosomes. However, the forespore chromosome is initially more condensed than the mother cell chromosome. A biochemical marker for late stage II is the synthesis of alkaline phosphatase. During stage II, genes in the two compartments of the sporulating cell may be expressed differentially.

Following septum formation, the mother cell plasma membrane engulfs the forespore, surrounding the forespore with two complete membranes, the inner and outer forespore (or spore) membranes (IM and OM). There are a number of events that occur in the transition from stage II to stage III, leading to the subdivision of stage II into three substages, two of which are shown in Fig. 2.2. In the transition from stage III to stage IV, a large PG structure termed

the cortex is laid down between the IM and OM (29). The cortex PG has a structure similar to that of cell wall PG, but with a number of differences (described below). The spore's germ cell wall is made at the same time as the cortex but appears to have the same structure as growing cell wall PG. During the transition from stage III to stage IV, the forespore synthesizes glucose dehydrogenase and SASP. The developing forespore acquires full UV resistance and some chemical resistance at this time, the forespore pH decreases by 1 to 1.5 units, and forespore dehydration begins.

In the transition from stage IV to stage V, the proteinaceous coat layers are laid down outside the OM (23), in a process that requires a protein made in the mother cell to recognize and bind to the curved engulfed forespore's OM (30). The coats of spores of *Bacillus* species contain up to ~80 proteins, almost all of which are unique to spores. The reason for the plethora of coat proteins is not clear, as many *B. subtilis* coat proteins can be lost with no apparent phenotypic effect. Forespore gamma radiation resistance begins to be acquired during this period, as is further chemical resistance, and forespore dehydration continues (8, 12). During the stage V-stage VI transition, the spore core's depot of DPA is accumulated following DPA synthesis in the mother cell. CaDPA is taken into the spore core by a SpoVV transporter in the OM and a SpoVA channel in the IM (4, 31); significant amounts of Mg^{2+} and Mn^{2+} are also taken up, almost all in the spore core (25). The precise state of CaDPA in the spore core is not known, although the amount in spores exceeds its solubility. During this period, the spore's central region or core undergoes the final process of dehydration. Because of the high ratio of solids to water in the spore core at this stage, the spore appears bright in phase-contrast microscopy. It has been suggested that the spore core is in a glass-like state, but this suggestion now appears incorrect (32–34). Because of permeability changes in the spore membranes, most likely the IM, the spore at this stage stains poorly, if at all, with common bacteriological stains, in particular nucleic acid stains. The spore also becomes metabolically dormant during this period and acquires further gamma radiation and

chemical resistance (8, 12). Finally, in the transition to stage VII, autolysins are produced in the mother cell, resulting in its lysis and release of the spore.

The eight stages are particularly useful in characterizing various asporogenous or *spo* mutants that have no defect in growth but are blocked in a particular stage in sporulation. These *spo* mutants are given an added designation denoting the stage in which they are blocked. Hence, *spo0* and *spoII* mutants are blocked in stages 0 and II, respectively. The various stages have also allowed correlation of biochemical changes with morphological changes (Fig. 2.2). However, the sporulation scheme outlined above is an oversimplification for several reasons. First, since the various stages are intermediates in a continuous developmental process, it is probably misleading to think of the stages as discrete entities. Second, the scheme is only for rod-shaped bacteria that sporulate without terminal swelling of the forespore. There are many sporeformers in which the forespore compartment swells considerably and the mother cell elongates, such as the toxigenic clostridia *Clostridium botulinum* and *Clostridium tetani* (13). Some sporeformers (e.g., *Sporosarcina* species) grow as cocci, and their sporulation septum is placed symmetrically; other quite different sporulation patterns have also been observed (13, 18, 19).

Regulation of Gene Expression during Sporulation

Much of our knowledge of regulation of gene expression during sporulation has been derived from analysis of *spo* mutants in *B. subtilis*, and asporogeny can be caused by mutations in >75 genes (2, 4–7). The identification of biochemical or physiological markers for the sporulation stages provides another aid to understanding gene regulation during sporulation (Fig. 2.2). Analysis of these markers in *spo* mutants indicates that sporulation is primarily a linear sequence of events, although development in the two cell types must be coordinated. In general, *spo0* mutants exhibit no sporulation-specific markers, *spoII* mutants exhibit only stage 0-specific events, etc.

While analysis of *spo* mutants has furnished a broad outline of regulation of gene expression during sporulation, molecular genetics has provided a detailed understanding of this process. Sporulation requires transcription of many new genes, as has been elegantly demonstrated by microarray and "-omics" technologies (2, 5–7). These changes in transcription during sporulation are directed in large part by changes in the specificity of the cell's RNA (E) polymerase due to synthesis of five new σ factors that have promoter specificities distinct from that of the main housekeeping sigma factor, σ^A. The sporulation-specific sigma factors direct transcription in the predivisional cell (σ^H), the mother cell compartment (σ^E followed by σ^K), and the forespore compartment (σ^F followed by σ^G). In addition, changes in sporulation-specific gene expression require modulation of transcription by (i) activation or inactivation of factors by covalent and noncovalent modification, (ii) regulatory communication to coordinate mother cell and forespore development, (iii) synthesis of DNA binding proteins to activate or repress transcription, (iv) degradation of DNA binding proteins and σ factors, (v) phosphorylation of serine/threonine residues by protein kinases (35), and (vi) synthesis of some small noncoding RNAs. This information has provided a detailed picture of the control of gene expression during sporulation that is striking not only in its complexity but also in the redundancy of its control mechanisms. The following discussion of these control mechanisms is simplified and concentrates on major regulatory gene products.

Initiation of *B. subtilis* sporulation requires expression of *spo0* gene products in vegetative cells (1, 2, 5–7, 22). The most important of these *spo0* gene products is Spo0A, the response regulator half of a two-component regulatory system. These signal transduction systems transmit signals, often by binding to DNA and affecting transcription, when an aspartyl residue in the response regulator is phosphorylated by a sensor kinase. In growing cells, Spo0A is primarily in the dephosphorylated state. However, under conditions that initiate sporulation, the level of Spo0A rises, as does its degree

of phosphorylation, the latter through the action of multiple sensor kinases. In *B. subtilis*, the majority of phosphate on Spo0A is derived via a phosphorelay initiated by phosphorylation of Spo0F (Fig. 2.3 and 2.4), and phosphate is then transferred from phosphorylated Spo0F (Spo0F~P) to a Spo0A by Spo0B. Note that this phosphorelay appears to be absent in at least some members of the *Clostridiales* (13, 14). In *Bacillus* species, there are two major kinases, KinA and KinB, as well other minor kinases that initiate the phosphorelay. Mutations in either *kinA* or *kinB* have little or no effect on sporulation, but a *kinA kinB* double mutant is asporogenous.

In addition to the kinases, there are many phosphatases that can dephosphorylate Spo0A~P, either directly or through dephosphorylation of Spo0F~P (Fig. 2.3). This multiplicity of kinases and phosphatases allows a variety of environmental signals to be integrated to determine intracellular levels of Spo0A~P, and a threshold concentration of Spo0A~P is needed to initiate sporulation by modulating the expression of ~100 genes (1, 2, 5–7, 22). A number of regulators of the kinases and phosphatases that modulate Spo0A~P levels have been identified, and overexpression of kinases that generate Spo0A~P triggers sporulation in growing cells. Not all cells in a population choose to sporulate, and the major factor influencing this decision is the Spo0A~P level, which is quite heterogeneous between individual cells in sporulating populations, and stochasticity in the overall phosphorelay appears to play a major role in the heterogeneity in Spo0A~P levels (1, 2, 27).

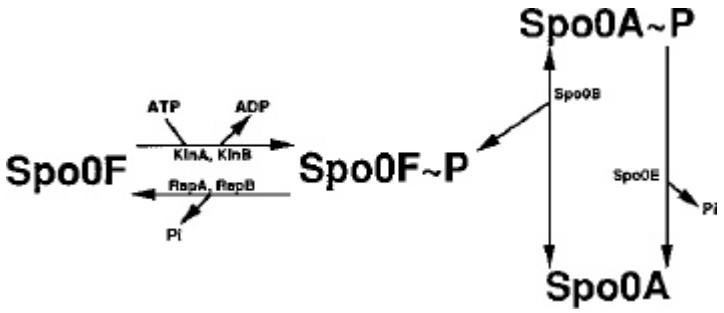

Figure 2.3 Some gene products and reactions that affect levels of Spo0A~P. Spo0E is a phosphatase that acts on Spo0A~P; RapA and RapB are phosphatases that act on Spo0F~P (6).

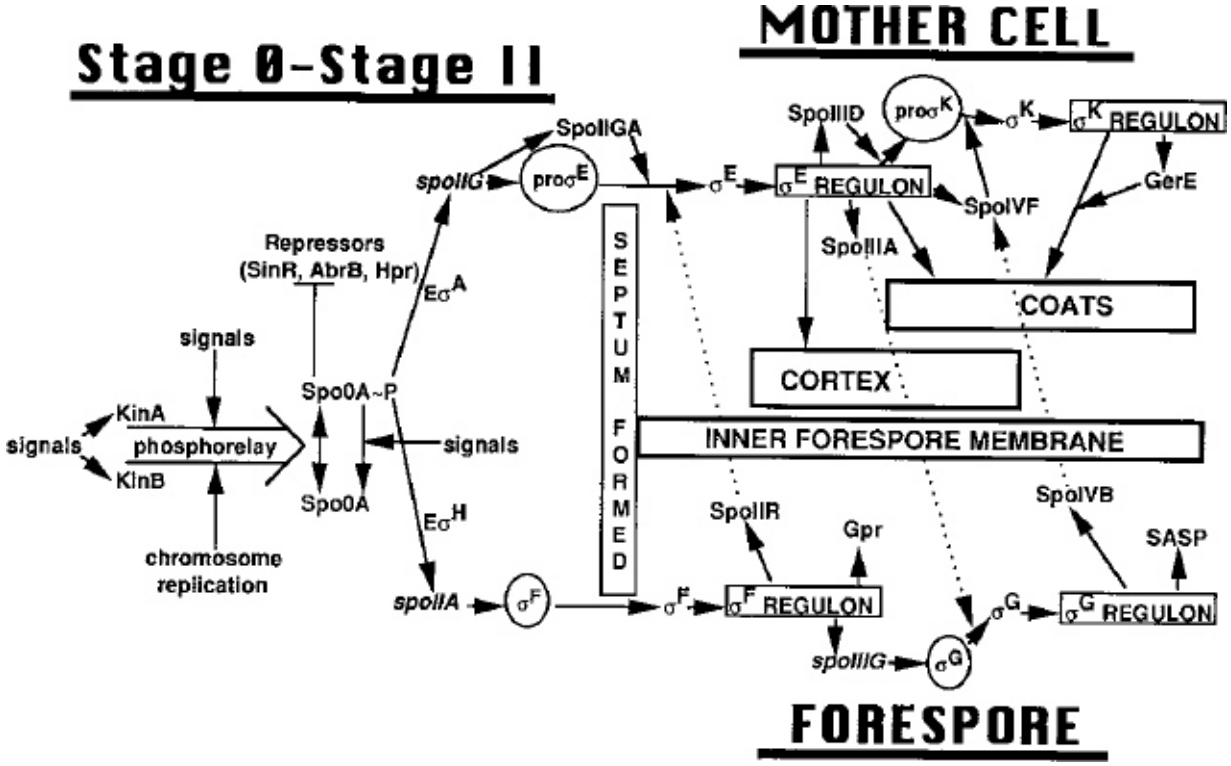

Figure 2.4 Regulation of gene expression during sporulation. The effect of Spo0A~P on repressors is negative; other effects of regulatory molecules on reactions are generally positive, although the effect of signals may be positive or negative. The enclosure of the pro-σfactors and σ factors indicates that at this time, these factors are inactive.

The phosphorylation of Spo0A increases its affinity for binding to sites upstream of several key genes, although different sites have

different affinities for Spo0A~P. The *abrB* gene has a high affinity for Spo0A~P, and binding of Spo0A~P decreases *abrB* transcription. Since AbrB is labile, a decrease in *abrB* transcription rapidly decreases intracellular AbrB concentration. AbrB is a repressor of a number of genes normally expressed in the stage 0-stage II transition, including *spo0H*, which encodes σ^H. AbrB is also an activator for synthesis of a second repressor, Hpr, that represses additional stage 0-expressed genes, especially genes for several proteases. In addition to AbrB and Hpr, there is a third repressor, SinR, that represses other genes expressed in the stage 0-stage II transition, including those of the *spoIIG* and *spoIIA* operons. SinR action is blocked by synthesis of a protein termed SinI that binds to SinR and blocks its action. Synthesis of SinI is stimulated by Spo0A~P and probably repressed by AbrB and Hpr.

There is also a fourth repressor, CodY, that represses many genes whose expression is needed early in stationary phase/sporulation, including genes whose products are involved in competence, motility, and the TCA cycle (36). CodY also represses genes required for sporulation, including *spo0A*. The repressor function of CodY requires branched-chain amino acids and GTP, and the latter effect likely explains why decoyinine, an inhibitor of guanine nucleotide biosynthesis, can induce sporulation in growing cells. The consequences of this regulation are that early in the stage 0-stage II transition, many genes normally repressed during vegetative growth are derepressed through a decrease in GTP levels and an increase in the level of Spo0A~P (Fig. 2.4). Among these stage 0-to-stage II genes is *spo0H*, encoding σ^H and early in sporulation, there is an increase in $E\sigma^H$ transcription. As Spo0A~P levels increase, concentrations become sufficient to bind the promoters of the *spoIIG* and *spoIIA* operons from which SinR has been removed, triggering the transcription of these two operons.

The *spoIIA* operon is transcribed by $E\sigma^H$ and encodes three proteins, with the third cistron (*spoIIAC*) encoding another sigma factor, termed σ^F The *spoIIAB* gene encodes an inhibitor of σ^F

function, whereas *spol IAA* encodes a SpoIIAB antagonist; SpoIIAB is also a protein kinase that can phosphorylate SpoIIAA. Prior to septation, σ^F is inactive in the sporulating cell due to its interaction with SpoIIAB, and interaction of SpoIIAB with SpoIIAA is blocked by phosphorylation of SpoIIAA by SpoIIAB.

The *spoIIG* operon is transcribed by $E\sigma^H$ and encodes two proteins, with the second cistron, *spoIIGB*, encoding another σ factor for RNA polymerase, σ^E Unlike σ^F and σ^H, σ^E is synthesized as an inactive precursor termed pro-σ^E The first gene of the *spoIIG* operon (*spoIIGA*) is the protease responsible for processing pro-σ^E to σ^E. Action of SpoIIGA on pro-σ^E requires gene expression under σ^F control in the forespore (Fig. 2.4). Although *spoIIG* is transcribed before septum formation, σ^E is not generated until after septation and then only in the mother cell. σ^F is also produced before septum formation and is maintained in an inactive state by interaction with SpoIIAB as noted above. However, following septation, σ^F becomes active in the forespore, as SpoIIAB leaves σ^F and interacts with SpoIIAA. This process is promoted largely by dephosphorylation of SpoIIAA~P by the SpoIIE phosphatase that resides in the sporulation septum (3, 5–7).

$E\sigma^F$ -transcribed genes include *rsfA*, *spoIIR*, *gpr*, and *spoIIIG* (2) (Fig. 2.4). RsfA is a DNA-binding protein that modifies the specificity of $E\sigma^F$ SpoIIR promotes pro-σ^E processing by SpoIIGA in the mother cell shortly after septation, and this requirement for *spoIIR* transcription in the forespore for pro-σ^E processing in the mother cell is the first example of cross talk between the two compartments of the sporulating cell that coordinate mother cell and forespore development. The *gpr* gene encodes a protease that acts on SASP in the first minute of spore outgrowth, and *spoIIIG* encodes another σ factor, termed σ^G, that is responsible for the bulk of forespore-specific transcription (2, 5–7). However, σ^G is not active following its synthesis in stage III, at least in part because of the product of the σ^F-controlled *csfB* gene.

Ultimately, mother cell-specific events, including transcription of the *spoIIIA* operon by $E\sigma^E$, are required for generation of active $E\sigma^G$ (Fig. 2.3 and 2.4). At least SpoIIIA proteins as well as SpoIIQ are essential components of a channel termed a feeding tube between the mother cell and forespore compartments, and although the molecules that pass through this channel have not been definitively identified, at least some are likely to be nutrients (3, 37). This is the second example of cross talk between mother cell and forespore, although the precise mechanism for the regulation of σ^G activity in the forespore and the identities of the molecules that pass through the feeding tube are not clear. The generation of σ^F only in the mother cell and the activation of σ^F and synthesis of σ^G only in the forespore now establish compartment-specific transcription during sporulation. As noted above, EG transcribes a number of genes expressed only in the forespore. As the third example of regulatory cross talk, one such gene (*spoIVB*) is responsible for communicating with the mother cell and coordinating gene expression in this compartment (Fig. 2.4; see below). The *ssp* genes are a large set of genes transcribed by $E\sigma^G$. These genes encode the SASP that are major protein components of the spore core (see below) (2, 8, 10–12). Transcription of genes by $E\sigma^G$ is modulated by the DNA binding protein SpoVT, and the *spoVT* gene is transcribed by $E\sigma^G$

In contrast to $E\sigma^G$, $E\sigma^E$ transcribes genes only in the mother cell, including genes needed for cortex biosynthesis and some genes (*cot* genes) needed for coat formation and assembly (2, 5–7, 23, 29). $E\sigma^E$ also transcribes *gerR* and *spoIIID*, which encode DNA-binding proteins that modulate $E\sigma^E$ action, resulting in transcription of different classes of $E\sigma^E$ -dependent genes. One such $E\sigma^E$ dependent gene that requires SpoIIID for transcription is *sigK*, which encodes a final new σ factor, termed. σ^K In some *B. subtilis* strains, the *sigK* gene has an intervening sequence that is removed only from the mother cell genome by a recombinase. Expression of the recombinase is regulated such that generation of an intact *sigK* gene

precedes *sigK* transcription. However, this intervening sequence is absent in the *sigK* genes of many other sporeformers (2, 5–7, 13). As is the case with σ^E, σ^K is synthesized as inactive pro-σ^K and is processed proteolytically about 1 hour after its synthesis. Conversion of pro-σ^k to σ^K in the mother cell requires expression of a gene (*spoIVB*) in the forespore (the third example of cross talk) and participation of the σ^E controlled *spoIVF* operon in the mother cell (Fig. 2.4). SpoIVFB is the protease that processes pro-σ^k, and SpoIVFA is an inhibitor of SpoIVFB function. Eσ^K also transcribes *sigK* (in conjunction with SpoIIID), the gene for DPA synthase, other *cot* genes, and *gerE*, which encodes a DNA-binding protein that modulates Eσ^K specificity (Fig. 2.4). Most knowledge of gene expression during sporulation ends at this point, including information about genes that may be required for mother cell lysis. However, the gene for one autolytic enzyme (CwlC) is transcribed by Eσ^K.

The preceding picture of regulation of gene expression during sporulation is derived predominantly from detailed studies with *B. subtilis*. However, as noted above, genomic sequence data indicate that many key sporulation regulatory genes, such as *spo0A*, *spoIIA* to *-C*, *spoIIGA* and *-B*, *spoIIIG*, *sigK*, etc., are present in other sporeformers, including *Clostridium* spp. (13–19). The conservation of the sequences of the shared proteins and the organization of these genes strongly suggest that regulation of sporulation across *Bacillus* and *Clostridium* species is relatively similar, and this has generally been determined to be the case, although details often differ.

THE SPORE

Spore Structure

The structure of the dormant spore is very different from that of a growing cell (Fig. 2.5), as some spore structures, including the

exosporium and coats, have no counterparts in growing cells. The outermost spore layer, the exosporium, varies significantly in size between species, being prominent in spores of *Bacillus cereus*, *B. anthracis*, *Bacillus thuringiensis*, and some members of the *Clostridiales*, and may not be present in spores of other species, such as *B. subtilis* (23, 24). This structure can exclude large molecules such as antibodies, can influence spore surface adhesion, and may play some role in spore pathogenesis. The exosporium is composed of lipid, carbohydrate, and protein, including glycoprotein, and the proteins are unique to spores.

Under the exosporium are the spore coats. In *B. subtilis* spores, a number of distinct coat layers are seen in electron micrographs. The coats are composed primarily of protein, with ~80 different proteins in *B. subtilis* spore coats, almost all of which are unique to spores. Some coat proteins are essential for assembly of the multilayered coat structure, but specific roles for many individual coat proteins are not known. Coat proteins for which roles are known or predicted include the following (2, 4, 8, 9, 12, 23): (i) proteins essential for assembly of another protein in the coat; (ii) enzymes in the coat that can detoxify reactive oxidative oxygen species; (iii) proteins that appear to facilitate nutrient germinant access to nutrient germinant receptors (nGRs); (iv) enzymes that can inactivate possible germinants; and (v) enzymes that can generate protein-protein cross-links in coat proteins. These cross-links include dityrosine and γ-glutamyllysine cross-links and may be important in spore coat structure. Spore coats also protect spore PG from attack by lytic enzymes, including those in many eukaryotic bacterivores, and the spore's inner layers against many chemicals. Spore coats can also play minor roles in UV and wet-heat resistance. Underlying the coats is the OM, a functional membrane in the developing forespore, but its functionality in the dormant spore is not clear (12, 38). The protein composition of the OM is different from that of the IM.

Underlying the OM is the cortex. Cortical PG is structurally similar to cell wall PG, but with several differences (29): cortical PG

contains diaminopimelic acid even if vegetative-cell PG contains lysine, and many of the muramic acid residues in cortical PG lack peptide residues. Although some muramic acid residues contain a single d-alanine, or in some species a dipeptide, much is present as muramic acid–δ-lactam (MAL), a compound not present in growing-cell PG. A number of genes involved in cortex synthesis have been identified and characterized, and the pathway for MAL synthesis during sporulation is understood. The timing of cortex biosynthesis and cross-linking during sporulation has been determined, and cortex PG is generally less cross-linked than growing-cell PG, although the precise distribution of crosslinks throughout the cortex is not known. The exact function of cortex PG cross-linking is also not known, but it likely plays roles in spore germination and resistance. Between the cortex and the IM is the germ cell wall, and germ cell wall PG appears to be identical to vegetative-cell PG.

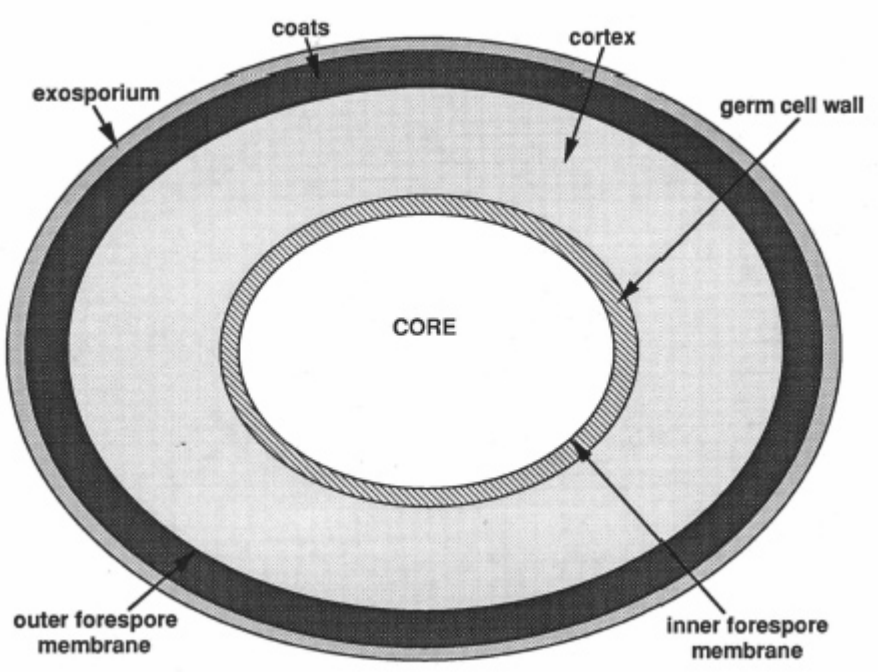

Figure 2.5 Structure of a dormant spore. The various structures are not drawn precisely to scale, especially the exosporium, whose size varies tremendously between spores of different species. The germ cell wall is also generally smaller than shown. The positions of the inner and outer forespore membranes, between the core and the germ cell wall and between the cortex and coats, respectively, are also noted.

The next structure, the IM, is a functional membrane and an extremely strong permeability barrier slowing the entry of almost all molecules, including perhaps even water, into the spore core (8, 12, 38). A lipid probe in the IM is largely immobile, suggesting that this membrane has a relatively “frozen” structure (8, 12, 39). However, the IM’s phospholipid content is similar to that of growing cells. The volume surrounded by the inner forespore membrane appears smaller than expected based on this membrane’s phospholipid content. However, the core’s volume expands significantly upon completion of spore germination and in the absence of membrane synthesis (39). A lipid probe in the IM also becomes fully mobile at this time. Notably, a number of crucial germination proteins are in the IM (see below).

Finally, the central region, or core, contains the spore's DNA, ribosomes, and most enzymes, as well as CaDPA and most other divalent cations. There are also unique gene products in the dormant spore, including the large SASP pool (ca. 10% of spore protein), much of which is bound to spore DNA (8, 12; also, see below). A notable feature of the spore core is its low water content (25). While vegetative cells have ca. 4 g of water per g of dry weight, the spore core has only 0.4 to 1 g of water per g of dry weight. The core's low water content likely plays a major role in spore dormancy and in spore resistance to a variety of agents. The core's low water content is also likely the reason for the immobility of ions and protein in the spore core (40). In contrast to the low water content in the spore core, the water content in other regions of the spore is similar to that in growing cells.

Spore Macromolecules

Some proteins in the spore core and outer layers are not present in growing cells. The SASP, SpoVV, SpoVA, nGR proteins, and cortex-lytic enzymes (CLEs) (see below) are particularly noteworthy, as some of these proteins play major roles in spore resistance and germination (4, 8–12, 31). SASP and SpoVA proteins are synthesized in the forespore during stage III of sporulation, when their coding genes are transcribed primarily by $E\sigma^G$, and are located in the spore core. There are two kinds of major SASP in *Bacillus* spp., the γtype and the α/βtype. The 75-to 105-residue γ-type SASP comprise ca. 5% of spore protein and do not bind other spore macromolecules. Their only known function is to be degraded during outgrowth by GPR, providing amino acids for metabolism and protein synthesis. γ-type SASP are encoded by a single gene in *Bacillus* spp. but are not present in spores of *Clostridium* species or in members of one clade in the *Bacillales* (41). The sequences of γ-type SASP are not homologous to those of other proteins, and these proteins' sequences have diverged significantly during evolution.

The α/β-type SASP make up 3 to 5% of total spore protein and are in all spore-forming *Bacillales* and *Clostridiales* species that have been studied (8, 12, 14, 17, 18). In contrast to γ-type SASP, α/β-type SASP are encoded by up to seven genes, all of which are expressed in parallel, although in some species two proteins are expressed at high levels and the remainder at lower levels. However, all α/β-type SASP have similar properties *in vitro* and *in vivo* (see below). The amino acid sequences of these small (60-to 75-residue) proteins are highly conserved both within and across species, although they too have no sequence homology to other proteins. The α/β-type SASP are also degraded to amino acids in the first minutes of spore outgrowth in a germination protease (GPR)-initiated process.

The α/β-type SASP are DNA-binding proteins, both *in vivo* and *in vitro* (8, 12, 14). *In vivo*, these proteins saturate the spore chromosome and provide much of the spore DNA's resistance to various treatments (see below). Binding of α/β-type SASP to DNA is not sequence specific but exhibits a preference for GC-rich regions, although AT-rich regions are bound. The proteins bind to the outside of the DNA helix, interacting primarily with the sugar phosphate backbone. This binding alters DNA structure, provides resistance to chemical and enzymatic cleavage of the DNA backbone, alters the DNA's UV photochemistry, and greatly slows DNA depurination (see below). A number of proteins present in vegetative cells are absent from *Bacillus* spores. These include amino acid and nucleotide biosynthetic enzymes that are degraded during sporulation and resynthesized during spore outgrowth (11). Other proteins, including enzymes of amino acid and carbohydrate catabolism, are present at similar levels in spores and cells, and spores also contain enzymes for RNA and protein synthesis and DNA repair. However, at least one protein needed for initiation of DNA replication may be absent. Enzyme activities common to both cell and spore proteins are almost always due to the same gene product. In general, spore and cell rRNAs and tRNAs are similar if not identical, although much tRNA in spores lacks the 3′-terminal A residue and little spore tRNA is aminoacylated. Spores do contain

some mRNA that has been identified by microarray and -omics technologies (42–44), although the function of this spore mRNA is not clear. Spore DNA appears identical to growing-cell DNA but has a different structure due to different associated proteins, as noted above and below.

Spore Small Molecules

Spores differ from growing cells in their small molecules (Table 2.1), which are located in the core. The small amount of core water and the huge depot of DPA and divalent cations are noted above. The ions in the spore core are immobile, as is at least one normally mobile protein (40), consistent with a dearth of free water in spores. The pH in the spore core is 1 to 1.5 units lower than in a growing cell or the mother cell compartment. Spores of most species accumulate a large depot of 3-phosphoglyceric acid (3PGA) shortly after and in response to the forespore pH decrease (11). However, spores have small amounts of nucleoside triphosphates and reduced numbers of reduced pyridine nucleotides or acyl coenzyme A (CoA), although the "low-energy" forms of these compounds are present. The high-energy forms are lost from the forespore late in sporulation (Fig. 2.2). Much of the CoA in spores is in disulfide linkage, some as a CoA disulfide and some linked to protein. The function of these disulfides is unknown, but they are reduced early in spore outgrowth. Spores also have low levels of most free amino acids but often have high levels of glutamate.

Spore Dormancy

Spores are metabolically dormant, catalyzing minimal metabolism of endogenous or exogenous compounds. However, incubation of dormant spores for extended times at 37 to 50°C or for shorter times at 60 to 70°C does lead to extensive degradation of at least spore rRNA (44, 45). However, this degradation itself does not lead to spore death, as rRNA is resynthesized early in outgrowth. Synthesis of some mRNAs has also been reported in spores incubated for long periods at 37 to 50°C (44), but detectable ATP

levels have not been found in spores incubated in this manner (46). The major Cause of spores' extremely low metabolism is undoubtedly the low water content of the spore core, which precludes protein mobility and enzyme action (25, 40). A reflection of this dormancy is that the spore core contains at least two enzyme-substrate pairs that are stable for years but interact in the early minutes of spore outgrowth, resulting in substrate degradation. These two enzyme-substrate pairs are 3PGA-phosphoglycerate mutase (PGM) and SASP-GPR (11). Although regulatory mechanisms other than dehydration initially stabilize 3PGA and SASP in the developing forespore despite the presence of PGM and GPR, the lack of PGM and GPR action on their substrates in dormant spores over very long periods at low temperatures and even during incubation at 37 to 50°C may be largely due to spore core dehydration.

Table 2.1 Small molecules in cells and spores of *Bacillus* species

Molecule(s)	Content (μ mol/g dry wt)	
	Cells[a]	Spores[b]
ATP	3.6	≤0.005
ADP	1	0.2
AMP	1	1.2–1.3
Deoxynucleotides	0.59[c]	<0.025[d]
NADH	0.35	<0.002[e]
NAD	1.95	0.1P
NADPH	0.52	<0.001[e]
NADP	0.44	0.018[e]
Acyl-CoA	0.6	<0.01[e]
CoASH[f]	0.7	0.26[e]
CoASSX[g]	<0.1	0.54[e]
3PGA	<0.2	5-18
Glutamic acid	38	24-30
DPA	<0.1	410-470
Ca^{2+}		380-916
Mg^{2+}		86-120
Mn^{2+}		27-56
H+[h]	7.6-8.1	6.3-6.9

[a] Values for *B. megaterium* in mid-log phase are from reference 6

[b] Values are the ranges for spores of *B. cereus*, *B. subtilis*, and *B. megaterium* and are from reference 6.

[c] Value is the total for all four deoxynucleoside triphosphates.

[d] Value is the sum for all four deoxynucleotides.

[e] Values are for *B. megaterium* only.

[f] CoASH, free CoA.

[g] CoASSX, CoA in disulfde linkage to CoA or a protein.

[h] Values are expressed as pH and are the ranges for *B. cereus*, *B. megaterium*, and *B. subtilis*.

SPORE RESISTANCE

Spores can survive for extremely long times, and claims have been made for spore survival for millions of years (19). While the latter claims are controversial, it is clear that spores can survive for at least hundreds of years. The spore's metabolic dormancy is undoubtedly one factor in its survival in the absence of nutrients. A second factor is the spore's extreme resistance to potentially lethal treatments, including heat, radiation, chemicals, desiccation, high pressure, and various types of high-energy plasma (8, 12, 14). Representative data on resistance or susceptibility of growing cells and spores of *B. subtilis* to different potentially lethal treatments are shown in Table 2.2. There are, however, some *Bacillales* and *Clostridiales* species which form much more resistant spores than *B. subtilis*. Spore resistance is due to a variety of factors, with core dehydration and α/β-type SASP being involved in many types of resistance, whereas the impermeability of the spore's inner membrane may be involved in only one.

Since different and sometimes multiple factors contribute to different types of spore resistance, it is not surprising that spore resistance to different treatments is acquired at different times in sporulation (Fig. 2.2). In recent years, some mechanisms of spore resistance to heat, UV, and chemicals have been elucidated. The following discussion of spore resistance concentrates on *B. subtilis* spores because of the detailed mechanistic data available for these spores. However, studies with spores of other *Bacillus* species as well as some with *C. perfringens* have found that factors involved in

resistance of *B. subtilis* spores are also involved in resistance of spores of other bacterial genera.

Freezing and Desiccation Resistance

Growing bacteria are killed during freezing and desiccation, unless special precautions are taken. The mechanism of this killing is not clear but may involve DNA damage. In contrast to the sensitivity of growing cells to freezedrying, spores are resistant to multiple exposures to freeze-drying (Table 2.2). The α/β-type SASP are one factor providing spore resistance to freeze-drying by preventing DNA damage (Table 2.2). The spore's DPA is another factor providing spore desiccation resistance, as spores deficient in DPA are more sensitive to desiccation than their DPA-replete counterparts, and killing of DPA-less spores by desiccation is also due to DNA damage (47). However, bacterial spores do not achieve desiccation resistance by accumulating sugars such as trehalose (12).

Pressure Resistance

Spores are more resistant to high pressures (>50 MPa) than are growing vegetative cells (48). Notably, spore killing by high pressure is probably due to initial induction of germination followed by the killing of the much less resistant germinated spores. The most effective way to kill high-pressure-germinated spores is by heat, and hence, high-pressure treatments are often carried out at temperatures that are elevated but not nearly as high as those needed to kill dormant spores. Spore germination induced by pressures of 100 to 350 MPa is due to activation of the spore's nGRs, and this decreases at elevated temperatures. In contrast, germination promoted by pressures of ≥ 450 MPa does not require nGRs but directly activates the SpoVA CaDPA channel, even at elevated temperatures (4, 48). The latter conditions are now used to reduce spore loads in foods or foodstuffs, as even if the high-pressure-germinated spore goes no further in germination than

CaDPA release, CaDPA-less spores are much more heat sensitive than dormant spores.

Gamma Radiation Resistance

Spores are more resistant to gamma radiation and high energy ions than are growing cells, and this resistance is acquired 1 to 2 h before acquisition of heat resistance (8, 12, 49). The α/β-type SASP are one factor contributing to spore gamma radiation and high-energy-ion resistance, as is DNA repair in spore outgrowth, although the precise damage caused by these agents is not known (50). Several mutations that result in increased spore core water also result in slightly lower spore resistance to high-energy ions and gamma radiation.

UV Radiation Resistance

Spores are generally 7 to 50 times more resistant than growing cells to UV radiation at 254 nm, the wavelength giving maximal killing (8, 12) (Table 2.2). Spores are also more resistant than growing cells at longer and shorter UV wavelengths. UV resistance is acquired by the developing forespore ca. 2 hours before acquisition of heat resistance (Fig. 2.2), in parallel with synthesis of α/β-type SASP. The α/β-type SASP are essential for spore UV resistance, but spore coats, cortex, and core dehydration are generally not. However, for some species, pigments in spores' outer layers may provide some UV protection (12, 23). Spore UV resistance is largely due to a different UV photochemistry of DNA in spores and in growing cells. The major photoproducts formed by UV irradiation of growing cells or purified DNA are cyclobutane-type dimers between adjacent pyrimidines. The most abundant of these are between adjacent thymine residues (TT) (Fig. 2.6A), with smaller amounts formed between adjacent cytosine and thymine residues (CT) or adjacent cytosine residues (CC). In addition, UV irradiation of cells or purified DNA generates various 6,4-photoproducts (64PP) also formed between adjacent pyrimidines. All these photoproducts can be lethal as well as mutagenic. In contrast, UV irradiation of spores

generates few cyclobutane-type dimers and 64PP but rather large amounts of a thyminyl-thymine adductinitially termed the spore photoproduct (SP) (Fig. 2.6B). The yield of the SP as a function of UV fluence in spores is similar to yields of TT as a function of UV fluence in growing cells, and SP is a potentially lethal photoproduct. Hence, the difference in UV photochemistry alone between DNA in growing cells and spores is insufficient to explain spore UV resistance, as there must be a difference in the capacity of cells and spores to repair TT and SP. Indeed, spores have two major mechanisms for SP repair, both of which operate in the first minute of spore outgrowth. One mechanism is an excision repair system that repairs TT and other lesions in growing cells. Spores lacking this repair system are 2-to 3-fold more UV sensitive than are wild-type spores. The second repair system, unique to both spores and SP, monomerizes SP to two thymines without excision of the lesion and makes very few errors. Spores lacking this SP-specific repair system are 5-to 10-fold more UV sensitive than are wild-type spores, and those lacking both repair systems are 20-to 40-fold more UV sensitive. SP-specific repair is catalyzed by the SP lyase (Spl), an iron-sulfur protein that uses *S*-adenosylmethionine (SAM) as a cofactor. Spl is a member of the “radical SAM” family of enzymes that use an [Fe-S] center plus SAM to generate a catalytic adenosyl radical. In contrast to enzymes of excision repair that are present in growing cells and spores, Spl is present only in spores.

Table 2.2 Killing and mutagenesis of spores and cells of *B. subtilis* by various treatments[a].

A. Freeze-drying			
		Survival (%)	
No. of freeze-drying cycles	Cells[b]	Wild-type spores	α–β– spores[c]
1 3	2	 100 (<0.5)	 7 (14)

[a] Data are from reference 6. Values in parentheses are the percentages of survivors with asporogenous or auxotrophic mutations when spores undergo 30 to 99% killing.

[b] Cells in log-phase growth. Similar results have been obtained with wild-type and $\alpha^-\beta^-$ cells.

[c] These spores lack the two major α/β-type SASP and thus ca. 80% of the α/β-type SASP pool.

[d] UV irradiation with light predominantly at 254 nm.

The major factor causing the altered UV photochemistry of spore DNA is the saturation of DNA with α/β-type SASP; all α/β-type SASP appear relatively interchangeable in this regard. Spores lacking ca. 80% of these proteins (α–β–spores) are more UV sensitive than are growing cells (Table 2.2), and UV irradiation of α–β– spores generates significant amounts of TT and 64PP and reduced amounts of SP.UV irradiation of DNA saturated *in vitro* with any of a number of purified α/β-type SASP generates SP and minimal TT, CT, CC, or 64PP. However, yields of SP as a function of UV fluence in these complexes are ca. 10-fold lower than yields in spores. This difference is due to the spore's CaDPA, which acts as a photosensitizer. The change in the UV photochemistry of DNA upon binding of α/β-type SASP indicates that the DNA in this complex has an altered structure, and this is a structure between those of A- and B-DNA. During spore outgrowth, α/β-type SASP are degraded to amino acids, a process initiated by GPR (11). Because of the photosensitizing action of CaDPA, spores early in outgrowth are

more UV resistant than are dormant spores, due to CaDPA release prior to SASP degradation. However, as SASP degradation proceeds, UV resistance falls from this elevated level to that of vegetative cells.

Chemical Resistance

Spores are more resistant than growing cells to chemicals, including aldehydes, oxidizing agents (Table 2.2), phenols, chloroform, octanol, alkylating agents such as ethylene oxide, iodine, and detergents, as well as to pH extremes and lytic enzymes such as lysozyme (8, 12, 14). Resistance of spores to these agents is acquired at different times in sporulation (Fig. 2.2). For enzymes such as lysozyme, spores that lack coat protein due to chemical treatment or mutation are sensitive to cortex degradation by lytic enzymes, and coats protect spores against digestion by bacterivores (23). Coat-defective spores are more sensitive to many chemicals, including oxidizing agents, perhaps because coat proteins serve as a "reactive armor" that inactivates toxic chemicals before they reach more-sensitive targets further within the spore. The spore coats of some species also contain enzymes such as catalase and superoxide dismutase that can increase spore resistance to these enzymes' substrates (8, 12). The slow passage of hydrophilic molecules across the spore's IM is also important in spore resistance to chemicals (12, 38). Some chemicals, including formaldehyde, alkylating agents, and nitrite, kill spores at least in part by DNA damage, and the α/β-type SASP are essential in protection against inactivation of *Bacillus* and *Clostridium* spores by these agents. In contrast, many oxidizing agents kill spores not by DNA damage but rather by damaging the spore's IM such that even if the treated spores are germinated artificially, the IM ruptures, leading to spore death.

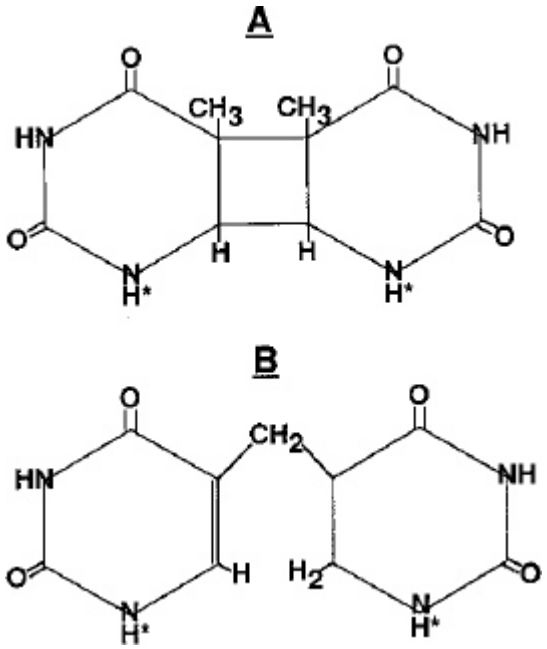

Figure 2.6 Structure of the cyclobutane-type TT dimer (A) and the 5-thyminyl-5,6-dihydrothymine adduct (spore photoproduct) (B). The positions of the hydrogens noted by the asterisks are the locations of the glycosylic bond in DNA

Some detailed information is available about the points raised above for oxidizing agents such as peroxides that kill growing cells by several mechanisms, a major one being generation of hydroxyl radicals that cause DNA damage. However, spore killing by hydrogen peroxide or organic hydroperoxides such as *t*-butylhydroperoxide (tBHP) is not accompanied by significant DNA damage or mutagenesis (Table 2.2) (8, 12). Consequently, DNA in spores must be well protected by these agents. While the spore coat, low core water content, and the low-permeability IM may play some role in resistance to H_2O_2 and tBHP, these factors do not directly protect spore DNA, and this protection is due to saturation of spore DNA with α/β-type SASP, as $\alpha^-\beta^-$ spores are much more sensitive to these peroxides (Table 2.2). In addition, wild-type spores are not appreciably mutagenized by H^2O^2 or tBHP, whereas $\alpha^-\beta^-$ spores are heavily mutagenized (Table 2.2). These results suggest that saturation of DNA with α/β-type SASP provides such good protection against DNA damage that killing of wild-type spores by

such peroxides is by other mechanisms. However, in α/β– spores, the rates of DNA damage caused by peroxides are greatly increased, such that DNA damage is a significant cause of spore death. Supporting this simple model is that spores of wild-type but not α/β– strains acquire one component of H^2O^2 resistance during sporulation in parallel with accumulation of α/β-type SASP. However, α/β-type SASP binding to DNA is not the only factor in spore hydrogen peroxide resistance. Indeed, an additional component of this resistance is acquired during sporulation at the time of final spore core dehydration. This may reflect roles in hydrogen peroxide resistance for spore core dehydration or the low permeability of the spore's IM or the fact that the loss of reduced pyridine nucleotides from the developing spore (which also occurs at this time) decreases production of hydroxyl radicals through the Fenton reaction. Unlike the situation in growing cells, spore core enzymes, such as catalases, alkylhydroperoxide reductases, and superoxide dismutase, and the DNA-binding protein MrgA play no role in spore resistance to peroxides.

Heat Resistance

The extreme resistance of spores to moist heat, the spore resistance most familiar to food microbiologists, has great implications for the food industry and is probably the most studied spore resistance property (8, 12, 25, 51). Spore moist heat resistance is remarkable, as spores of many species can withstand 100°C for many minutes. Heat resistance is often quantified as a *DT* value, which is the time in minutes at temperature *T* needed to kill 90% of a cell or spore population. Generally, *D* values for spores at a temperature of *T* + 40°C are approximately equal to those for their vegetative cell counterparts at temperature *T*. The extended survival of spores at elevated temperatures is paralleled by even longer survival times at lower temperatures, as spore *D* values increase 4-to 10-fold for each 10°C decrease in temperature (25). Consequently, a spore with a *D* value at 90°C (*D*90°C) of 30 min may have a *D*20°C value of many years. The spore cortex appears to play a major role in spore wet

heat resistance, as there is a good correlation between spores' cortex PG level and their wet-heat resistance, but how the cortex exerts its effect is not clear.

Knowledge of the identity of the target(s) that is damaged in spore killing by moist heat is crucial to an understanding of spore moist-heat resistance. This target is not DNA, as moist-heat killing of spores is associated with neither DNA damage nor mutagenesis (Table 2.2). Recent work has indicated that spore killing by moist heat occurs through damage to one or more proteins, although the identity of specific target proteins is not yet known (8, 12). Sublethal heat treatment can also damage spores in some way, with this damage being repairable during spore outgrowth (52). Although the specific damage is not known, it may well again be damage to one or more proteins. Perhaps not surprisingly, moistheat resistance can vary substantially between individual spores in populations (53), although the reason for this has not been elucidated. In contrast to our lack of knowledge about the mechanism(s) of killing spores by heat, there is much more information on factors that modulate spore heat resistance, as discussed below.

Sporulation Temperature

Elevated sporulation temperatures to an optimum increase spore moist-heat resistance (8, 12). Indeed, spores of thermophiles generally have much higher moist-heat resistance than do spores of mesophiles. Since spore proteins are generally identical to cell proteins, spore proteins are not intrinsically heat resistant. Presumably, proteins from thermophiles are more heat stable than those from mesophiles, accounting for the higher moist-heat resistance of spores of thermophiles. However, spores of the same strain are also often more heat resistant when prepared at higher temperatures (Table 2.3). This is probably due to the reduced core water content in spores prepared at higher temperatures (54) (Table 2.3), although how higher sporulation temperatures cause reduced spore core water content is not known. Elevated sporulation

temperatures do not alter spore resistance to dry heat or UV radiation but do increase spore resistance to a number of chemicals. The latter effect may be due to changes in levels of spore coat proteins as a function of the sporulation temperature. In contrast to the situation in growing bacteria, heat shock proteins play no role in spore heat resistance.

α/β-Type SASP

The killing of spores by moist heat is not by DNA damage, as neither general mutagenesis (Table 2.2) nor DNA damage accompanies spore killing, even though high temperatures could cause DNA depurination. Therefore, spore DNA is well protected against moist heat. Protection of DNA in both *Bacillus* and *Clostridium* spores against moist heat damage appears to be due to the saturation of spore DNA by α/β-type SASP (8, 12, 14) and spores of *B. subtilis* have *D* values 5-to 10-fold lower than those of wild-type spores (Tables 2.2 and 2.3). In addition, while moist-heat killing of wild-type spores generates <0.5% mutants in survivors, such killing of $\alpha^-\beta^-$ spores produces up to 18% mutants among survivors (Table 2.2). Killing of $\alpha^-\beta^-$ spores by moist heat is also accompanied by a large amount of DNA damage, including a basic sites, and α/βtype SASP markedly slow rates of DNA depurination in solution.

Table 2.3 Heat resistance of *B. subtilis* spores prepared at different temperatures with different cations and with or without α/β-type SASP[a]

Spore	Prepn temp (°C)	Mineralization	H^2O (g/g of spore core wet wt)	*D*100°C (min)
B. subtilis	50	Native	0.335	45
	37	Ca^{2+}	0.425	37
	37	Native	0.50	8.9
	37	H^+	0.571	2.7
	20	Native	0.55	4.9
B. subtilis 168 wild type	37	Native	0.37	360[b]
B. subtilis 168 $\alpha^-\beta^-$	37	Native	0.37	15[b]

[a] Data are from reference 6.

[b] D 85°C

Wild-type spores are much more resistant to dry heat than to moist heat and exhibit a high level of DNA damage and mutagenesis accompanying dry heat killing, whereas $\alpha^-\beta^-$ spores are more sensitive to dry heat than are wild-type spores and exhibit dry heat resistance similar to that of dry vegetative cells (Table 2.2). These findings suggest that (i)α/β-type SASP are a major factor in increasing the dry heat resistance of wild-type spores and (ii) α/β-type SASP provide significant DNA protection against dry heat damage, but (iii) wild-type dry spores are so well protected against mechanisms of heat killing other than DNA damage that at elevated temperatures, DNA damage does eventually kill wild-type dry spores. In support of these findings, α/β-type SASP slow the

depurination caused by dry-heat treatment of purified DNA, although not as much as for DNA in solution.

Spore Mineralization

Spores accumulate large amounts of divalent cations late in sporulation, approximately in parallel with DPA. Analyses of mutations in *B. subtilis* that eliminate DPA synthase have revealed that CaDPA-less spores are much less resistant to moist heat than are their CaDPA-replete counterparts (8, 12). Much of the latter effect is likely due to the increased core water content of CaDPA-less spores (see below). However, CaDPA also provides Significant protection to spore DNA against damage by either dry or moist heat when α/β-type SASP are absent (47). CaDPA is also required for dormant-spore stability, as CaDPA-less spores germinate spontaneously, although they can be stabilized by other mutations.

The amount and type of mineral ions accumulated also affect spore heat resistance (25, 54). Analyses of spores of several species from which mineral ions were removed by titration with acid and which were then back-titrated with a mineral hydroxide showed heat resistance with different cations in the following order: $H^+ < Na^+ < K^+ < Mg^{2+} < Mn^{2+} < Ca^{2+} <$ untreated. Despite the clear role for mineral ions in spore heat resistance, the mechanism of this effect remains unclear. Alteration of spore mineralization can alter spore core water content (Table 2.3), which presumably causes a significant effect on heat resistance. However, mineralization may also affect spore heat resistance independently of its effects on core water content, perhaps by modulating the heat resistance of specific spore proteins (Table 2.3).

Spore Core Water Content

Low core water content is the major factor contributing to spore heat resistance. Dehydration of the spore begins in the stage III-stage IV transition and continues through stages IV and V, with final dehydration taking place approximately in parallel with

acquisition of full spore heat resistance (8, 12, 25, 54). Synthesis of the spore cortex is essential both for effecting this dehydration and for maintaining the dehydrated state of the spore core. This is likely due to the ability of PG to change its volume upon changes in ionic strength and/or pH. If an expansion in cortex volume is restricted to one direction, i.e., towards the spore core, core water would be extruded via mechanical action. Although the precise mechanism of this process is unclear, the important role of the cortex in heat resistance is shown by the inverse correlation between spore heat resistance and the volume occupied by the spore cortex relative to that of the core (25). This correlates not only across species but also in a single species in which spore cortex biosynthesis has been altered by mutation (29). Presumably, the volume of the spore cortex influences the degree of core dehydration, and the amount of cortex and presumably its mechanical strength are crucial to the spore's ability to maintain core dehydration during heat treatment. Another factor determining spore core water content is CaDPA, as CaDPA-less spores have higher core water levels than otherwise identical CaDPA-replete spores (8, 12). Presumably, the core volume normally occupied by CaDPA is occupied by water in CaDPA-less spores. As noted above, CaDPA-less spores are more sensitive to moist heat than are CaDPA-replete spores.

Studies of spores from many species have revealed a good correlation between core water content and moist heat resistance over a 20-fold range of *D* values (25) (Fig. 2.7). However, at the extremes of core water contents, *D* values vary widely, presumably reflecting the importance of other factors such as sporulation temperature, cortex structure, etc., in modulating spore moist-heat resistance. One value that is unfortunately missing from analyses of core water content is the amount of core water that is free water. Studies of protein and ion movement in spores have indicated that these molecules are relatively immobile (8, 12, 33, 40), consistent with a dearth of free water in the core. Presumably, the low water content in the spore core causes heat resistance as well as long-term spore survival by slowing water-driven chemical reactions, such as

DNA depurination and protein deamidation. A low water content also stabilizes proteins against denaturation by restricting their molecular motion. It would be informative to know the precise amount of water associated with spore core macromolecules in order to calculate the degree of their stabilization by the low core water content.

DNA Repair

DNA repair is essential for spore resistance to UV and chemicals that kill spores by DNA damage (8, 12, 14). However, spore resistance to moist heat is not altered by loss of DNA repair functions, including those mediated by RecA. This is not surprising because moist heat does not kill wild-type spores by DNA damage. However, spore resistance to dry heat, a treatment that does kill spores by DNA damage, is markedly decreased by loss of various DNA repair activities, including RecA and other proteins.

Altered SpoVA Proteins

Recent work (51, 55–58) has found that some *B. subtilis*, *Bacillus amyloliquefaciens*, and *Bacillus lichenifor mis* food isolates that make very highly wet-heat-resistant spores contain transposons that carry a *spoVA* operon with only three of the highly conserved *spoVA* genes, *spoVAC*, *spoVAD*, and *spoVAEb*. The presence of this novel *spoVA* operon, termed *spoVA2*^{mob}, is the major cause of the spores of these strains' high wet-heat resistance. While the mechanism of the effect of SpoVA2^{mob} proteins on spore wet-heat resistance is not completely clear, these proteins also significantly slow CaDPA release during spore germination triggered by several types of germinants (see below).

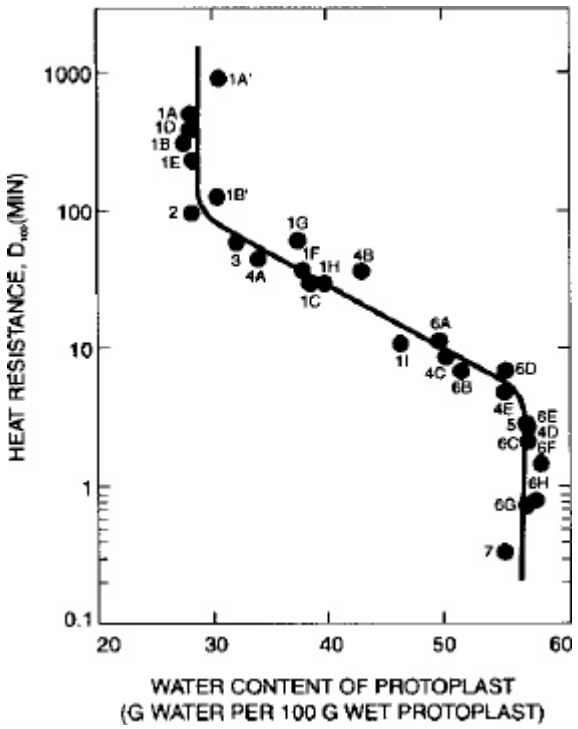

Figure 2.7 Correlation of spore heat resistance and protoplast (core) water content of lysozyme-sensitive spore types from seven *Bacillus* species that vary in thermal adaptation and mineralization. The numbers indicate species, as follows: 1, *G. stearothermophilus*; 2, "*Bacillus caldolyticus*"; 3, *B. coagulans*; 4, *B. subtilis*; 5, *B. thuringiensis*; 6, *B. cereus*; 7, *Bacillus macquariensis*. The letters denote the sporulation temperature or the mineralization of the spores of various species as described in the original publication. Reprinted from reference 25 with permission.

SPORE ACTIVATION, GERMINATION, AND OUTGROWTH

Activation

Although spores are metabolically dormant and can remain so for many years, if given the proper stimulus they return to active metabolism within minutes through spore germination (Fig. 2.8). Spore populations often germinate more rapidly and completely if

activated prior to germinant addition (4, 9, 11). However, the requirement for activation varies widely among spores of different species and between individual spores in populations and for the germinants used, as only nGR dependent germination requires activation (4). A number of agents cause spore activation, including low pH and some chemicals, although the most widely used agent is sublethal heat. The precise changes induced by spore activation are not clear but may involve reversible changes in protein structure, at least nGR structure, as different nGRs respond differently to heat activation (56, 59). However, it is also possible that heat activation affects the SpoVA channel for CaDPA release (56).

Germination

The precise period encompassed by spore germination, as distinguished from subsequent outgrowth, has been given a number of definitions. For the purposes of this review, we consider germination the events that take place without the need for metabolic energy. During germination, a dormant spore with a cortex and a large pool of DPA and mineral ions is transformed into a germinated spore in which the cortex has been degraded, DPA and most mineral ions have been excreted, and the core water content has become that of a growing cell (4, 6, 9–11). However, conversion of the germinated spore into a growing cell requires exogenous nutrients and the process of outgrowth. Notably, there is also one report that protein synthesis is essential for completion of germination of *B. subtilis* spores (60).

The initiation of spore germination can be triggered by many compounds, including nutrient germinants such as nucleosides, amino acids, sugars, and, for some spores, salts, and also CaDPA, long-chain alkylamines, and some PG fragments, although this germinant has not been well studied, in addition to high pressure (4, 6, 9–11). *C. difficile* spore germination is also triggered by various bile salts, presumably signaling the environment of the mammalian large intestine (4, 15, 61). CaDPA, alkylamines, and high pressure (described above) are relatively universal germinants,

although CaDPA is not a germinant for spores of *C. difficile* (61). In contrast, the nutrients that act as germinants vary from species to species, and metabolism of such germinants is not required. l-Alanine is a common nutrient germinant, and its action is sometimes inhibited strongly by d-alanine. Interestingly, l-alanine germination can be modulated by a spore-specific alanine racemase in spore coats that can generate d-alanine (4, 9, 62). The stereospecificity for nutrient germinants is due to these germinants' interaction with specific nGRs that are generally the products of tricistronic or tetracistronic operons. Sporeformers usually have between two and seven of these operons, which are expressed in the developing forespore during sporulation (4, 9).

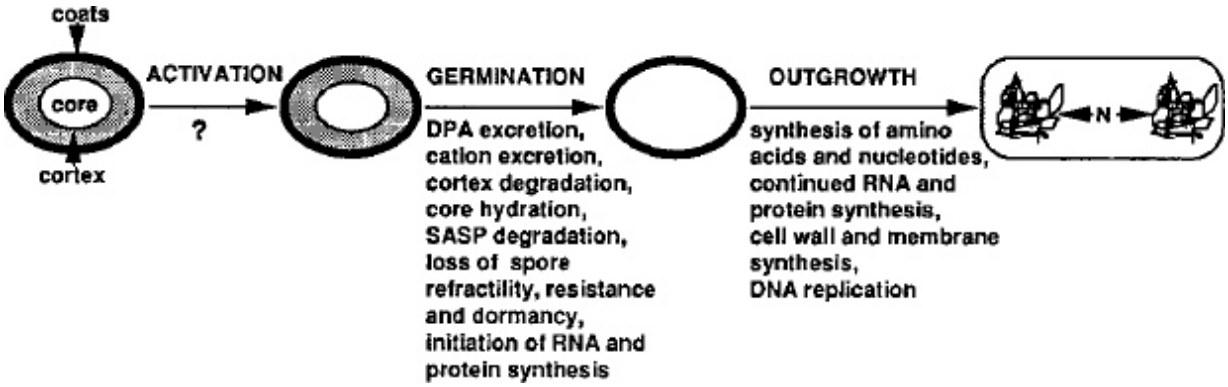

Figure 2.8 Spore activation, germination, and outgrowth. The events in activation are not known, hence the question mark. The loss of the spore cortex and the hydration and swelling of the core are shown in the germinated spore. Adapted from Fig. 3 in reference 10.

Different nGRs have different, although sometimes overlapping, specificities for nutrient germinants and can cooperate and even exhibit synergy in responding to germinant mixtures. In *B. subtilis*, allnGRs colocalize in the spores' IM in one or two foci, with the auxiliary IM germination protein, GerD, being essential for focus formation and rapid nGR-dependent germination (4, 9, 63). Loss of allnGRs almost completely eliminates spores' germination with nutrients, except for slow spontaneous germination (4, 9, 64). However, spores of *C. difficile* and close relatives have no IM GRs;

rather, its GRs are in spores' outer layer, and at least one such GR is a modified subtilisin-like protease that responds to bile salts (4, 9, 15). The nGRs are probably most often a complex of the three or four proteins encoded by individual *ger* operons, although variations in this arrangement exist (4, 9, 13, 14). Three nGR subunits appear likely to be integral IM proteins and one a peripheral IM protein, and nGRs are present exclusively in spores' IM with a number of domains outside the IM (4). Unfortunately, how nGRs function is not known, and analysis of the primary sequences or high-resolution structures of their subunits has not been informative in this regard. Notably, the *spoVA2*mob operons described above, which can greatly increase spore wet-heat resistance, also greatly decrease spore germination rates via nGRs and also via the cationic surfactant dodecylamine, which directly opens the SpoVA channel for CaDPA (56, 58, 65).

In addition to the genes encoding nGRs, there are other *ger* genes in *B. subtilis* mutations which alter spore germination (11). The functions of some of these additional *ger* genes are known, whereas those of others are not. In general, *ger* genes identified in *B. subtilis* have counterparts in other *Bacillus* species, and some of these genes, in particular those encoding nGRs, are also found in *Clostridium* species (4, 9, 13–15, 17). However, the *gerD* gene, which is essential for rapid *Bacillus* spore germination via nGRs, is not present in *Clostridium* species.

The earliest biochemical event in spore germination after nutrient germinant addition is the release of protons and other monovalent cations (4, 9–11). This event appears to be concomitant with commitment, in which spores are irreversibly committed to germinate, even if germinants are removed, and is paralleled by changes in IM permeability that in addition to allowing rapid monovalent cation release also allow slow leakage of ~10% of CaDPA and fast release of CaDPA at temperatures such as 75°C, which have no effects on dormant spores. However, the mechanism of these changes associated with commitment is not known. In *Bacillus* spores and spores of some *Clostridium* species, in

particular those that have the same CLEs as *Bacillus* spores, fast CaDPA release follows commitment and takes place via IM SpoVA protein channels. All CaDPA release can be completed in as little as 30 s for an individual spore, although individual spores initiate DPA release after very different lag times following germinant addition, lag times that can be minutes, hours, or even longer (4). Spores with extremely long lag times are termed superdormant and are of special concern to the food industry. Such superdormant spores have been isolated from populations of spores of a few *Bacillus* species, and factors contributing to spores' superdormancy have been identified (4). In *B. subtilis*, the replacement of released DPA and ions by water increases the core water content by ~30%. This reduces spore moist-heat resistance but has little effect on resistance to other agents and is not sufficient for resumption of enzyme action or protein mobility (8, 12, 40). The release of DPA and other ions is termed stage I of germination, and germination can be halted after stage I by mutations that block degradation of the spore cortex.

Initiation of cortex degradation is the next event in germination and allows a rapid approximately 2-fold increase in spore core volume through water uptake once the cortex that restricts core expansion is removed. This is termed stage II of germination and leads to spore outgrowth. The importance of cortex lysis in germination has focused attention on CLEs. A number of CLEs have been identified from spores of different species, including CwlJ, SleB, SleC, SleL, and SleM (4, 9–11, 14). These enzymes are located in the spore's outer layers and are active only on PG-containing MAL. This is consistent with the lack of cortex degradation during germination of spores of a *B. subtilis cwlD* mutant, as CwlD is required for MAL formation and thus for completion of spore germination. CLEs' specificity prevents these enzymes from hydrolyzing the germ cell wall during spore germination.

The function of the CLEs *in vivo* has been established in spores of several *Bacillus* species, in which SleB and one or two CwlJ homologs play redundant roles in cortex degradation (4, 8–11, 14).

However, *cwlJ sleB* spores of *Bacillus* species complete stage I of spore germination. CwlJ and SleB in spores are in a mature, potentially active form and thus must be regulated. While regulation of SleB is not understood, CwlJ activation requires either exposure to CaDPA released in stage I of germination or high concentrations of exogenous CaDPA, as in CaDPA triggered germination. In contrast to *Bacillus* spores, spores of some *Clostridium* species, including *C. difficile* and *C. perfringens*, contain a single essential CLE, SleC, present in spores as a zymogen that is activated by proteolysis early in germination (4, 9, 14, 15).

The pattern of germination noted above for spores of *Bacillus* and some *Clostridium* species is different in other *Clostridium* species. Thus, with spores, such as those of *C. perfringens*, that contain IM nGRs, or with *C. difficile* spores that lack IM nGRs but have outer layer GRs, GR activation does not directly activate CaDPA release. Rather, in these spores, activated GRs trigger pro-SleC cleavage by subtilisin-like proteases, and SleC then hydrolyzes cortex PG. This event then triggers CaDPA release by spore core osmotic pressure (66), much as lysozyme digestion of an nGR-deficient *Bacillus* spore triggers CaDPA release (4).

Outgrowth

Following completion of stage II of spore germination, core hydration is equivalent to that of a growing cell protoplast, and protein mobility is restored and enzymatic reactions begin in the core (11). These reactions include utilization of the spore's depot of 3PGA to generate ATP and NADH, degradation of SASP initiated by GPR, catabolism of some amino acids produced by SASP degradation, and catabolism of exogenous compounds. Carbohydrate metabolism early in outgrowth uses glycolysis and/or the hexose monophosphate shunt but may stop at acetate, as spores often lack enzymes of the TCA cycle. In *Bacillus megaterium*, endogenous energy reserves can support ATP production during the first 10 min of outgrowth.

RNA synthesis begins in the first minute of outgrowth, using nucleotides stored in the spore or generated by breakdown of spore RNA. The RNAs made at this time have been studied in *B. subtilis* and are composed of many mRNAs (11), although if dormant spores' rRNA has been degraded, massive rRNA synthesis begins early in outgrowth (45); protein synthesis begins shortly after mRNA synthesis. All components of the protein synthesizing machinery stored in the dormant spore appear functional, with the exception of some tRNA lacking the 3′-terminal adenosine residue that is repaired by tRNA nucleotidyltransferase early in outgrowth. Endogenous amino acids derived largely from SASP breakdown can support most protein synthesis in the first 25 min or so of outgrowth, but completion of outgrowth requires exogenous nutrients (4, 11). The spore regains the ability to synthesize amino acids, nucleotides, and other small molecules due to synthesis of biosynthetic enzymes at defined times in outgrowth, but regulation of gene expression throughout outgrowth has not been thoroughly studied. DNA replication is not generally initiated until late in outgrowth, although DNA repair can occur well before DNA replication, as spores contain deoxynucleoside triphosphates by the first minutes of outgrowth (11). However, the importance of DNA repair in the first minutes of outgrowth, other than repair of UV damage, has not been well studied. During spore outgrowth, the volume of the outgrowing spore continues to increase, requiring the synthesis of membrane and cell wall components. One question that remains intriguing is whether there are genes that are needed for outgrowth but no other stage of growth. A number of mutations affecting outgrowth (termed outmutations) have been isolated in *B. subtilis*, and most have been identified (11). While the functions of some of these genes have been established, to date, none has been shown to function solely in outgrowth.

PRACTICAL PROBLEMS OF SPORES IN THE FOOD INDUSTRY

Overview

Endospores of bacteria and heat-resistant spores of fungi pose safety and spoilage problems for the food industry. The primary sporeformers of importance in foods belong to the orders *Bacillales*, *Clostridiales*, and *Thermoanaerobacterales*. Three species of food-related sporeformers, *C. botulinum*, *C. perfringens*, and *B. cereus*, produce toxins that cause illness in humans and animals (51, 67, 68). Rare strains of *Clostridium butyricum* and *Clostridium baratii* may also produce botulinal neurotoxin (69). In the United States, *C. botulinum* is designated a select agent of the highest security level (tier 1) and can be studied only in strictly approved laboratories with qualified personnel (70, 71).

Sporeformers also cause spoilage of foods with drastic economic repercussions, contributing to the estimated 20 to 30% global spoilage of foods produced (72–74). The primary genera of nonpathogenic sporeformers causing food spoilage are *Anoxybacillus*, *Alicyclobacillus*, *Bacillus*, *Clostridium*, *Desulfotomaculum*, *Geobacillus*, *Paenibacillus*, *Thermoanaerobacter*, *Moorella*, and *Sporolactobacillus* (Table 2.1) (67, 68, 75, 76). Processing and formulation of foods to prevent foodborne illness and spoilage by sporeformers have become more challenging in the past decade due to consumer demands for foods that appear and taste fresh and lack chemical antimicrobials, thereby providing a “clean” label (77, 78). This consumer demand for fresh quality can compromise traditional methods of processing and formulation and can also change the microbial ecology of foods, creating the food microbiome (79). Moreover, the food supply is more international, with ingredients and processing of foods derived from various countries, which poses challenges in control of sporeformers (77, 78)

Sporeformers that pose health concerns are particularly important in low-acid foods with a pH of >4.6 (see below). To prevent foodborne illness and spoilage by sporeformers, many low-acid foods are processed by heat, which remains the cornerstone of food

preservation by physical technologies (80–82). Newer physiological technologies, such as high-pressure processing (HPP), as well as preventive food formulations are being evaluated and implemented in the food industry (83–87). Certain species of sporeformers also cause spoilage of high-acid and acidified foods (equilibrium pH ≤4.6) (75, 76). Thermophilic sporeformers (growth range of 50 to 110°C) are a cause of serious spoilage in certain food service applications, at elevated storage temperatures, and in warm climates. Psychrophilic (growth range, −5 to 20°C) and psychrotrophic (growth range, −5 to 30°C) sporeformers can grow and cause spoilage of refrigerated foods and of foods processed and stored in cold climates at temperatures of 0 to 20°C (75, 76, 88–92). Fungi that produce heat-resistant ascospores as well as many yeasts are an important cause of spoilage of raw materials, such as grains, and of processed food, often acidic beverages and fruits and vegetable products (92–94). Fungal spores and vegetative fungi and yeasts generally are more sensitive to heat than bacterial endospores. The spoilage properties and control of fungi and yeasts are described in several excellent sources (27–29, 95).

DISCOVERY OF PATHOGENIC AND SPOILAGE SPORE-FORMING BACTERIA AND DEVELOPMENT OF EARLY CONTROL PROCESSES

In the 1850s, Louis Pasteur discovered an anaerobic spore-forming bacterium during butyric acid spoilage in wines (95–97). Pasteur was able to isolate an obligately anaerobic bacterium he termed *Vibrion butyrique*, which is probably the same microorganism now classified as *C. butyricum* Prazmowski, the type species of the genus *Clostridium* (98). Trecul coined the name "*Clostridium*," following from the Greek word "kloth" (a small spindle) to describe a microorganism in its sporulating form; this term was then transformed to the Latin *Clostridium* (96). The first pathogenic

Clostridium species isolated in pure culture was *Clostridium tetani* by Kitasoto in 1889 (95–98). *C. perfringens* was isolated in pure culture in the 1890s (96) and was characterized by Welch and Nuttal in the 1890s. *C. perfringens* was found to be important in food poisoning and in wounds, sometimes causing gas gangrene (96). Pathogenicity and death of humans from *C. perfringens* were demonstrated in 1917 to be due not to blood invasion but rather to a poisonous substance produced by the bacterium (96). MacFarland and Knight (96) showed that the lethal factor was lecithinase C, the first bacterial toxin shown to have enzymatic activity (96). *C. botulinum* was discovered by van Ermengem in a remarkable series of experiments that was reported in a landmark publication in 1897 (99). Many of the biological and control concepts observed by van Ermengem are still relevant today and form the basis of food laws (such as low-acid canned foods). *C. difficile* was first reported by Hall and O'Toole in 1935 (96). *C. difficile* is a toxigenic sporeformer that has become one of the most common causes of human and animal intestinal disease during the past 2 decades (97) and raised concern about transmission in foods.

Endospores were discovered independently by Ferdinand Cohn and Robert Koch in the 1870s (100). Investigations by Pasteur and Koch led to the association of microbial activity with the safety and quality of foods and understanding of the pathogenicity of sporeformers. During investigation of the anthrax bacillus, *B. anthracis*, the famous Koch's postulates were born (101). These procedures provided proof that a disease is caused by a specific microorganism and also led to the development of pure-culture techniques. Diseases and spoilage problems caused by sporeformers have historically been mainly associated with foods that are thermally processed, because heat selects for survival and subsequent growth of spore-forming microorganisms. Growth of the sporeformer is primarily due to survival of exposure to heat and to the absence of competitor microbiota in the thermally processed food. Competitive microbiota in foods and in the intestinal tracts of

humans and animals is an extremely important factor in the prevention of growth of several pathogenic sporeformers (102–105).

The process of appertizing, or preserving food sterilized by heat in hermetically sealed containers, was invented in the late 1700s by Appert (106), who theorized that the elimination of air was responsible for the long shelf life of thermally processed foods. In the late 1800s and early 1900s, several scientists and engineers were instrumental in developing scientific principles and processes to ensure the safety and prevention of spoilage of thermally processed foods (107–111). In early studies of canned-food spoilage by sporeformers, Prescott and Underwood at the Massachusetts Institute of Technology and Russell at the University of Wisconsin found that endospore-forming bacilli caused the spoilage of thermally processed clams, lobsters, corn, and other foods (108, 109), and other seminal studies were performed in the United States and in Europe (110, 111). The classic studies of Esty and Meyer (112) in California provided definitive values of the heat resistance of *C. botulinum* type A and B spores and helped rescue the United States canning industry from its near demise as a result of botulism in commercially canned olives and other foods in the 1920s (113–117). The empirical use of thermal treatments gradually developed into modern-day thermal processing industries. As a result of these studies, thermal processing of foods in hermetically sealed containers became an important industry and remains the foundation of preservation of foods today.

Thermally processed commercial canned foods have an exemplary record of microbiological safety, particularly with regard to the agent of botulism as the primary organism of concern, with only seven major outbreaks of botulism involving several humans occurring from 1963 through 2013 (118–121; also see https://www.cdc.gov/botulism/surveillance.html for recent epidemiological updates). In 1975, Lynt et al. (122) estimated that during the 45-year period from 1940 to 1975, 775 billion cans of commercially canned foods were consumed, with only four known

deaths from botulism, documenting the safety of thermal processing.

Quantitative thermal processes, understanding of spore heat resistance, aseptic processing, and implementation of hazard analysis and critical control points (HACCP), food safety objectives (FSO), and other engineering concepts as well as establishment of microbiological criteria also resulted largely from developments in the canned-food industry (82, 123, 124).

MICROBIOLOGY OF SPOREFORMERS IN FOODS

Ecology and Distribution of Spores

The environments in which spores reside are mainly associated with selection for spore resistance phenotypes including temperature, acidity, and water activity. Common habitats include soils, sediments, vegetation, animal intestines, and rotting vegetation and animal carcasses (125–127). Sporeformers comprise saprophytic and proteolytic groups, and each group is associated with the habitat for optimal growth and survival. Dormant spores can exist in certain environments for hundreds to thousands of years (128), and many species are commonly found in soils and other relatively static habitats. Thermophilic sporeformers (growth at 50 to 110°C) are found in high-temperature environments and may survive and grow in thermally processed foods (80). Similarly, psychrophilic and psychrotrophic sporeformers reside in environments where they can become associated with foods present in a cold chain, such as cold packed meats, dairy products, and other foods that undergo refrigerated storage (75, 89, 90). Despite their differential distribution, it is often not feasible to predict the presence of sporeformers in foods, since many foods consist of blends of ingredients from diverse worldwide sources. Recent studies indicated that sporeformers are more prevalent in soils and in the human microbiome than previously assumed (129–131).

Characterization of Spores in the Environment and in Foods

Traditionally, the detection and characterization of sporeformers were performed using culture techniques and phenotypic tests (20, 132). Currently, molecular methods, including PCR, DNA sequencing, and -omics technologies, are used for detection and study of vegetative cells of sporeformers. Advanced genetic strategies and methods, particularly genome sequencing, and gene designations and polymorphisms are currently used for study of species designations, phylogeny, and evolution, as well as metabolic activities (133–138). These techniques have been employed to detect pathogens and spoilage organisms in food microbiomes (79, 138). However, techniques such as PCR and metagenomics and other methods do not necessarily detect living microorganisms, and many organisms cannot be cultured. Therefore, these techniques are not suitable for quantitation and for regulatory purposes (138). Considering the virtual solid state of bacterial endospores, extraction of nucleic acids would be challenging. Quantitative aspects of microbiological food testing were recently reviewed (123).

CONTROL OF SPOREFORMERS IN FOODS

Importance of Sporeformers in Low-Acid Canned Foods

C. botulinum is the central sporeformer of primary importance in many foods due to its resistance to environmental stresses, processing procedures, and chemical compounds compared to vegetative pathogens (80–82). *C. botulinum* produces the most poisonous toxin known and is the cause of the severe disease botulism (139). An outbreak of botulism is considered a public health emergency (140). Processing methods, product formulations, and other strategies of food preservation have been designed to control it in foods. The U.S. Food and Drug Administration (FDA)

and the U.S. Department of Agriculture (USDA) Food Safety Inspection Service define a low-acid canned food as a product with a finished equilibrium pH of >4.6 and a water activity (aw) of >0.85, excluding tomatoes and tomato products having a finished equilibrium pH of <4.7 (82–84). Certain countries in the European Union define a low-acid food as one having a pH of >3.5. Thermal processing is the cornerstone of food processing to control pathogenic and many other sporeformers. The regulations regarding thermal processing of canned foods are described in the U.S. *Code of Federal Regulations* (21 CFR, parts108 to 114 [www.govinfo.gov/help/cfr]). In the United States, the USDA has regulatory oversight of products that contain at least 3% raw red meat or 2% cooked poultry, and the FDA regulates other food products. Detailed descriptions of the thermal process, including the environment within the facility, equipment specifications, and formulations, must be filed with the proper governmental agency prior to commercial processing. The processor must also report process deviations or instances of spoilage to the FDA or USDA. Processing facilities are also inspected regularly. Guidance for industry in the United States and Europe can be found at https://www.fda.gov, https://www.usda.gov, www.fao.org, and https://www.who.int.

Low-acid foods are packaged in hermetically sealed containers, often cans or glass jars but also plastic pouches and other types of containers. These “cans” (as collectively defined in this chapter) containing low-acid food products must be processed by heat to achieve commercial sterility (141), which is a condition achieved by application of heat that inactivates microorganisms of public health significance, as well as any microorganisms that are not of health significance but are capable of reproducing in the food at the temperature of storage and distribution. Commercial sterility is an empirical term to indicate a low level of microbial survival and provision of shelf stability. Preservation procedures such as acidification or lowering water activity by brining or other means can also be used to attain commercial sterility. Chemical

preservation procedures are often combined with a reduced-heat treatment in processing of many foods (82, 83).

In thermal processing of low-acid canned foods to control *C. botulinum*, the degree of heat treatment applied varies considerably according to the class of food, the spore numbers, pH and acidity of the food, storage conditions, and other intrinsic and extrinsic factors. For example, canned low-acid vegetables and uncured meats usually receive a 12*D* process or "botulinum cook" (see below). Lower-heat treatments are applied to shelf-stable canned cured meats as well as to foods with reduced water activity or other antimicrobial factors that inhibit growth of spore-forming bacteria. In practice, the spore content of ingredients and the cleanliness of the cannery environment are of major importance for successful heat treatment of low-acid canned foods. Certain foods and food ingredients, such as mushrooms, potatoes, spices, sugars, and starches, can contain high numbers of spores of *C. botulinum* and other species (142, 143), which may be monitored for their spore input in a process (144).

Researchers in the early and mid-1900s designed thermal processes to prevent botulism and spoilage in canned foods (106–111, 145, 146), and these processes have theoretically and technically advanced during the past several decades. Pflug (146–148) refined the semilogarithmic microbial destruction model and designed a strategy to achieve the required heat process *FT* value. He also introduced the concept of the probability of a nonsterile unit on a one-container basis. This reasoning logically explains the traditional term 12*D*, which designates the time required in a thermal process for a 12-log reduction of *C. botulinum* spores. In thermal processing (or other processing methods, such as HPP), two values have traditionally been used to describe the thermal inactivation of an organism: the *D* value is the time required for a 1-log reduction of a microorganism at a defined temperature, and the *z* value is the temperature increment required to change the *D* value by a factor of 10, or 1 $\log_{10}$ (79–81). While the *D* value represents the resistance of a microorganism to a specific temperature, the *z* value represents

the relative resistance of a microorganism to inactivation at different temperatures. The thermal process for the 10^{-11} to 10^{-13} level of probability of a botulism incident occurring will depend on the initial number of *C. botulinum* spores present in a container. This initial spore number can be relatively high in certain food, for example, 10^4 for a container of mushrooms, or very low, such as 10^1 or less for a container of a meat or dairy product (142–144). Pflug (146–148) emphasized that the thermal processing industry should prioritize process design to protect against (i) a public health hazard (botulism) from *C. botulinum* spores, (ii) spoilage from mesophilic spore-forming microorganisms, and (iii) spoilage from thermophilic microorganisms in containers stored in warm climates or environments. Generally, low-acid foods in hermetically sealed containers are heated to achieve 3 to 6 minutes at a temperature of 121°C (250°F) or equivalent at the center or most heat-impermeable region of a food. This ensures inactivation of the most heat-resistant *C. botulinum* spores with a *D*121°C (250°F) of 0.21 min and a *z* of 10°C (18°F). *C. sporogenes* spores, which have an approximately10-fold-higher heat resistance (*D*121°C of ca. 1 min) than those of *C. botulinum*, are frequently used as a surrogate in thermal processing for inactivation of *C. botulinum* spores (149–151). Spoilage with economic impact is also avoided by achieving ca. 5*D* killing of mesophilic spores that typically have a *D*121°C of ca. 0.1 to 1 min. Recently, Schill et al. (151) reported that there are two clades of *C. sporogenes* PA3679 that differ in heat stability. Therefore, it is important to use the correct strain of *C. sporogenes* PA3679 as a surrogate and to ascertain purity periodically by single-colony isolation and formation of fresh spore stocks. Foods that are distributed in warm climates of tropical or desert areas require a particularly high thermal treatment of ca. 20 min at 121°C to achieve a 5*D* killing of *Thermoanaerobacterium* (*Clostridium*) *saccharolyticum*, *Geobacillus stearothermophilus*, and *Desulfotomaculum nigrificans* because these thermophilic organisms have a *D*121°C of ca. 3 to 4 min (Table 2.4) and can cause spoilage with severe economic effects (68, 89). High thermal

treatments can have a detrimental impact on nutrient content and organoleptic qualities, but they ensure a shelf-stable food (68, 75, 76). Consequently, other processing technologies are in development to preserve the organoleptic properties of certain thermally processed foods.

The concept of semilogarithmic or first-order kinetics of heat inactivation of spores and the use of D and z values have been carefully reevaluated over the years (152–154).have studies have led to the finding that populations within the same crops of spores often differ in heat sensitivities and that non-log-linear death kinetics more accurately explain spore inactivation of most spore populations. Analysis using non-log-linear kinetics can explain the tailing and curving that are commonly observed in heat inactivation of spore populations. The kinetics of heat inactivation of spore populations closely followed a cumulative Weibull distribution, i.e., $\log S = b(\mathrm{T})^{tn(\mathrm{T})}$, where S is the survival ratio, $b(\mathrm{T})$ and $n(\mathrm{T})$ are temperaturedependent coefficients, and t is time (minutes) (155–157). Kinetics models for inactivation and recovery of bacterial spores have been valuable in evaluating and developing improved procedures within the food industry (80–82,152–154). Advanced kinetics and predictive models of spore inactivation have been outlined to simulate growth of proteolytic *C. botulinum* during cooling of heated foods (155).

Table 2.4 Heat resistance of sporeformers of importance in foods[a]

	Approx D value[b] at temp (°C)						
Bacterium	80	85	90	95	100	110	120
Spores of public health significance							
Group I C. botulinum types A and B		50		7–30	1–3	0.1–0.2	
Group II C. botulinum type B		1–30	0.1–3	0.03–2			
C. botulinum type E	0.3–3				0.01		
B. cereus					3–200	0.03–2.4	
C. perfringens			3–145	0.3–18	2.3–5.2		
Mesophilic aerobes							
B. subtilis					7–70	6.9	0.5
B. licheniformis					13.5	0.5	
B. megaterium					1		
B. polymyxa			4–5		0.1–0.5		
Bacillus coagulans subsp.			11–30		2–3		
thermoacidurans							
A. acidoterrestris			16	2.6			
Thermophilic aerobes							
G. stearothermophilus				100–1,600	1–6		
B. coagulans				20–	2–3		

				300			
Mesophilic anaerobes							
C. butyricum	4–5	0.4–0.8					
C. sporogenes					80–100	21	0.1–1.5
C. tyrobutyricum	13						
Thermophilic anaerobes							
D. nigrificans					<480		2–3
T. thermosaccharolyticum				400		3–4	

[a] Sources: see text for references.

[b] At pH ca. 7 and an aw >0.95.

Thermal processing is often applied to aseptically processed low-acid canned foods, whereby manufactured and usually processed product is used to fill presterilized containers, followed by aseptic hermetic sealing with a closure in a sterile environment (156, 157). This technology was initially used for commercial sterilization of milk and cream in the 1950s (157) and then expanded to other food products, such as soups, eggnog, cheese spreads, sour cream dips, puddings, and high-acid products such as fruit and vegetable drinks. Aseptic processing and packaging systems have the potential to reduce energy, packaging, and distribution costs (156).

Spores of *C. botulinum* can survive for long periods in high-acid foods with pH values of ≤4.6 (158, 159). Growth of *C. botulinum* and outbreaks of botulism in high-acid foods under special conditions have been reported (89, 158, 159). Some outbreaks in high-acid foods have been associated with inadvertent increases in pH, such as by growth of molds with catabolism of organic acids, referred to as metabiosis (89). Recently, there has been increased interest in using nontraditional lower-heat treatments, often combined with HPP, for infant foods (157). Such changes to the

thermal process for infant foods must be performed with caution and with appropriate validations to eliminate spores of *C. botulinum*, since if spores survive, they could cause infant botulism. Recent evidence of plasmid-mediated transfer of genes encoding botulinum neurotoxin type A and complexing proteins to nontoxigenic clostridia, including *C. sporogenes* (160, 161), could result in botulinum neurotoxin-producing strains with greater thermotolerance than group I (proteolytic types A, B, and F) *C. botulinum*. However, the frequency of genetic transfer of botulinum neurotoxin genes appears to be very low under laboratory conditions, and such transfer seems to occur infrequently in the environment, intestinal tracts of animals and humans, and foods (160, 161).

Properties of Pathogenic and Spoilage Sporeformers Relevant to Food Processing

The principal microbial hazard in thermally processed foods and in minimally processed refrigerated foods is *C. botulinum*. Other toxigenic sporeformers, including *C. perfringens* and potentially *C. difficile* and *B. anthracis*, are of concern in certain thermally processed foods (162). The biological and pathogenic properties of toxigenic species of *Clostridium* and *Bacillus* are described in other chapters, and only properties related to spores and foods are described here. *C. botulinum* and certain other pathogenic bacteria produce spores that swell the mother sporangium, giving it a spindle or club shape (Fig. 2.9). Spores of *C. botulinum* types B and E frequently possess an exosporium (163), and serotypes types A and E and *C. sporogenes* characteristically produce appendages (Fig. 2.10) (163). *B. cereus* and *B. anthracis* also possess an exosporium and bear appendages on the spore surface (163).

C. botulinum has traditionally been divided into four physiological groups (I through IV) on the basis of phenotypic properties (69, 97, 132, 164, 165). Group I consists of proteolytic strains that produce neurotoxin types A, B, and F, and group II comprises nonproteolytic

strains that produce neurotoxin serotypes B, E, and F. Strains in groups I and II are the causes of human botulism and are of concern in food safety. They have certain phenotypic properties that affect their resistance to processing and their ability to grow in foods (97, 166, 167) (Table 2.5). In particular, group I spores have high tolerance to acid and salt and produce spores with high heat resistance. Group II strains have considerably less heat resistance than group I spores and are more sensitive to acidity and salt (69, 97, 132, 164, 165).

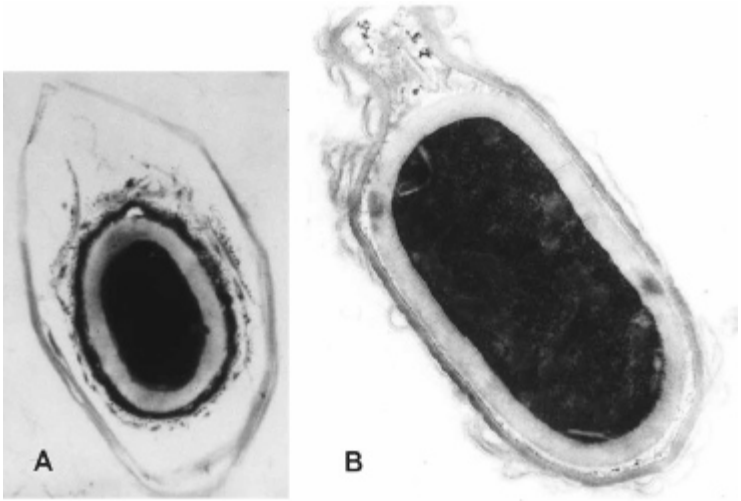

Figure 2.10 Electron micrographs of *C. botulinum* type B (A) and E (B) spores, showing characteristic exosporium in types B and E and appendages in type E. Courtesy of Philipp Gerhardt from spores produced in E.A.J.'s laboratory. *Botuli*

As described in detail in chapter 18 of this volume, nearly all(>98%) foodborne, infant, and wound botulism cases in the continental United States are caused by proteolytic group I *C. botulinum* strains that form type A and B botulinum toxins. The most common event that leads to foodborne botulism by group I strains is temperature abuse of a food product that contains *C. botulinum* spores and has a permissive acidity (pH >4.6) and water activity (>0.93) (97, 105, 168, 169). Improper commercial processing has also led to global outbreaks of botulism (165, 168). Group I strains can grow rapidly at temperatures of 25 to 40°C, particularly if the food is not formulated with antimicrobials and a competitive microbiota is not present due to processing or the nature of the food. It has been estimated that 1 to 10 ng of botulinum toxin per kg body weight is sufficient to kill an adult human by the oral route (139, 170, 171).

The ability of group II *C. botulinum* to grow at low temperatures has generated concern in the United States and certain other countries that refrigerated food products could lead to botulism outbreaks (172–174). Type E has caused several outbreaks of foodborne botulism (169, 175), particularly from consumption of fish, marine mammals, and other substrates associated with marine and terrestrial water environments as well as some terrestrial foods in which *C. butyricum* producing type E botulinum toxin is formed (169). In the United States and most other countries, nonproteolytic types B and F have rarely caused confirmed foodborne botulism. Nonproteolytic strains of *C. botulinum* serotypes B are also not a significant cause of infant or wound botulism globally (103). Nonproteolytic botulism caused by types B and F appears to be more common in the United Kingdom and in certain other countries (106–108). In experimental food substrates, group II *C. botulinum* strains can grow and produce botulinum toxin at refrigeration temperatures (≥3.3°C) during extended storage, generally requiring a minimum of 10 days but usually several weeks to months to produce sufficient botulinum neurotoxin to cause mouse lethality (51, 144). Most strains of *C. botulinum* grow very slowly below 5°C, and the levels of botulinum toxin produced by

nonproteolytic strains are often very low (142). To control nonproteolytic *C. botulinum* serotypes B, E, and F, it has been recommended that refrigerated products with a shelf life greater than 5 days receive a heat treatment to kill 6 log10 of psychrotrophic or psychrophilic spores of *C. botulinum* and that additional intrinsic or extrinsic preservation factors be included to ensure safety (105, 173, 174).

Table 2.5 Growth requirements of sporeformers of public health significance[a]

	Inhibitory condition			
Bacterium	Minimum pH	NaCl concn (%)	Minimum a_w	Temp range for growth (°C)
Group I *C. botulinum*	4.6	10	0.94	10–50
Group II *C. botulinum*	5.0	5	0.97	3.3–45
C. butyricum (toxigenic)	4.8	12		
C. *baratii* (toxigenic)				10-45
B. cereus	4.35–4.9	ca. 10	0.91–0.95	5–50
C. perfringens	5.0	ca. 7	0.95–0.97	15–50

[a] See text for references.

In recent years, advances have been made in the genomics of *C. botulinum*, including the discovery of traits related to sporulation and spore resistance. The first strain to have its genome sequenced was *C. botulinum* type A 3502, which yielded considerable insights into the genes affecting biological properties (reviewed in references 176 and 177). Genomic analyses of *C. botulinum* groups I and II have revealed several features regarding sporulation, spore resistance, and germination. The genome sequences of ca. 200

strains of *C. botulinum* as well as numerous strains of *C. perfringens* and *B. cereus* are currently available in GenBank. The properties garnered from the genome sequences related to *C. botuli num* and botulism are mainly described in chapter 18 [*C. botulinum*]. Genome analyses have shown that components of the well-defined *Bacillus* phosphorelay signal transduction pathway, including Spo0F and Spo0B, are absent from essentially all *Clostridium* species, indicating that the initiation of sporulation occurs through direct phosphorylation of the Spo0A transcription factor by orphan sensor histidine kinases (177–180). Moreover, there is not conservation of amino acid sequence or structure for sensor domains of these kinases, indicating that each species may respond to different initiating signals (111–114). Bioinformatics analyses of the genome sequence are beginning to reveal characteristics underlying spore activation, germination, spore resistance, and properties governing growth and toxin formation in foods (111–114).

An important sporeformer among the pathogenic clostridia is *C. perfringens*, which is widespread in soils and is a normal resident of the intestinal tracts of humans and certain animals (181) (see chapter 19). The properties of *C. perfringens* related to foods were recently reviewed (181). *C. perfringens* spores are large, oval, and centrally or subterminally located and swell the rod-shaped cells (181). *C. perfringens* can grow extremely rapidly in high-protein foods, such as meats, that have been cooked to eliminate vegetative bacteria and yeast competitors and are inadequately cooled, allowing this pathogen to produce an enterotoxin that causes diarrheal disease. It also produces a diversity of other extracellular toxins and degradative enzymes (182), which can cause animal and human illness, and at least one toxin (epsilon) of *C. perfringens* acts on neuronal tissue (183). *C. perfringens* is very important in infectious diseases in animals (see chapter 19). *C. perfringens* differs from many other clostridia in being nonmotile, reducing nitrate, and carrying out a stormy fermentation of lactose in milk.

The ability of *C. perfringens* to cause foodborne illness is related to its ubiquitous distribution in foods and food environments, the formation of endospores that can survive cooking of foods, and extremely rapid growth in warm foods (doubling time of 6 to 9 minutes at 43 to 45°C) (181) (see chapter 19). The optimum temperature for growth of vegetative cells is ca. 43 to 45°C (109 to 113°F). Due to the rapid growth of *C. perfringens* in many foods, cell numbers sufficient to cause foodborne illness can be produced rapidly (see chapter 19). Germination of spores and growth of cells can occur at temperatures up to 50°C (ca. 122°F). *C. perfringens* does not generally grow below 15°C (68°F), and true psychrotrophic strains of the bacterium have not been isolated. *C. perfringens* can grow over a pH range of 5.0 to 8.5 to 9.0, and the optimum is ca. 6.5 (see chapter 19). At temperatures below 45°C (113°F), some strains will grow at pH 5. As with most bacteria, organic acids and their salts, including acetate, lactate, and citrate, are much more effective than are mineral acids for inhibiting growth of *C. perfringens*. Growth of most strains is also inhibited by 5 to 6% sodium chloride (Table 2.5). Sodium nitrite in cured meat products also inhibits growth. Conditions for growth and toxin formation of *C. perfringens* in many foods have been reviewed (181) (see chapter 19).

The heat resistance of *C. perfringens* spores is strain dependent and varies considerably among different isolates (181). In general, two classes of heat sensitivity of spores are observed. Heat-resistant spores have $D_{90°C}$(194°F) values of 15 to 145 min and z values of 9 to 16°C (16 to 29°F), in contrast to heat-sensitive spores, which have $D_{90°C}$ values of 3 to 5 min and z values of 6 to 8°C (11 to 14°F). The resistance of *C. perfringens* spores is considerably less than those of proteolytic *C. botulinum* group I (181). The spores of the heat-resistant class generally require a heat shock of ≥75°C (≥167°F) for 5 to 20 min in order to germinate. The basis of the wide variation in heat resistance of *C. perfringens* spores is not currently understood. The spores of both classes may survive cooking of foods and may be stimulated by heat shock for germination during heating procedures. Both classes can cause diarrheal foodborne illness,

although it would be expected that the heat-resistant forms would be a more frequent cause of illness.

Foodborne illness caused by *C. perfringens* nearly always involves temperature abuse of a cooked food, and the vast majority of foodborne illnesses caused by *C. perfringens* could be avoided if cooked foods were eaten immediately after cooking or rapidly chilled and reheated before consumption to inactivate vegetative cells. The objective in prevention of foodborne illnesses by *C. perfringens* is to limit the multiplication of vegetative cells in the food prior to ingestion. Since the spores are widespread and are moderately resistant to heat, they often survive the cooking procedure, germinate, and rapidly outgrow to large vegetative-cell populations if the rate of cooling is inadequate. This property has led the USDA to develop performance standards for cooling in the production of ready-to-eat meat and poultry products (184, 185). The USDA-FSIS draft guidelines state that cooked meat products should be cooled at a rate adequate to prevent a 1-log10 increase of *C. perfringens* (181, 184, 185). If foods are not rapidly cooled, they should be held at 60°C (140°F) or higher. Modeling studies have been conducted to evaluate and prevent *C. perfringens* growth on cooling of certain foods (184, 185). For cooled foods, the maximum internal temperature should not remain between 130°F and 80°F for more than 1.5 hours, and not between 80°F and 40°F for more than 5 hours. For products that undergo a pasteurization step, the entire process must not allow growth greater than 1 log10 in the product during processing and cooling. Methods for inactivation and control of *C. perfringens* spores in foods were recently reviewed (181).

Several *Bacillus* species are important in food safety and food spoilage (186, 187). *Bacillus* is a large genus, but only *B. cereus* and *B. anthracis* are definitive human pathogens. *B. cereus* produces a heat-labile enterotoxin causing diarrheal illness, as well as the toxins hemolysin HL and cytotoxin K, and a heat-stable lowmolecular-weight toxin(s) causing an emetic response in humans (186, 187) (see chapter 20). The emetic toxin has been

identified as cereulide, a non-ribosomally produced peptide (186, 187). Generally *B. cereus* must grow to very high numbers (>106/g of food) to cause human illness. *B. cereus* is closely related to *B. megaterium*, *B. thuringiensis*, and *B. anthracis*, but *B. cereus* can be distinguished from these species by biochemical tests, the absence of toxin crystals, and more recently by genetic typing and genomic methods. Other bacilli, including *B. licheniformis*, *B. subtilis*, and *Bacillus pumilus*, have been reported to rarely cause foodborne disease outbreaks, primarily in the United Kingdom (186–188).

B. cereus spores occur widely in foods and are commonly found in milk, cereals, starches, herbs, spices, and other dried foodstuffs (186–188). They are also frequently found on the surfaces of meats and poultry, probably because of soil or dust contamination. Investigators in Sweden reported isolation of *B. cereus* from 47.8% of 3,888 different food samples. In the United Kingdom, *B. cereus* was isolated from 98 of 108 (91%) rice samples. The bacterium causes spoilage of raw and unpasteurized milk (186–188), and foods containing dried milks, such as infant formulas, may possess high levels of spores or cells.

B. cereus grows over a temperature range of approximately 10 to 48°C (50 to 118.4°F), with an optimum of 28 to 35°C (82.4 to 95°F) (Table 2.5). Psychrotrophic strains that produce enterotoxin in milk have been isolated (186, 187). The doubling time at the optimum temperature in a nutritious medium is 18 to 27 minutes. Several strains can grow slowly in high-protein foods containing 7.5% sodium chloride. The minimum water activity for growth is 0.95. The bacterium grows over a pH range of approximately 4.9 to 9.3, but these environmental limits for growth are dependent on water activity, temperature, and other interrelated intrinsic and extrinsic parameters.

Spores of *B. cereus* are ellipsoidal and central to subterminal and do not distend the sporangium. Spore germination can occur over the temperature range of 8 to 30°C (46.4 to 86°F). Spores from strains associated with foodborne illness had a heat resistance of

*D*95°C(203°F) of ca. 24 minutes. Strains not associated with foodborne illness have a wider range of heat resistance. It is likely that strains involved in foodborne illness have higher heat resistances and are more apt to survive cooking.

Since spores of *B. cereus* are widespread in nature and survive extended storage in dried food products, it is not practical to eliminate low numbers of spores from foods (186, 187). Control against foodborne illness should be directed at preventing germination of spores and multiplication of large populations of the bacterium. Cooked foods should rapidly and efficiently be cooled to less than 7°C (45°F), or maintained above 60°C (140°F) and should be thoroughly reheated before serving (186). Other factors affecting food safety and spoilage by *B. cereus* are described in chapter 20.

The virulent pathogen *B. anthracis* has occasionally been associated with gastrointestinal anthrax from consumption of foods, particularly meats and animal byproducts, such as skins (188–190). Anthrax also results from occupational exposure, such as in tanning of hides. In late 2001, the deliberate release of *B. anthracis* spores revealed that the pathogen could also cause disease and death as a bioterrorism agent, mainly by aerosolization but also by dissemination in foods (189, 190). The resistance properties of spores of *B. anthracis* have been reviewed and provide a framework for control (177, 178, 182). Certain other species of *Bacillus*, such as *B. licheniformis*, *B. subtilis*, and *B. pumilus*, have also been reported to sporadically cause foodborne disease through production of toxins, including lipopeptides (186–188), but their incidence and importance in food safety are not well understood.

TECHNOLOGIES FOR INACTIVATION OF SPOREFORMERS IN FOODS

Thermal Inactivation of *C. botulinum* Spores

C. botulinum is the primary concern for public health safety from thermally processed foods, as well as other common processing methods, such as HPP. Severe outbreaks of botulism in canned olives and certain other commercial foods in California in the 1920s and 1930s led to concepts and practices for control of *C. botulinum* in canned foods (113–117). *C. botulinum* is categorized in four groups (I to IV) based on physiological properties and spore resistance (69, 97, 169). Group I *C. botulinum* type A and B strains can produce spores with remarkable heat resistance, with thermal resistances greater than those of all other foodborne pathogens except prions. The control of *C. botulinum* in foods is of paramount importance in food safety, and adequate processing and formulation are integral to the control of its growth and toxin formation in foods. From the 1920s to the present, thermal processing has been used to control *C. botulinum* in canned and many categories of foods. The classic investigation on the heat resistance of *C. botulinum* spores was carried out by Esty and Meyer in the 1920s (112) in California as a result of the commercial outbreaks of botulism in canned foods. They examined 109 type A and B strains at five heating temperatures over the range 100 to 120°C (212 to 248°F). They found that the initial inactivation rate was logarithmic between 100 and 120°C and depended on the spore concentration, the pH, and the heating menstruum. As with thermal treatments of other organisms, tailing and a plateau are typically observed after the initial several logs of inactivation. The use of a reproducible system is valuable in periodically determining the heat resistance of existing and new spore isolates and spore crops prepared in the laboratory. Extrapolating the data of Esty and Meyer gives a maximum value of $D_{121.1°C}$ of 0.21 min for *C. botulinum* type A and B spores in phosphate buffer (112, 149). Owing to these seminal studies, the thermal processing industries have used $D_{121°C}$ as a standard in calculating process requirements. Spores of nonproteolytic *C. botulinum* types B, E, and F have much lower heat resistance (100-to 1,000-fold) than spores of proteolytic type A and B strains. Typically, type E spores have a $D_{70°C(158°F)}$ varying from 29

to 33 min, a $D_{80°C(176°F)}$ of 0.3 to 3 min, and a $D_{100°C(212°F)}$ of <0.1 to 0.5 min depending on the strain. The *z* value ranges from 13 to 15°F. Spores of nonproteolytic *C. botulinum* type B have heat resistance higher than that of type E spores yet lower than that of spores from proteolytic strains. Scott and Bernard (191) determined that the $D_{82.2°C}$ of spores of nonproteolytic type B strains ranged from 1.5 to 32.3 min, compared with a $D_{82.2°C}$ of 0.33 min for a type E strain. Media containing lysozyme can enhance recovery of group II *C. botulinum* spores, because lysozyme substitutes for spore lytic enzymes that are inactivated by heat (192). *D* values at 85 and 95°C were 100 and 4.4 min, respectively, for spores of strain 17B and 45.6 and 2.8 min, respectively, for spores of strain Beluga E recovered on media containing lysozyme.

The thermal resistance of *C. botulinum* spores is strongly dependent on environmental and recovery conditions. Heat resistance is markedly affected by acidity, and spores have lower heat resistance at low pH values (149). Esty and Meyer (112) found that spores had maximum resistance at pH 6.3 and 6.9, and resistance decreased markedly at pH values below 5 or above 9. Increased levels of sodium chloride or sucrose resulting in decreased aw increased the heat resistance of *C. botulinum* spores (166). Sugiyama (193) found that spores grown in media containing fatty acids exhibited increased heat resistance. *C. botulinum* spores coated in oil were more resistant to heat (194). As with *Bacillus* spp., sporulation of *C. botulinum* at higher temperatures results in spore crops with greater heat resistance (25, 195), possibly related to acquired thermotolerance due to heat shock proteins (195). Compared to *Bacillus*, the compositional factors contributing to heat resistance of *C. botulinum* spores are not well defined. The factors described for heat resistance for *Bacillus* outlined in the first part of this chapter are found in *C. botulinum*, i.e., reduced water content, SASP, mineral deposition and matrix, and DPA content; however, undefined factors also likely contribute to sporulation and heat resistance. Zinc ions in the medium enhanced the sporulation of proteolytic *C. botulinum* type B (196). As a strict anaerobe, *C.*

botulinum grown in medium with a low redox potential can accumulate reduced transition metals such as $Fe^{2+}$and Cu^{2+}, which resulted in enhanced heat sensitivity in laboratory conditions (197). A supply of hydrogen gas in the heating menstruum led to more rapid spore inactivation (198). It is likely that production of gases, including hydrogen and carbon dioxide, and organic acids in anaerobic metabolism also affects heat resistance (198).

Recently, several studies have described the diversity in thermal resistance of *C. sporogenes*, which is closely related to group I *C. botulinum*. Although closely related to proteolytic *C. botulinum* type A, *C. sporogenes* spores usually have a much higher heat resistance (approximately 7-to 10-fold-higher resistance depending on the strain). Consequently, *C. sporogenes* is often used as a conservative surrogate for *C. botulinum* in thermal processing. In a recent study, two clades of *C. sporogenes* were identified based on pulsed-field gel electrophoresis and whole-genome sequencing (151). Clade I had a lower heat resistance than clade II, while strain PA3679 in clade 2 produced spores that have about a 10-foldincreased heat resistance relative to *C. botulinum* type A spores, and strains from this clade have been widely used in validation of thermal food processes. A meta-analysis of data collected from 38 studies indicated that PA3679 had significantly higher heat resistance than proteolytic *C. botulinum*. The *D* values at 121.1°C were estimated to be 0.19 min for *C. botulinum* type A and 1.28 min for *C. sporogenes*, while the *z* values were very similar at 11.3 and 11.1°C for the two species (151). Genomic studies were conducted to reveal genes responsible for heat resistance in *C. sporogenes* compared to *C. botulinum* (25, 199). The most significant difference was the acquisition of a second *spoVA* operon, which is responsible for transport of DPA into the spore core during sporulation. Advanced genetic and genomic tools previously not available for *C. botulinum* and related clostridia, including clustered regularly interspaced short palindromic repeat (CRISPR)-Cas systems and transcriptomics and genome mining, should lead to a greater

understanding of heat resistance in this critical group of sporeformers playing a role in food safety.

Nonthermal Processing Methods for Control of Sporeformers

Several nonthermal methods and sporicidal chemicals have been evaluated for control of sporeformers in foods and food contact surfaces (83–85, 87, 200–202). One of the most common newer technologies being used in industry is HPP and especially HPP combined with thermal processing (HPTP). HPP and HPTP are being widely introduced into the food industry and are emphasized here. Other methods of control of sporeformers have been thoroughly described in expert treatises (201, 203).

Fundamental studies of high pressure have been performed with the model organism *B. subtilis*, as described in the first section of this chapter. Applied studies for food safety and prevention of spoilage have mainly been directed at spores of *C. botulinum* groups I and II and certain spoilage organisms, such as *Alicyclobacillus acidoterrestris*, as described in this section. Sporicides such as chlorine compounds have been evaluated for inactivation of spores, and most fundamental studies have been conducted with *B. subtilis*. Several expert treatises have addressed sporicides for food preservation (201–203). This section emphasizes inactivation of spores of *C. botulinum*, since it is the most important sporeformer with regard to severity of foodborne illness and regulatory actions.

Traditional Physical Methods and Sporicidal Chemicals

Gamma Irradiation and Oxidizing Chemicals Spores of *C. botulinum* groups I and II, as well as other sporeformers, are highly resistant to gamma irradiation, compared to vegetative cells of most microorganisms (201–204). In many foods, it is impractical to inactivate spores by irradiation. Moreover, due to consumer concerns about irradiation and its required labeling, its application

is limited to certain foods or ingredients, such as spices (205). *C. botulinum* spores have a *D* value of 0.1 to 0.45 megarads (2.0 to 4.5 kGy). *C. botulinum* spore gamma radiation resistance varies depending on the serotype and strain; proteolytic types A, B, and F are most resistant (202). UV irradiation has been used to control vegetative bacterial and fungal spoilage on certain food products, including fruits. However, UV treatment needs to be used with caution, as it was shown to enable rapid growth of *C. botulinum* and toxin formation on melons treated with UV to prevent mold spoilage (206), highlighting the importance of the food microbiota in controlling this pathogen.

C. botulinum spores can be inactivated by ethylene oxide, halogen sanitizers, and hydrogen peroxide (201–203). Hydrogen peroxide is commonly used for sanitizing surfaces in aseptic packaging, and halogen sanitizers are used in cannery cooling waters. Alternatives to hydrogen peroxide such as peracetic acid have received consideration due to the deleterious effects of hydrogen peroxide on packaging equipment and materials. The assessment of biocides and food preservatives in sporicidal efficacy has been reviewed (201–203).

Biological Control of Sporeformers

In many food systems, sporeformers, including *C. botulinum*, do not compete well with the inherent microbiota in the food microbiome. The mechanisms governing the inability of *C. botulinum* to compete with inherent microbiota in foods and in the adult intestinal tract are not well defined, but they likely include competition for nutrients, inherent inhibitory substances such as bacteriocins and defensins in foods and the gastrointestinal tract, and in foods the lowering of the pH to a point at which *C. botulinum* cannot grow and form botulinum neurotoxin (207–210). In addition to these factors, in the gas trointestinal tracts of animals and humans, immune responses are elicited in response to pathogens, which adds an important dimension not observed in foods.

One of the most effective methods for control of *C. botulinum* and other pathogens in foods is the addition of or production of lactic acid and other fermentative inhibitory metabolites, including proteinaceous bacteriocins (105, 207, 209, 210). The production of acids generally requires a source of fermentable carbohydrates in the food which is converted to organic acid end products, lowering the pH and preventing growth and toxin formation. When foods are processed to inactivate vegetative lactic acid bacteria and other inhibitory bacteria (e.g., by pasteurization and HPP), this can lead to a permissive environment for pathogens to grow. The ability of competitor bacteria and fungi to inhibit toxin formation has been illustrated in various food systems (207, 208, 210). Competitor organisms, their succession and growth in foods, and the inhibitory mechanisms are an important area for development of food safety and quality systems. With advanced methods, including denaturing gradient gel electrophoresis-PCR, length heterogeneity-PCR, metagenomics, and other advanced genetic methods, potentially combined with traditional culture techniques, there is the potential to determine changes in microbiota in foods and reach a more in-depth understanding of the organisms important in competitive control (91, 102, 138, 211–214).

Innovative Processing Technologies

Newer preservation procedures are increasingly being adapted and employed by industry (83–87). These technologies include high pressure with or without thermal treatment, pulsed electric fields, radiofrequency, ultrasound, acoustic technologies, cold plasma, membrane filtration, and new chemical sporicidal chemical systems. The description and efficacy of allof these technologies are outside the scope of this chapter, and the emphasis here is on HPP, as this technology has widely been incorporated into food processing (86).

HPP and HPTP

The most common high-pressure system combines pressure and thermal processes (HPTP). HPTP processors typically use temperatures from ambient to >100°C and pressures of 100 to 900 MPa (86, 87). Exposure times can range from a few seconds to over 20 min but are usually 3 to 5 min. HPP generally kills vegetative cells of yeast, molds, and bacteria and can extend the shelf life of the foods and avoid destruction of nutrients and organoleptic properties, which may occur with thermal processing. The product is usually packaged in a flexible container such as a patch or plastic bottle, although spoil multilayer plastic and aluminum packaging is also used. The product is processed in a high-pressure chamber filled with a pressure-transmitting hydraulic fluid (usually water).

Vegetative pathogens and yeasts and molds in foods can generally be eliminated with process pressures of 200 to 800 mPa at ambient temperatures (85, 86). HPP and HTPT inactivate pathogens and spoilage organisms, including *Salmonella*, *Escherichia coli* O157:H7, *Listeria* spp., *Campylobacter* spp., and *Staphylococcus aureus* (85–87). Overall, HPP and HPTP inactivate microorganisms in the following order: mold and yeast vegetative cells >Gram-negative bacteria >Gram-positive bacteria >bacterial spores. The mechanisms of inactivation probably include cytoplasmic membrane and cell wall damage, essential enzyme inactivation by noncovalent disruptions, and DNA damage. Similar to thermal processing, inactivation of organisms by HPP and HPTP usually exhibits nonlinear kinetics, possibly due to a heterogeneous population of organisms. The efficacy of inactivation of vegetative cells and spores is dependent on the food commodity.

Research on HPP and HPTP for inactivation of bacterial sporeformers has mainly been performed with species of *Bacillus*, *Clostridium*, and *Alicyclobacillus*. The primary food safety target of HPP and HPTP in many foods is the inactivation of spores of *C. botulinum*, and several studies in laboratory media and in foods in contained facilities have been performed (215–218). Interestingly, inactivation of spores by HPP and HPTP does not correlate with inactivation by thermal processing for *C. botulinum* and certain

other sporeformers. For example, *C. botulinum* type B spores are more resistant to HPTP than type A spores (218), which contrasts with susceptibility to thermal processing. *C. botulinum* type E spores are less resistant than nonproteolytic type B and F spores to HPTP (219). In addition to vegetative spoilage organisms, spores of the important spoilage organism *A. acidoterrestris* can be inactivated by HPTP (220). Further experiments are necessary to evaluate the inactivation of other spoilage sporeformers by HPP and HPTP.

Currently, the processing factors used in HPP and HPTP are mainly empirical in the inactivation of sporeformers. In contrast to thermal processing, concise models and practical parameters are not yet precisely defined. With certain pathogens, particularly *C. botulinum*, it is not permitted in the United States to conduct research on HPP except in facilities that are approved for work with select agents, which limits the availability of data for quantitative analysis and modeling. Nonpathogenic surrogates of *C. botulinum* would be useful for evaluation of pathogen survival of HPP and HPTP processes. However, unlike the utility of established surrogate systems for thermal processing (for example, the use of defined strains of *C. sporogenes*), surrogates are only in development for HPP treatments. The ideal surrogate would be a strain that is isogenic except for the deletion of pathogenicity genes, e.g., deletion of the gene encoding botulinum toxin in *C. botulinum*. With the development of new genetic tools, such as CRISPR-Cas9 systems, these surrogates should be attainable in the near future and could be evaluated in facilities that do not handle select agents.

Additional Innovative Technologies for Control of Sporeformers

Other technologies are being explored and have been implemented in sectors of the food industry. These technologies include electric and electromagnetic fields, pulsed electric fields, plasma, and ultrasonics (84, 85, 87). Generally, these methods are effective in

inactivating vegetative cells but are relatively ineffective compared to heat in killing spores.

IMPORTANCE OF BIOFILMS IN CONTROL OF SPOREFORMERS IN FOODS AND MANUFACTURING

Biofilms have been increasingly recognized as an important area for food safety and quality (221–223). Bacterial spores are hydrophobic and attach to food contact surfaces, which can lead to biofilms (224). These structures have enhanced resistance to inactivation by chemicals and physical processes. Biofilms of pathogens and spoilage bacteria are generally more resistant to cleaning and sanitation procedures than planktonic cells (221, 222). Fundamental studies on the formation and properties of biofilms have been conducted with *B. subtilis* (223), and these can serve as a conceptual model for biofilms of food-related sporeformers.

SPOILAGE OF FOODS BY SPOREFORMERS

Bacteria and fungi cause enormous economic losses of foods by spoilage (72, 73). It has been estimated that 20 to 30% of commercial foods undergo microbial spoilage with associated loss of consumption. With the global increase in population and the need for sustainable food resources, technologies to prevent spoilage would greatly help to alleviate food shortages and spoilage and contribute to food security and sustainability. The physiological states of sporeformers contribute to their ability to grow in and spoil foods (137). Spore-forming bacteria and fungi are responsible for spoilage of several classes of foods. The primary genera of sporeformers causing spoilage of foods are *Anoxybacillus*, *Alicyclobacillus*, *Bacillus*, *Clostridium*, *Desulfotomaculum*, *Geobacillus*, *Paenibacillus*, *Thermoanaerobacter*, *Moorella*, and *Sporolactobacillus* (68, 75, 76, 89).

Spoilage sporeformers can be divided into various genetic and physiological groups depending primarily on their growth temperature, acid resistance, and spoilage manifestations. The principal groups of sporeformers causing spoilage are thermophilic organisms causing flat sour spoilage, thermophilic anaerobes not producing hydrogen sulfide, thermophilic anaerobes forming hydrogen sulfide, putrefactive anaerobes, facultative *Bacillus* mesophiles, butyric clostridia, lactobacilli, and heat-resistant molds and yeasts (68, 88, 89, 93). Spoilage sporeformers have certain physiological properties that affect their propensity to spoil foods. *Bacillus* species are aerobic and generally not osmotolerant. Some *Bacillus* species and strains are psychrotrophic, including *B. cereus*, which can spoil refrigerated dairy products; others, such as *B. subtilis*, are mesophilic and can spoil bakery products. Psychrophilic strains of *Bacillus* have been isolated from spoiled dairy products (225). Thermophilic sporeformers can spoil canned foods and foods in hermetically sealed packages (89).

Clostridia range from being strict anaerobes to mildly aerotolerant, and most species are not osmotolerant, although *C. sporogenes* can grow at an aw of ≥0.93. Clostridia generally spoil foods with low oxygen-reduction potential, such as canned or vacuum-packaged foods. However, the microbiota of a food can rapidly utilize oxygen and lower the oxidation potential, allowing clostridia to proliferate in many foods, including products produced in an aerobic atmosphere. The main *Clostridium* species causing spoilage are *C. sporogenes*, *C. butyricum*, and *T.* (*C.*) *saccharolyticum* (89).

Table 2.6 Spoilage of canned foods by sporeformers[a]

Type of spoilage	pH	Major sporeformer(s) responsible	Spoilage defects
Flat sour	≥5.3	*B. coagulans*, G. *stearothermophilus*	No gas, pH lowered. May have abnormal odor and cloudy liquor.
Thermophilic anaerobe	≥4.8	*T. thermosaccharolyticum*	Can swells, may burst. Anaerobic anaerobe and products give sour, fermented, or butyric odor. Typical foods are spinach and corn.
Sulfide spoilage	≥5.3	*D. nigrificans, C. bifermentans*	Hydrogen sulfide produced, giving rotten egg odor. Iron sulfide precipitate gives blackened appearance. Typical foods are corn and peas.
Putrefactive anaerobe	≥4.8	*C. sporogenes*	Plentiful gas. Disgusting putrid odor. pH often increased. Typical foods are corn and asparagus.
Psychrotrophic clostridia	≥4.6		Spoilage of vacuum-packaged chilled meats. Production of

			gas, off flavors and odors, discoloration.
Aerobic sporeformers	≥4.8	*Bacillus* spp.	Gas usually absent except for cured meats; milk is coagu-lated. Typical foods are milk, meats, and beets.
Butyric spoilage	≥4.0	*C. butyricum*, *C. tertium*	Gas, acetic and butyric odor. Typical foods are tomatoes, peas, olives, and cucumbers.
Acid spoilage	≥4.2	*B. coagulans* subsp. *thermoacidurans*	Flat (*Bacillus*) or gas (butyric anaerobes). Off odors depend on organism. Common foods are tomatoes, tomato products, and other fruits.
	≥4	*A. acidoterrestris*	Flat spoilage with off flavors. Most common in fruit juices and acid vegetables and also reported to spoil iced tea.

Acidic canned foods often receive a pasteurization treatment to inactivate vegetative spoilage organisms. Spoilage of acid canned foods is carried out by relatively few species of sporeformers (89). The primary organisms of concern in high-acid foods (≤pH 3.8) are yeasts and *A. acidoterrestris*, particularly in juices (68, 76). Moderately acidic canned foods in the pH range of 3.8 to 4.5 include foods such as canned fruits in syrups and tomatoes. Certain species

of *Clostridium*, including *Clostridium pasteurianum*, *C. sporogenes*, *C. tyrobutyricum*, and *C. beijerinckii*, as well as the species *Paenibacillus polymyxa*, *Bacillus coagulans* subsp. *acidurans*, and *Bacillus coagulans* (*Lactobacillus sporogenes*), have been isolated from moderately acidic canned foods (76, 89). Certain strains have been characterized as being extremely acid tolerant (89). Prominent bacterial thermophilic (>55°C) sporeformers include *G. stearothermophilus*, *D. nigrificans*, *Thermoanaerobacterium thermosaccharolyticum*, and *Moorella thermoacetica* (68, 73, 88) (Table 2.6).

Alicyclobacillus species are highly acid tolerant and grow at low pHs of 2.0 to 6.0 (220). They are also moderately thermophilic but not osmotolerant, growing only above a water activity of 0.98. *Alicyclobacillus* has been recognized as a prominent spoilage organism of acidic products, such as pasteurized fruit or vegetable juices that are improperly cooled or stored at high temperatures (75, 76, 88).

Acidic and acidified foods with an equilibrium pH of ≤4.6 are generally not processed sufficiently to inactivate all spores, since most species of sporeformers do not grow under acid conditions and inactivation of allspores would be detrimental to food quality and nutritional composition. Certain foods, such as cured meats and hams, do not undergo a thermal process sufficient to inactivate sporeformers and thus must be kept under refrigerated conditions for microbial stability. These classes of foods present opportunities for the growth of sporeformers which do not present a public health hazard but which can cause spoilage that results in economic losses (68, 76). Most of the spoilage organisms and their characteristic spoilage patterns have been recognized for many years (89).

Heat-resistant fungi and yeasts are spoilers of acidic foods with economic significance, particularly fruit-derived and high-sugar products (92, 93). While most filamentous fungi and yeasts are killed by heating for a few minutes at 60 to 75°C, heat-resistant fungi produce thickwalled ascospores that survive heating at ca.

85°C for 5 minutes (94). The most common genera of heat-resistant fungi causing spoilage are *Byssochlamys*, *Neosartorya*, *Talaromyces*, and *Eupenicillium* (93, 94). Certain heatresistant fungi also produce toxic secondary metabolites collectively referred to as mycotoxins (89, 93).

Practical control of spoilage sporeformers includes monitoring of raw foods entering the cannery, particularly sugars, starches, spices, soil-borne foods such as onions, garlic, and mushrooms, and dried foods (76, 89). Dry ingredients such as sugar, starches, flours, and spices often contain high levels of sporeformers (89, 205). Spore populations can also accumulate in a food plant, such as thermophilic spores on heated equipment and saccharolytic clostridia in plants processing sugar-rich foods, such as fruits. A goal is to limit the initial spore load in a food product. Adequate thermal processing depends on rapid cooling of products, chlorination of cooling water, and implementing and maintaining good manufacturing practices within the food plant; appropriate storage and distribution conditions are also required. In practice, the inherent spore contamination of foods and food ingredients and of the cannery environment contributes to spoilage problems (76, 89). Development of processing methods to prevent or minimize spoilage depends on physical and chemical methods to inactivate the target organisms and on formulation of foods and the use of microbial inhibitors to prevent growth.

SPOILAGE OF SPECIFIC FOOD CLASSES BY SPOREFORMERS

Dairy Ingredients and Finished Products

Thermophilic sporeformers can be a majorcause of spoilage in the manufacture of dairy ingredients (68, 76, 89, 134). Of particular Importance in dairy ingredient manufacture are the sporeformers *G. stearothermophilus*, *Geobacillus thermoleovorans*, and *Anoxybacillus flavithermus*. The presence of these spoilage

thermophiles can lead to off flavors and textures through their formation of degradative enzymes, and these organisms are indicators of poor hygiene, particularly in heated areas of the plants, such as evaporators. Many thermophilic Bacilli form biofilms that are difficult to control by cleaning in place and other hygienic procedures. *C. tyrobutyricum* and related organisms can cause gas formation "blowing" and butyric acid odors in hard cheeses. The presence of the pathogens *C. botulinum*,*C. perfringens*, *B. cereus*, and potentially *C. difficile* is a concern in finished dairy products, particularly infant formulas and medical foods (68). Heat-resistant clostridia, Including *C. sporogenes* and *T. thermosaccharolyticum*, can cause swelling through gas production and off flavors through production of degradative enzymes in canned milk products that have undergone ultrahigh-temperature treatment (89). Fermented milk and products such as cheeses have been spoiled by clostridia, including *C. tyrobutyricum*, *C. butyricum*, *C. sporogenes*, and *C. beijerinckii*. *Paenibacillus* and *Bacillus* can cause spoilage of pasteurized milk. Sterilized milk can be spoiled by *Bacillus stearothermophilus*, and dehydrated milk by *G. stearothermophilus*.

Refrigerated Meat Products

Psychrotrophic clostridia can spoil refrigerated meat products in several ways, including via the production of noxious gases such as hydrogen sulfides, formation of putrefactive amines, formation of slime, and protein and carbohydrate degradation (135, 226–228). They can also cause swelling of cans and packages. The primary Species involved in ready-to-eat meat and poultry spoilage are *Clostridium laramie*, *C. estertheticum*, *C. gasigenes*, *C. butyricum*, and *C. pasteurianum*. In particular, *C. estertheticum* and *C. gasigenes* can cause "blown-pack" spoilage, which occurs in refrigerated batches of vacuum-packaged meats and involves the production of large quantities of gas, putrid odors, and a metallic sheen on the meat. Me sophilic bacilli such as *B. coagulans* can also cause off odors described as medicinal and phenolic.

Fruit and Vegetable Juices

Sporeformers are a serious cause of spoilage in several types of fruit and vegetable juices (76, 89, 229). *Alicyclobacillus* spp. have been recognized as a particular problem, leading to medicinal off flavors. Souring and gas formation also occur in dairy-based products by thermophilic bacilli and clostridia. Shelf-stable high-acid products can be spoiled by various clostridia and bacilli, including *C. pasteurianum*. These sporeformers can also carry out gas formation and acid production in fruitcontaining products, such as pastries.

Bakery Products

Various *Bacillus* spp., including *B. amyloliquefaciens*, *B. subtilis*, *B. pumilus*, and *B. cereus*, are recognized as causing a defect in bakery products known as ropiness, in which fruity odors such as that of overripe melons are produced (68, 76). This is followed by enzymatic activities leading to discoloration, changes in texture, and stickiness due to the production of extracellular polysaccharides. Spores are commonly present in flours and other raw ingredients and introduced into the dough, and they survive the baking process and then proliferate and cause the ropiness. This type of spoilage can mostly be prevented by careful monitoring of raw ingredients for the presence of aerobic sporeformers.

Detection of Food Spoilage Sporeformers

Physical, chemical, and microbiological methods for determination of food spoilage have been described (68, 75, 76, 89, 134). Safety procedures used in working with spore-forming pathogens, including *C. botulinum* and *B. anthracis*, need to be carefully controlled and tested in an approved laboratory (70). There was a tremendous impact on the industry from a massive recall of infant formula that may have contained *C. botulinum* spores (unpublished data). This incidence of the presumptive presence of *C. botulinum* spores in dried infant formula produced in New Zealand and the

resulting massive recall of products highlight the importance of rapid and definitive detection methods for high-risk pathogens.

Traditionally, culture methods have been used for detection of spores, but culture-independent molecular methods are being adapted for detection of sporeformers in foods (133, 134). These include protein-based methods for surface molecules, including immunobased methods such as enzyme-linked immunosorbent assays. Currently, there is a trend of utilizing approaches linked to nucleic acid detection, such as PCR and high-throughput and next-generation DNA sequencing. Most protein and DNA methods generally require germination of spores, as intracellular proteins and nucleic acids are difficult to isolate from intact dormant spores, which may limit the utility of *in situ* detection methods.

SPORES AS PROBIOTIC AGENTS

Species of *Bacillus* and *Clostridium* have been used for decades as probiotic agents to purportedly prevent disease and improve health of animals and humans (230–237). Their primary benefits have been stated to be inhibitory actions towards pathogens in the gastrointestinal tract, and the sporeformers may also stimulate beneficial immune responses. The mechanisms of persistence and inhibitory action towards pathogens have not been elucidated, but they may include competition for adherence and nutrients, production of inhibitory metabolites, and avoidance of innate and antibody-mediated immune responses. For use in animals, including poultry and monogastric animals, spore probiotics have been demonstrated to enhance food conversion and probably affect pathogen infection. The safety of aerobic endosporeforming bacteria is critical for their use as probiotics (234, 235, 237, 238). Methods for safety assessments have been outlined. Antibiotic resistance, genetic modification, and gene transfer in the gastrointestinal tract are among major concerns. Several commercial companies are investigating *Bacillus* spp. as probiotics for humans and animals.

MODELING OF SPOREFORMER GROWTH IN FOODS AND ASSESSMENT OF SAFETY

Abundant information exists on the behavior of microorganisms in foods, and it is often useful to generate statistical models to quantify safety risks in foods. Two general types of models have mainly been used in food microbiology: (i) those analyzing experimental growth and survival data using simple and higher-order polynomials and (ii) theoretical models derived from basic scientific principles and computer analysis, used to predict microbial survival. Statistical models can be particularly useful to define important variables and predict microbial behavior in advance of practical testing.

The safety of thermally processed low-acid foods can be enhanced by application of risk management programs, including HACCP, FSO, and stepwise and interactive evaluation of food safety by an expert system, among others (123, 144, 239). The Food Safety Modernization Act incorporates measures of safety and spoilage by sporeformers. These systems entail a systematic and quantitative risk assessment program to ensure the safety of foods. They were designed to have strict control over all aspects of the safety of food production, including raw materials, processing methods, the food plant environment, personnel, storage, and distribution. In practice, the identification of potential hazards for a given process and meticulous control of critical control points are required. Methods for HACCP and FSO quality assurance programs for thermally processed foods have been expertly reviewed (123, 142).

Various modeling strategies have been used in assessing microbiological growth and phenotypic properties of microorganisms in foods (123, 144). Certain companies and institutions use advanced models such as neural nets. These can be valuable, since they are adaptive and improve in precision and predictive capability over time. An example of a model used extensively in the dairy industry is that of Tanaka et al. (240) for

preventing growth of *C. botulinum* in processed cheese. Although models can provide guidelines for food safety, the assurance of sterility generally needs to be ascertained by laboratory challenge studies (105, 123, 144).

Work in the Setlow laboratory has been supported by the Army Research Office, the NIH (GM19698), the USDA, and a Multi-University Research Initiative (MURI) award from the U.S. Department of Defense. Research in the Johnson laboratory has been supported by the FDA, USDA, NIAID, University of Wisconsin —Madison, and industrial sponsors of the Food Research Institute.

Microbiological Criteria and Indicator Microorganisms

The concepts and principles for the establishment of microbiological criteria (MCs) were elaborated in the mid-1980s by the International Commission on Microbiological Specifications for Foods (ICMSF) (1). These concepts have been used to develop recommendations for criteria for foods in international trade or for criteria specific to pathogens, such as *Listeria monocytogenes*, in foods (2, 3). They are also the basis of the Codex Alimentarius Commission document *Principles and Guidelines for the Establishment and Application of Microbiological Criteria Related to Foods*, first issued in 1997 (4) and revised in 2013 (5). This document defines an MC as a risk management metric which indicates the acceptability of a food or the performance of either a process or a food safety control system following the outcome of sampling and testing for microorganisms, their toxins and metabolites, or markers associated with pathogenicity or other traits at a specified point of the food chain.

While the Codex Alimentarius Commission currently recognizes only the general category "microbiological criterion," other national, transnational, and international organizations, trade associations, and other stake holders in the food chain often describe microbiological standards, guidelines, or specifications that can be differentiated as follows:

- *Microbiological standard* is a mandatory criterion included in a law or a regulatory ordinance.

- *Microbiological guideline* is an advisory criterion issued by either authorities, industry associations, or food manufacturers. Such guidelines are indicative of what can be expected for certain microbiological parameters when a food is manufactured according to best hygienic or manufacturing practices.
- *Microbiological specification* is an element of purchasing agreements between a buyer and a supplier of a raw material or a food product. Its use may be mandatory or advisory depending on the agreements between the two parties.

The general category "microbiological criterion" recognized by the Codex Alimentarius Commission covers both MC utilities related to the safety and acceptability of discrete lots of food products and MC applications concerning food hygiene and process assessment and monitoring (6, 7). Interestingly, the European Commission (EC) has split these two types of utility and recognizes "food safety" criteria next to "food hygiene process" criteria (8). The consequences in case of noncompliance are in principle similar for the two different utilities in both the Codex Alimentarius Commission and EC contexts. Lots that fail to meet MCs that target human pathogens specifically (i.e., food safety criteria) are considered not suitable to be placed on the market, while food lots and/or food operations failing criteria for microorganisms or groups of microorganisms that are not human pathogens or may include such pathogens as a subfraction are not deemed unsafe as such, but they would require, for instance, increased scrutiny of hygiene and processing measures and of raw materials as well as finished goods as appropriate to ensure operational control over food safety. The term "MC" is used throughout this chapter, since the underlying principles for their establishment and application are valid for all three subcategories mentioned above as well as for criteria specific to safety or hygiene/process control.

MCs have traditionally been developed around significant pathogens, relevant commensals, and hygiene indicators as

reflected in the ICMSF cases, which were first published in 1986 (1) and more recently updated (9, 10). They are widely used today to discriminate between acceptable and unacceptable lots of food products.

In order to address the need for science-based risk assessment, the ICMSF has explored the potential applications of risk assessment techniques to microbiological issues (11). This initial work has triggered an evolution from hazard-based to risk-based food safety management, as observed during the last decade. Numerous discussions have since then taken place to develop the concepts further. These activities have culminated in the publication of the document *Principles and Guidelines for the Conduct of Microbiological Risk Management* (MRM) by the Codex Alimentarius Commission (12).

The evolution of the traditional metrics, including MCs, to include additional risk-based metrics has taken place over many years and has allowed a better understanding of the utility, performance, and limitations of MCs. These elements are discussed below, along with the role of microbiological indicators.

MRM METRICS

Details on the establishment and implementation of microbiological risk management (MRM) metrics are outlined in Annex II of *Principles and Guidelines for the Conduct of Microbiological Risk Management (MRM)*, adopted by the Codex Alimentarius Commission in 2007 (12). The scope of this document was to provide a framework for the MRM process to the Commission as well as to Commission members and member organizations. The purpose was also to provide guidance to the food industry and other stakeholders who design, validate, and implement control measures ensuring the manufacture of safe food that consistently achieves the targets defined in the MRM metrics.

The principles for their establishment and implementation are outlined as follows in the document (12) and are applied in addition to those described in the guidelines themselves.

- The establishment and implementation of MRM metrics should follow a structured approach, with both the risk assessment phase and the subsequent risk management decisions being fully transparent and documented.
- MRM metrics should be applied only to the extent necessary to protect human life or health and set at a level that is not more trade restrictive than required to achieve an importing member's appropriate level of protection.
- MRM metrics should be feasible, appropriate for the intended purpose, and applied within a specific food chain context at the appropriate step in that food chain.
- MRM metrics should be developed and appropriately implemented so that they are consistent with the requirements of the regulatory and/or legal system in which they will be used.

Metrics used by competent authorities to express the expected level of control have been based traditionally on the following criteria:

- The *product criterion* (PdC) specifies chemical or physical characteristics of a food (e.g., pH and water activity), which affect the safety of a food product. Different elements are related to (and impact) a PdC, such as the frequency and level of contamination, the effectiveness of control measures, the conditions under which the product will be used, and other parameters ensuring that it will not contain the pathogen at an unacceptable level when the product is consumed. Each of the factors that may impact the effectiveness of a PdC has to be considered in a transparent manner.

- The *process criterion* specifies the conditions of treatments to be applied at a specific step of the manufacturing process to achieve the targeted level of control of a microbiological hazard. Again, there are a number of parameters, such as the initial level of the target pathogen, the type and resistance of the target pathogen, and the impact of the food matrices, that influence the expected effect.
- The MC is used for the examination of foods at a specified point of the food chain to determine the compliance of a food with a pre-established limit. Such a criterion can be used as a direct control measure for manufactured lots or, in the framework of a food safety control system, to periodically verify that the system is functioning as intended. Elements pertaining to an MC are defined in "Introduction to MC and Sampling Plans" below and also require the definition of necessary actions to be taken should a tested (lot) product exceed the established MC.

These metrics have existed for a long time but have been, and are still, evolving over time. This is linked to the shift of the management of food safety issues from a hazard-based to a risk-based approach. Thus, the evolving focus for managing such issues has led to the establishment by the Codex Alimentarius Commission of more-quantitative risk-based metrics outlined below.

Food Safety Objectives

The food safety objectives (FSO) metric expresses the maximum frequency and/or concentration of a pathogen in a food at the time of consumption that provides or contributes to the appropriate level of protection defined by a government. This risk-based limit, established by competent authorities, should be achieved operationally within the food chain, while flexibility is given to individual elements such as primary production or manufacturing.

While the FSO represents the final outcome, it does not specify how individual steps will contribute.

Performance Objectives

The performance objectives (PO) metric represents an operational risk-based limit at a specific point in the food chain, i.e., the concentration of a microbiological hazard in a food at that point that should not be exceeded in order to achieve the established FSO. Since it contributes to achieving an FSO, a PO should be considered and established in the light of previous and subsequent steps and their corresponding POs. An industry may find it beneficial to establish its own POs, taking into account its position within the food chain, the impact of subsequent steps, including the intended use of the end product, and the degree of risk it is willing to tolerate.

Performance Criterion

The performance criterion (PC) expresses the outcome achieved by a single control measure or a combination of control measures, usually microbicidal and/or microbiostatic control measures. This metric articulates the desired reduction and/or maximum acceptable increase of the hazard. The PC usually describes the required outcome to achieve the defined PO. The PC needs, therefore, to take into account variability of pathogens, food composition, and processing parameters along the segment of the food chain for which the PO has been established.

INTRODUCTION TO MC AND SAMPLING PLANS

The groundwork for the establishment of MCs within the global regulatory food safety management context was initially developed during joint consultations of the World Health Organization (WHO) and Food and Agriculture Organization (FAO) in the 1990s. The Codex Alimentarius Commission has a role in recommending MCs

at the international level. National governments may choose to adopt Codex MC into their national systems or use them as a starting point for addressing their intended public health goals. National governments also may establish and apply their own MCs. Food business operators may establish and apply MCs within the context of their food safety control systems. Importantly, according to the Codex Alimentarius Commission (5), the need for an MC should be demonstrated, e.g., by epidemiological evidence that the food under consideration may represent a significant public health risk and that a criterion is meaningful for consumer protection.

The outcome of the above long-term consultations has been continuously evolving with the input of, for instance, the ICMSF, national governments, and academic researchers. These efforts resulted in the preparation of a document on the principles for the establishment of MCs, first issued by the Codex Alimentarius Commission in 1997 (4) and revised in 2013 (5). The revision of this document was initiated in 2010 to take into account new developments in food safety management systems and in particular the MRM concepts. General overviews of sampling plans and MCs in the context of microbiological testing, including differences between MCs and FSO/PO, as well as how to operationalize MCs regarding these MRM metrics, have been published (10, 13–16).

Traditionally and historically, MCs have been established to determine whether a lot of product is suitable for commercial distribution and consumption. Acceptability of such a product was defined as the compliance with requirements for certain microorganisms (including parasites) and/or their toxins or metabolites. Requirements have been expressed as absence or as maximal numbers or concentrations of these parameters per unit of mass, volume, area, or lot. MCs have been and are still widely used to make a decision upon analysis of a food for defined parameters (9, 10, 14). The analytical results obtained are compared to the established requirements and serve as a basis to decide whether a lot is acceptable or needs to be rejected.

Importantly, the thinking of the Codex Alimentarius Commission is that the microbiological safety of foods is best managed by the effective implementation of control measures that have been validated, where appropriate, throughout the food chain to minimize contamination and improve food safety. This preventive approach, according to the Commission (5), offers more advantages than sole reliance on microbiological testing through acceptance sampling of individual lots of the final product to be placed on the market. Nevertheless, the establishment of MC may be appropriate for verifying that food safety control systems are implemented correctly.

Whether an MC's utility is for lot acceptance or verification of control, the design of a meaningful MC is essential. It must be considered that the development of such criteria is a complex process requiring the appropriate knowledge and information, resources, and efforts. They should therefore be developed only when there are clear benefits and justified need and when they are effective and practical in serving their purpose (5).

MCs, if deemed necessary and justified, are established to meet one or more objectives, such as those listed below (5, 9, 10):

- evaluating a specific lot of food to determine its acceptance or rejection, in particular if its history is unknown (i.e., port-of-entry assessment)
- providing information to food business operators on microbiological levels which should be achieved when best practices are applied (i.e., good hygiene practices [GHPs], good agricultural practices [GAPs], and good manufacturing practices [GMPs])
- assessing the suitability of a food or raw material for a particular use, such as its consumption or further processing
- verifying the performance of a food safety control system or its elements along the food chain, e.g., prerequisite programs,

HACCP (hazard analysis and critical control point) systems, and/or environmental monitoring schemes

- evaluating the adequacy of particular processing applied to deliver an acceptable product and/or to signal the need for action to avoid loss of control

- verifying the microbiological status of foods in relation to acceptance criteria specified between food business operators and/or for due diligence assessments

- verifying that the selected control measures are meeting risk-based metrics such as POs and FSOs

- detecting potential unforeseen problems in the design and/or operation of a food safety control system

To fulfill these objectives, an MC needs to be established for a specific food or a defined category of food showing similar characteristics, taking into account a number of elements, including the following:

- evidence of recognized or potential hazards to health, e.g., based on epidemiological evidence or reasoning

- microbiological status of the raw materials used to manufacture the food

- effect of processing and other handling on the microbiological status of the food

- likelihood and consequences of microbial contamination during and after processing

- likelihood and consequences of microbial growth during subsequent handling, storage, and use of the food

- intended use of the food as well as possible unintended use

- intended category of consumer as well as others likely to be consuming the food

- costs and benefits associated with the application of the criterion
- point of the food supply chain at which the criterion will apply
- changes (e.g., decrease or increase in numbers) in the levels of the target microorganism likely to occur after the point at which the MC has been set
- relationship to PO/POs established by authorities or industries for particular food supply chains and/or to FSO metrics and/or a defined appropriate level of protection specified by a competent authority

Considering its intended purpose, an MC is then established by translating the general principles above into specific elements of an MC and associated sampling plan, specifying at least the following eight components (5):

- the purpose of the MC
- the food, process, or food safety control system to which the MC applies
- the specified point in the food chain where the MC applies
- the microorganism(s) and the reason for its selection
- the microbiological limits (m or M; see below) or other limits (e.g., a level of risk)
- a sampling plan defining the number of sample units to be taken (n), the size of the analytical unit, and, where appropriate, the acceptance number (c)
- depending on its purpose, an indication of the statistical performance of the sampling plan
- analytical methods and their performance parameters

Consideration should also be given to the corrective action to be taken related to the purpose of the MC when it is not met. Actions

to consider typically include more frequent sampling, inspection, and auditing, further processing, diversion to an alternate use, rework, rejection, containment and disposition, withdrawal, and/or recall. The specific action decided on should be based on an assessment of the risk to the consumer where relevant, the point in the food chain, and the food specified and may consider history of conformance. Food business operators should reevaluate their food safety control systems, including GHPs and operational procedures, and/or carry outfurther investigation to determine appropriate preventive actions to be taken.

In all cases and for any purpose, the microorganisms specified in MCs need to be relevant for the food in question and its process; they may encompass bacteria, viruses, yeasts and molds, algae, parasitic protozoa, and helminths as well as their toxins or metabolites. MCs typically include relevant pathogens, indicators of process hygiene and/or control, and utility or spoilage organisms. The current approach in the formatting of recently issued MCs is to make a clear distinction between food safety-related parameters and process hygiene/control indicators (7, 8, 17).

Given the many relevant objectives and parameters to consider when an MC is being established, it is evident that this is a rather complex task requiring specific expertise as well as good insight and supportive data regarding the food safety management system at hand. One of the overarching important principles of the Codex (5) approach to using MCs for food safety management is that their establishment and application should be based on scientific information and analysis. When sufficient data are available, a risk assessment may be conducted on foodstuffs and their use. However, MCs may also be developed based on empirical knowledge related to GHPs or using scientific knowledge of food safety control within the context of HACCP.

The different elements constituting an MC define the requirements and their stringency. They are usually called sampling plans and are characterized by the parameters n, c, m, and M, which are defined as

follows: *n* is the number of samples that must be analyzed; *c* is the maximum allowable number of defective sample units in a two-class plan or of marginally acceptable sample units in a three class plan; *m* is a microbiological limit that in a two-class plan separates good from defective quality or in a three class plan separates good quality from marginally acceptable quality; and *M* is a microbiological limit that in a three-class plan separates marginally acceptable quality from defective quality.

According to the Codex Alimentarius Commission (5), the required stringency of food safety control systems, including the MC used, should be appropriate to protect the health of the consumer and ensure fair practices in food trade. The MC used should be capable of verifying that the appropriate level of control is achieved.

Sampling plans can be categorized as attributes plans or variables plans (9, 10). The first are the most appropriate when no or little information is available on the performance of the process and hence its impact on the microbial flora. This is typically a situation encountered by regulatory authorities at a port of entry or by manufacturers purchasing raw materials from a new and thus poorly known supplier. Variables plans are suitable only when there is sufficient knowledge on the nature and frequency distribution of microorganisms within lots of a particular food. This type of plan is suitable for manufacturers having a deep understanding of their process and thorough monitoring of their production, such as would be expected from a well-established HACCP program.

Attributes plans can be further subdivided into two class and three-class plans (9, 10, 14). Two-class plans are used to accept or reject individual lots based on the analysis of a specified number of sample units (*n*) using qualitative or quantitative criteria to discriminate lots and to make a decision regarding, for example, populations of a microorganism(s) above or below a defined concentration or presence/absence of a microorganism(s). While two-class plans are usually used for pathogens (6–8, 10, 14), this is not exclusive, and this type of plan exists as well for indicators. An

example is sampling plans for *Enterobacteriaceae* in infant and follow-up formula with the following parameters: $n = 10$, $c = 2$, and $m = 0$ (in analytical units of 10 g) (7). The statistical analyses for evaluating two-class attribute-based sampling plans are different for presence/absence data and for stratified quantitative data (18).

Three-class plans are used in situations where the quality of the product can be divided into three different classes according to the concentrations of microorganisms within the sample units. While analytical results exceeding the limit m are undesirable, in a three-class plan, a limited number of samples as defined by c can nevertheless be accepted. However, results exceeding the upper limit M make the product unacceptable. This is typically used for criteria where quantitative data are stratified into three groupings. The statistical analyses for three-class plans are different from those of two-class plans (9, 10, 14)

PERFORMANCE OF SAMPLING PLANS

The statistical performance of a sampling plan is usually illustrated by its operating characteristic curve, which describes the probability of acceptance as a function of the actual proportion of nonconforming analytical units or concentration of the microorganisms in the food (9 10, 14, 16, 17,19–21). An operating characteristic curve can be used to evaluate the influence of individual parameters of the sampling plan on the overall performance of the plan and as such can be a basis to determine alternative sampling plan approaches delivering equivalent performance.

Sampling plans for finished products are used by authorities or by manufacturers to detect noncompliant lots of products, i.e., lots presenting a defect. The defect rate of manufactured food products relates to the actual fraction of servings that are contaminated (9, 10, 14). This defect rate is an important element to understand in

the context of microbiological sampling and testing activities, whether they are applied to within-lot or to lot-by-lot testing.

Attributes plans have the ability to detect a given level of contamination and thus to reject a nonconforming lot of product with a certain probability. This ability is defined as the performance of the sampling plan and can be calculated using calculation sheets such as the ones published by the ICMSF (http://www.icmsf.org/wp-content/uploads/2018/01/Standard-Program.xlsm), and sampling plan performances are illustrated for the ICMSF cases in Table 3.1. Other organizations have developed sampling tools and guidance to evaluate the performance of sampling plans generally or for specific applications, such as those developed by the Joint Expert Meetings on Microbiological Risk Assessment under the auspices of the FAO and the WHO (22, 23). The characteristics of some of these have been compared (17).

As illustrated in Table 3.1, the performances of sampling plans show that their ability to detect defects at very low rates (i.e., very low levels of contamination) requires quite an investment in resources. Generally, pathogens occur infrequently and at low levels in food. The more effective the implemented hygiene control measures are, the lower the defect rate will be, and the greater the number of samples that would need to be tested in order to increase the probability of detection. However, due to the destructive nature of microbiological testing, the required laboratory infrastructure and capacity, and the associated high costs, testing cannot be expanded indefinitely. A limitation of within-lot testing as performed by authorities—for example, at the port of entry or during distribution—is frequently a lack of information on the conditions under which a particular food was manufactured. In addition, such testing is performed only sporadically, and data are not necessarily used and managed in the most effective way. A useful review on the impact of distribution of microorganisms in foods on the utility and performance of MCs has been published (19), illustrating some limitations as well as misconceptions associated with the statistics for food safety sampling.

Examples of recently issued MCs with attendant probabilities have been published by the Codex Alimentarius Commission for ready-to-eat foods, powdered infant formula, and bottled water (6, 7, 24). Details as well as additional examples are provided elsewhere (14–16, 18, 20, 23). A recent report provides an overview of various MCs and microbiological limits recommended by the European Food Safety Authority (17) in its scientific opinions.

MCs formulated as "absence" of one or more pathogens have been established by some governments and companies and represent a special case. Occasionally, such requirements do not even specify the target pathogen or, even more frequently, do not associate them with any specific sampling plan. As a consequence, such requirements do not express any tangible target or numerical tolerance.

These types of criteria are not compatible with current MRM metrics and therefore do not provide any quantifiable target against which the effectiveness of implemented food safety measures could be compared and measured. The simple term "absence" does not take into account that even sampling plans with c values of 0 and an extremely high number of samples (n) do not ensure the complete absence of a pathogen. A "$c = 0$" parameter also does not take into account the discriminatory power of a sampling plan but rather emphasizes the wish to not detect a specific pathogen in a given set of samples. For example, in the case of a lot defect rate limit of 5%, a sampling plan with the parameters $n = 95$, $c = 1$, and $m = 0$ (in analytical units of 25 g) would be more stringent than a traditional sampling plan of $n = 60$, $c = 0$, $m = 0$ (in analytical units of 25 g), rejecting a greater number of defective lots. However, in addition to increasing the analytical burden, it would give the impression that the presence of the pathogen is being "tolerated," despite the fact that the 95-sample plan is actually more protective.

Additional factors such as the nonhomogeneous distribution of contaminants and lack of technologies or procedures applied during processing to eliminate pathogens do not yet allow the manufacture

of products such as raw meat or poultry to be totally free of pathogens. Considering these limitations, there is a need for a compromise between the desire to achieve “absence” of pathogens and the feasibility of reaching this goal as well as the ability to detect pathogens through the application of sampling plans.

The limitations of sampling plans for finished products to ensure their safety as illustrated in this section emphasize the need to place microbiological testing in the broader framework of the overall food safety management system. To do so, it is certainly important to have a more complete picture of elements and factors contributing to the contamination of food products, as discussed in the following section.

Table 3.1 Examples of the ICMSF cases approach (9, 10), with sampling plans and stringency (case) aligned with degree of risk and conditions of use[a]

Degree of concern relative to utility and health hazard type	Examples	Conditions under which food is expected to be handled and consumed after sampling in the usual course of events which may result in:		
		Reduced risk	No change in risk	Increased risk
Utility: general contamination, reduced shelf life, incipient spoilage	Aerobic colony count, yeasts and molds	**Case 1** (3 class) *n* = 5, *c* = 3, *m* = 1,000/g, *M* = 10,000/g Mean concn, 5,105/g	**Case 2** (3 class) *n* = 5, *c* = 2, *m* = 1,000/g, *M* = 10,000/g Mean concn, 3,282/g	**Case 3** (3 class) *n* = 5, *c* = 1, *m* = 1,000/g, *M* = 10,000/g Mean concn, 1,829/g
Indicator: low, indirect hazard	*Enterobacteriaceae*, generic *E. coli*	**Case 4** (3 class) *n* = 5, *c* = 3, *m* = 100/g, *M* = 1,000/g Mean concn, 511/g	**Case 5** (3 class) *n* = 5, *c* = 2, *m* = 100/g, *M* = 10,000/g Mean concn, 328/g	**Case 6** (3 class) *n* = 5, *c* = 1, *m* = 100/g, *M* = 10,000/g Mean concn, 183/g
Moderate hazard: not usually life-	*Staphylococcus aureus, Bacillus cereus, C.*	**Case 7** (3 class) *n* = 5, *c*	**Case 8** (3 class) *n* = 5, *c*	**Case 9** (3 class) *n* = 10, *c*

threatening, usually no sequelae, normally of short duration, symptoms self-limiting, can result in severe discomfort	*perfringens, Vibrio parahaemolyticus*	= 2, *m* = 10/g, *M* = 100/g Mean concn, 33/g	= 1, *m* = 10/g, *M* = 100/g Mean concn, 18/g	= 1, *m* = 10/g, *M* = 100/g Mean concn, 6/g
Serious hazard: incapacitating but not usually life-threatening; sequelae are rare, of moderate duration	*Salmonella* spp., *L. monocytogenes*	**Case 10** (2 class) *n* = 5, *c* = 0, *m* = 0/25 g Mean concn, 1/55 g	**Case 11** (2 class) *n* = 10, *c* = 1, *m* = 0/25 g Mean concn, 1/178 g	**Case 12** (2 class) *n* = 20, *c* = 1, *m* = 0/25 g Mean concn, 1/495 g
Severe hazard: for the general population or in foods intended for susceptible populations, causing life-threatening or substantial chronic sequelae or illness of long duration	For the general population, *E. coli* O157:H7, *C. botulinum* neurotoxin For restricted populations, *Salmonella* spp., *Crono-bacter* spp.; *L. monocytogenes*	**Case 13** (2 class) *n* = 15, *c* = 0, *m* = 0/25 g Mean concn, 1/328 g	**Case 14** (2 class) *n* = 30, *c* = 1, *m* = 0/25 g Mean concn, 1/854 g	**Case 15** (2 class) *n* = 60, *c* = 1, *m* = 0/25 g Mean concn, 1/2,034 g

[a] Relative performance values of ICMSF cases are illustrated in terms of the mean concentration that will result in rejection with at least 95% probability, assuming hypothetical criteria and a standard deviation of 0.8. Calculations were performed with ICMSF Microbiological Sampling Plan tool, version 2.08 (http://www.icmsf.org/wp-content/uploads/2018/01/Standard-Program.xlsm).

MICROBIOLOGICAL PROFILE OF A FOOD PRODUCT

The microbiota of a food product, including commensals, hygiene indicators, and pathogens, is a result of the history of the product along the whole food chain. It is a dynamic system that evolves through the different steps of the food chain, from primary production through finished product to final preparation and consumption by the final user. The composition of the microbiota of the finished product as well as the levels of individual microorganisms or groups thereof is a function of the initial flora of individual raw materials, which is influenced and evolving at each step of the food chain due to the conditions and factors contributing to their decrease or their increase.

Elements contributing to changes of the microbiota are illustrated in Fig. 3.1 for industrially processed foods. Similar schemes and considerations can also be established for unprocessed or minimally processed foods as well as for other segments of the food chain, such as primary production, distribution, marketing, or the preparation and handling by the final consumer in catering or institutional facilities or even at home.

The fate of individual pathogens along a processing line as illustrated in Fig. 3.1, or any other type of food preparation scheme in the food chain, can be described using the conceptual formula defined by the ICMSF (9, 10, 14):

$$H_0 - \Sigma R + \Sigma I \leq \text{FSO or PO}$$

In this conceptual formula, $H0$ is the initial level of the pathogen under consideration, ΣR is the total (cumulative) reduction that is achieved through one or several consecutive bactericidal steps, and ΣI is the total (cumulative) increase that can occur due to growth and/or recontamination. All elements of the formula are expressed in $\log_{10}$ units.

While this conceptual formula is usually used to describe the fate of pathogens, it can very well be used to describe the fate of other microorganisms, such as relevant hygiene indicators or spoilage organisms, and hence reflect the hygienic performance of the process in question and the resulting microbiological quality of the product.

With respect to the illustrated example, the impact of the raw materials subjected to a killing step, such as a heat treatment, on the microbiota of the finished product will be determined by the type and levels of the initial microbiota and the magnitude of the killing step. In the case of raw materials added after the heating process, no further reduction will occur other than a possible quantitative modification related to the addition ratio of the different raw materials.

Microorganisms such as pathogens or hygiene indicators present in the processing environment can lead to contamination of the intermediate product. This can occur either indirectly, from the production premises and external surfaces of equipment, or directly, through contaminated food contact surfaces. While direct contamination by food handlers is unlikely to occur in industrially manufactured products, events involving human interventions in the processing line can result in contamination. Such direct contamination may be significant in productions requiring important human handling, such as food service or catering operations. Production processes being dynamic, the occurrence of such contaminations may be continuous in certain cases and sporadic in others, and their importance will depend on the levels of microbial contaminants in the environment or in the processing lines. These elements will determine the occurrence and the distribution in the finished products.

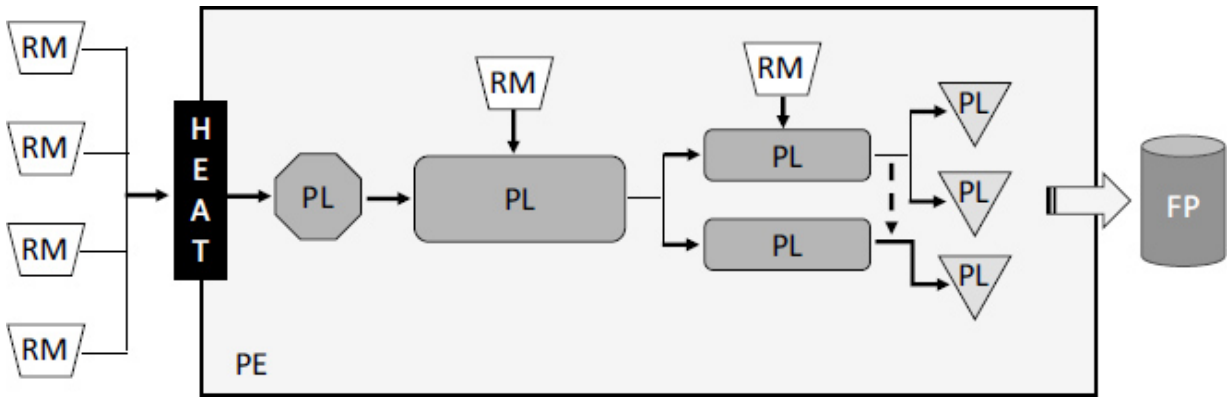

Figure 3.1 Schematic flow diagram of a food process, including raw materials (RM), a heat treatment, and food contact surfaces in the processing line (PL) as well as the processing environment located after the heat treatment (PE) up to the finished product (FP).

The consequences of such cross-contaminations will be the presence or an increased concentration of these microorganisms in intermediate and finished products. Microorganisms surviving a killing step or being introduced after this step may, given favorable intrinsic or extrinsic conditions, further increase due to growth at specific steps of the process, during distribution, or during preparation by the final consumer.

Although POs and FSOs are generally not intended to be verified by analytical means, POs may be suitable for such verification, and the use of MC for verification can be useful (13, 16). Verification that a PO is met on the basis of compliance with an MC may be very meaningful regarding due diligence documentation of ongoing safety and/or process control, trend analysis, and early warning for the need of corrective action. Compliance with the MC derived for a particular PO needs to be validated as part of the design of the overall food safety management system. The various measures implemented at the particular step, individually verified by other means, may include the following:

- establishment of a suitable MC for the end product, testing and statistical analysis

- verification (including monitoring and record keeping) of a pertinent and validated PC relating to the PO or of specific control measures underlying the PC and suitable for verification
- surveillance or screening programs on the prevalence of a microbial hazard in a food on the marketplace, which may be relevant mainly when a PO is established by a competent authority

In a concept paper by Zwietering et al. (16), three different cases of deriving an MC for a PO or FSO were developed, providing explicit and detailed guidance on various steps to be taken, the specific data needed, and assumptions and decisions to be made in the process.

PERFORMANCE OF CONTROL MEASURES

MCs have played and still play an important role in defining whether a food is acceptable and whether an individual lot complies with established limits. Sampling and testing are, however, rarely considered effective tools to control microbial hazards.

The safety of food products, and hence the protection of consumers, can be ensured only through the implementation of effective control measures. These control measures encompass actions and activities used to prevent, eliminate, or reduce food safety hazards to an acceptable level.

Control measures falling under GHPs applied by food manufacturers are usually generic and therefore applicable to the manufacture of different product categories. They are qualified as prerequisite programs (PRPs) and designed to minimize contamination from the processing line and the processing environment (Fig. 3.1). Examples of control measures that are typically considered GHP measures are given below:

- layoutof processing lines and zoning to control flows of air, pressure conditions within premises, movement of personnel, and mobile equipment as well as raw and packaging materials or intermediate products
- equipment design and installation for cleanability
- general cleaning and sanitization procedures
- preventive maintenance to minimize breakdowns and risks associated with unscheduled interventions
- appropriate waste management
- appropriate pest management
- training and behavior of personnel in PRPs, in particular, those related to microbiological considerations

The application of PRPs is valid as well for practices applied in different parts of the food chain such as good agricultural practices upstream and good distribution practices downstream. These programs represent a mandatory basis for the implementation of specific control measures as defined in hazard analysis and critical control point programs such as operational and critical control points. Specific control measures require a thorough validation in order to demonstrate their effectiveness in controlling relevant pathogens to the desired levels. Their performance during processing is determined through monitoring of relevant process parameters, such as temperature, time, flow rates, pressure, etc., against critical limits established during validation. In this context, testing of finished products against microbiological limits is normally performed during the validation procedure as well as during the ongoing verification of the overall performance of the food safety management system.

General control measures such as PRPs, as well as certain operational PRPs, such as specific cleaning and sanitization measures, can be verified through microbiological testing. Such measures are usually designed to prevent postprocess

contaminations occurring after specific control measures such as a heat treatment (critical control point). PRPs are combinations of measures aiming, in the first place, at preventing the ingress of pathogens into areas close to the processing line. In case ingress has occurred, the second line of defense is avoiding their establishment in processing areas, their subsequent multiplication, and finally their dissemination into different parts of the plant and the processing line, thus posing a direct threat to the finished product.

The establishment of testing plans for an appropriate verification of the effectiveness of control measures is more complex than the ones limited to finished products. Such plans need to take into consideration all elements contributing to the presence of microorganisms and, in particular, of pathogens in the finished products. They therefore have to include plans for sampling raw materials added after the control measure(s) and the processing environment and processing lines, i.e., product contact surfaces or intermediate product as appropriate.

ICMSF has published in detail on risk-based approaches to develop and apply environmental testing programs (14) and has provided case examples for a number of different food products (9, 10). Codex has elaborated the principles and guidelines for ready-to-eat food products and for powdered infant formula (6, 7)

The first step is usually to determine a baseline of the microbiota, focusing on the relevant pathogen(s) and hygiene indicator microorganism(s) present in the processing environment and processing lines, i.e., food contact surfaces and/or intermediate product. If no or only few historical data are available, it is important to collect this information through investigative sampling. Data for indicators can be obtained rapidly and at reduced costs and will provide sufficient initial information on the general hygiene status of the premises to allow development of a complementary sampling program for pathogens.

This baseline represents the situation and levels at which the plant and process are considered to be under control and at which the risk

of a product contamination is therefore minimal or negligible. This baseline is used as a benchmark to evaluate results and data generated through the sampling and testing activities defined in the sampling program against the established internal limits. This is done to verify and confirm that control is consistently maintained over time. If the findings demonstrate deviations, such as the presence of a pathogen in one or more sampling points in areas critical to the process and exposure to contamination or levels of the hygiene indicator exceeding internal limits, the actions need to be taken to restore control. Under such conditions, the testing frequency of the finished product is usually increased, and it becomes essential to perform a thorough investigative sampling to determine the source and origin of the contamination in order to take the appropriate measures.

INDEX AND INDICATOR MICROORGANISMS

Attempts to use certain microorganisms or groups of microorganisms requiring only simple, relatively rapid, and inexpensive methods to predict the presence of pathogens and to avoid expensive and lengthy testing have been made for more than 30 years. Initial work to define microorganisms able to “represent” pathogens was focused on water, and the concepts of model organisms or surrogate organisms (25) have been put forward by different authors, such as Havelaar and Pot-Hogeboom (26) and Payment and Franco (25). Over time, two different terms have been used to describe and define such microorganisms, namely, “index organisms” and “indicator organisms,” and they are well established today.

The distinction between index and indicator organisms was discussed initially by M. Ingram in 1977 (27, 28). Index microorganisms have been defined as microorganisms, groups of microorganisms, or microbial metabolites whose presence in numbers exceeding a specified limit indicates the possible presence of pathogens with similar behavior and ecology. Index organisms

are therefore to be used as direct predictors of the presence of specific pathogens. Such a prediction, however, is possible only if a statistically valid correlation between the organism used as index and the “associated” specific pathogen has been established. This correlation is, however, difficult to establish, in particular for pathogens that are found only sporadically and at low levels of index organisms.

Indicator microorganisms, on the other hand, have been defined as microorganisms, groups of microorganisms, or microbial metabolites whose presence in numbers exceeding specific limits indicates a failure in the adherence to GHPs. The intended role and purpose of indicator organisms are thus to serve as an indirect predictor of the presence of a pathogen. The presence of such organisms is therefore an indication of an increased risk related to a deviation from the implemented hygiene control measures. The direct testing for the specific pathogen cannot, however, be replaced by the testing for indicators, and combined programs including both of them are the rule.

It should be noted that several publications discuss, along with hygiene indicators, microorganisms, groups of microorganisms, or metabolites described as quality indicators. However, such quality indicators are usually related to physicochemical or organoleptic parameters and, hence, to quality attributes of a food product. While their presence and growth can be associated with defective control measures leading to spoilage of food products, they are, to our knowledge, not used to predict the presence of pathogens and hence are not within the scope of this chapter.

The use of indicators has been discussed by many authors, in particular in trying to define appropriate or ideal properties that allow them to fulfill their role in raw materials, the processing environment, and processing lines as well as in the end product. Several key properties are listed below (11), and these should be evaluated for any organism or metabolite being considered for use as an indicator:

- The history of the concomitant presence of the indicator(s) and the target pathogen or its toxin should be verified.
- The indicator(s) should usually be present at higher levels than the target pathogen.
- The presence of the indicator(s) should be indicative of an increased risk for faulty practices and/or faulty processes contributing to control of the target pathogen.
- The survival or stability of the indicator(s) should be similar to or greater than that of the target pathogen.
- The proliferation of the indicator(s) should be similar to or faster than that of the target pathogen.
- The indicator(s) should be easily detectable and/or quantifiable. • Identifiable characteristics of the indicator(s) need to be stable.
- Methods for indicator organisms need to fulfill the same requirements as the one for pathogens, i.e., they need to be reliable and validated; in addition, they should be more rapid and less expensive.
- Quantitative results on prevalence and/or concentration should show correlations between indicator and target pathogen.
- Results need to be applicable to process control or other control measures that indicate adequate control of the food safety system over the target pathogen or flag the need for corrective action.
- Analyst health should not be at risk and the analytical method should be suitable for in-plant use.

Because the behavior of a hygiene indicator should be similar to that of the associated pathogen, both will follow similar if not parallel patterns in the same processing facility. Although the outcome will be different, the conceptual formula of the ICMSF

illustrated in “Microbiological Profile of a Food Product” above can be used to describe their fate and provide useful information and insight on whether the targeted FSO and PO are likely to be achieved.

Numerous publications have been devoted to trying to determine the most appropriate hygiene indicator(s) for relevant pathogens, and it is not the purpose of this chapter to provide an exhaustive list of “ready-to-use” indicators. *Enterobacteriaceae* and *Listeria* spp. are certainly the most frequently used hygiene indicators in food processing and are associated with *Salmonella* and *L. monocytogenes*, respectively. This is also reflected in their inclusion in numerous MC. They are, however, not the only ones, and others, such as coliforms, fecal coliforms or *Escherichia coli*, fecal enterococci, sulfite-reducing clostridia (e.g., *Clostridium perfringens*), aerobic mesophilic counts, and certain metabolites, such as ATP, thermonuclease, and alkaline phosphatases, have been described as being suitable under certain circumstances.

However, even when there is knowledge that there is no consistent, systematic relationship between a target pathogen and an index or indicator organism, it may still be the best available option to use routine monitoring of the latter. As one example, the ICMSF has issued an opinion paper (29) on the use of sulfite-reducing clostridia (SRC) in powdered infant formula or associated ingredients in response to inquiries from industry and regulatory authorities to the ICMSF to provide advice on the appropriateness of testing for *Clostridium botulinum* in these products. Given that *C. botulinum* is not considered a hazard in powdered infant formula (7) and that the analysis of the pathogen is much constrained by its probably being heterogeneously distributed and occurring only at very low levels in powdered dairy products, the ICMSF did not recommend routine testing for this pathogen. Despite the fact that there is no direct mathematical correlation between levels of spores of SRC and those of *C. botulinum*, the ICMSF concluded that testing for SRC would be appropriate as an indicator of process hygiene with respect to the control of anaerobic sporeformers. ICMSF

considered that SRC levels exceeding a limit for *m* of 100 CFU/g, for example, would point to conditions potentially conducive to the multiplication of anaerobic clostridia in processing lines, or some source of external contamination (29). Considering the characteristics and behavior of various types of clostridia, such levels would then also point to conditions possibly supporting multiplication of *C. botulinum*, when present, beyond normal low levels. In contrast, SRC levels below this limit would confirm the effectiveness of the established hygiene control measures, such as adherence to GHPs and good manufacturing practices, and hence a negligible risk for *C. botulinum*.

The choice of an appropriate hygiene indicator depends on the knowledge of a number of factors related to the products manufactured and, in particular, its microbiota, the microbiota of the raw materials, the processing conditions applied, and their effect on the microbiota, the food's composition and characteristics and their effect on the behavior of microorganisms, the microbial ecology of the processing environment and lines, the aim of implemented control measures (such as PRPs), and the effects of different types of cleaning and sanitization procedures, among others.

An important but frequently underestimated or poorly managed aspect of environmental verification programs is the use and interpretation of generated data. Since hygiene indicators are associated with specific pathogens, their use is also associated with "predicting" and "anticipating" deviations and defects. It is therefore of utmost importance that the data generated, often at a higher frequency and in higher numbers than the ones for pathogens, be used in the most appropriate and beneficial way to fulfill their task. Failures in the interpretation and management of these data will jeopardize the usefulness of verification testing and, in particular, the ability to correct deviations identified at an early stage.

In any event, MCs for nonpathogens such as indicator organisms or even utility organisms do play an important role in their own right

in hygiene/process control, including environmental monitoring. In addition, the Codex Alimentarius Commission, for instance, has adopted the practice of recommending criteria for process hygiene where the safe production of particular products is dependent on maintaining a high level of hygienic control (7), specifically stating that these are not intended to be used by competent authorities but by manufacturers as a means of verification of their hygiene programs.

Responses in Foodborne Bacteria

Bacteria are the most abundant living forms on our planet and are capable of inhabiting all types of environments in nature, even those that would be considered inhospitable for all other living organisms. As a result of millions of years of evolution, bacteria have developed diverse catabolic and anabolic capabilities (1). Among the different bacterial taxa, heterotrophic bacteria often occupy niches associated with eukaryotic organisms, such as plants and animals. These heterotrophic bacteria have developed very close relations through commensal, mutual, symbiotic, or parasitic associations (2). Since most human foods are derived from plants and animals, large numbers and diverse taxa of heterotrophic microorganisms are naturally present in raw and fresh foodstuffs.

The microbiome associated with fresh and raw foods includes not only bacterial groups that are natural inhabitants of plants and animals but also those which can result from the attachment and colonization of other microorganisms to food matrices at different stages after harvesting or slaughtering (3). Very few foods are completely devoid of any bacterial population, and the transient or established presence of microorganisms is considered normal and frequently unavoidable. The association of microorganisms with foods often leads to spoilage and undesirable changes in products with intrinsic characteristics that permit bacterial growth. A more serious concern is contamination with organisms that may cause illnesses.

One of the major challenges that humans have faced since ancient times is the preservation of food materials in order to nourish large populations and to avoid ingesting pathogenic bacteria. The development of beneficial food processing was critical in history for

civilizations that were capable of sustaining large numbers of people with a supply of abundant and safe foods. As a result, a variety of technologies have been developed to modify or treat foods for the control of microorganisms (4). Early technologies such as fermentation with innocuous bacteria, cooking, drying, and salting allowed the preservation of foods for long periods after harvest. Over the last century, multiple effective preservation techniques have been developed in addition to those traditional methods.

The technologies of food preservation use different forms of energy to change the characteristics of the raw materials, to kill microorganisms, and/or to delay their growth. The food technologies developed over many centuries change the intrinsic properties of foods, affecting acidity, redox potential, water content, solute concentration, and presence of antimicrobial substances (5). Preservation technologies subject bacterial cells to different levels of stress, which in the most effective cases lead to their inactivation and death (3). For the purpose of this chapter, the term “stress” refers to any extracellular influence that threatens the ability of microorganisms to perform optimally.

Food preservation technologies aimed at rapidly inactivating microbial cells include thermal processes, irradiation, high-pressure processing, and the use of strong oxidant compounds. Other technologies accomplish the preservation of foods by inhibiting growth, and the most extensively used methods involve low-temperature storage (refrigeration and freezing), reduction of moisture content (concentration and drying), control of ox-redox potential (use of controlled atmospheres and vacuum packaging), and acidification (fermentation and addition of organic acids) (6).

The ability of heterotrophic microorganisms to survive multiple stressful conditions evolved over millions of years of natural selection. The stress responses that developed throughout evolution can be effective in overcoming different food preservation technologies (7). In nature, microorganisms are constantly exposed to changes in temperature, oxygen, moisture, light, pH, and

chemical composition, caused by abiotic and biotic factors threatening their viability. Unicellular microorganisms, especially bacteria, are able to survive those natural challenges as a result of their ability to adapt and/or acquire genes from other microorganisms that allow them to counteract those natural assaults (2, 8). The acquisition of stress response genetic mechanisms has proven quite useful in assisting heterotrophic microorganisms to attach to and colonize plants and animals in order to withstand physical and chemical insults advanced by food processing technologies. The process of developing stress responses is very sophisticated, and microbes employ complex networks of genetic responses to combat stress, with different levels of regulation (9).

These multifactorial networks of stress responses are often capable of protecting the cells, or in allowing their recovery, if the magnitude and type of stress are not lethal (9). Stress mechanism responses frequently lead to tolerance to increased stress after an initial exposure to lower stresses that were not severe enough to kill cells (stress adaptation). For example, the key mechanisms that allow *Escherichia coli* O157:H7 to survive extreme acid exposure are typically induced by previous growth at a mildly acidic pH (10). In addition, the presence of globally regulated stress tolerance systems often leads to increased resistance to more than one type of stress, referred to as cross-resistance or cross-protection. For example, the acid resistance of *E. coli* O157:H7 has been reported to be augmented following pretreatment at high temperatures (11).

Throughout millions of years of adaptation and gene uptake, bacteria have developed complex genetic regulatory systems that involve key components capable of controlling the expression of multiple operons. These key genes encode proteins referred to as global regulators (12). Almost every bacterial species has a globally regulated stress response system, and some of the key components are very well conserved throughout different phyla. In addition to these common global regulators, a number of bacterial species possess unique specific stress response genes. The objective of this

chapter is to provide a general overview at the molecular level of the different stress response mechanisms that have been characterized in foodborne pathogenic bacteria. In particular, responses to exposure to acid, osmotic, oxidative, pressure, light, and temperature stresses are covered. The focus is on Grampositive (*Listeria monocytogenes* and *Staphylococcus aureus*) and Gram-negative (*E. coli*, *Salmonella*, and *Campylobacter*) bacteria that have been thoroughly studied. The chapter first describes global regulator systems and then reviews the molecular mechanisms of tolerance to specific environmental stresses.

GLOBAL STRESS RESPONSES

Technologies intended to control microorganisms in food are effective because they are capable of causing serious damage to bacterial cells. High-temperature processes such as cooking and pasteurization inflict irreversible functional and structural destruction of multiple cell components (13). Heating of foods causes extensive bacterial death because of the denaturation of proteins, inactivation of ribosomes, and disruption of membrane integrity, as well as damage to DNA. Irradiation of foods is also an effective technology intended to cause widespread bacterial death. Bacterial inactivation caused by ionizing irradiation is largely due to DNA damage resulting from the generation of reactive oxygen species (ROS) from water (14). Most bacterial cells have DNA repair mechanisms, but if the DNA damage is very extensive, bacterial cells may be irreversibly inactivated and killed.

Because of its serious impact on viability, significant damage to the molecular structure of DNA triggers a series of extensive molecular responses in bacterial cells (15). Bacterial species have developed several global stress responses systems, and at least three such systems have been extensively characterized. The SOS stress response system is a universal cellular protection network induced by the presence of single-stranded DNA (ssDNA) that has been studied comprehensively in *Enterobacteriaceae* (16). The SOS

system evolved to counteract the generation of mutations caused by DNA disruption (16, 17). Under low-DNA-damage conditions, the SOS regulon is normally repressed, but large accumulations of ssDNA trigger the induction of more than 30 genes that make up this complex response (16, 18).

LexA is the natural repressor of SOS when the concentration of ssDNA is low. In the presence of large amounts of ssDNA, a bacterial recombinase protein, RecA, binds to the DNA strands and the self-proteolysis of LexA occurs (18). The degradation of LexA triggers the expression of multiple genes that encode enzymes that restore DNA structure and function via repair, recombination, and replication (15). Two examples of enzymes involved in DNA replication after LexA inactivation in *E. coli* are the DNA polymerases Pol IV and Pol V, encoded by *dinB* and *umuDC*. These polymerases have a high rate of synthesis, which can lead to high error rates and increased mutation frequency (19). The SOSregulated genes involved in DNA repair can be classified based on three DNA pathways in several enterobacteria: homologous recombination, nucleotide excision repair, and translesion synthesis (16). Other SOS-dependent genes are *sulA*, which encodes a protein involved in the inhibition of cell division, and *recN-ruvAB*, which encode enzymes that restore breaks in double-stranded DNA (19).

Despite advances in rapid genomic and proteomic analysis, most of our understanding of bacterial stress mechanisms to date originates from extensive studies with *E. coli* and *Salmonella* as model organisms. In those bacteria, additional global stress response systems have been identified and characterized: the general stress response, the stringent response, the heat shock response, and the polyphosphate-mediated nutrient limitation response (16–18). Other global stress responses reported in *Salmonella* include PhoPQ, Fur, and OmpR-EnvZ (20). Since the early 2000s, the important role of small RNA molecules as part of the complex network of bacterial stress responses has been increasingly recognized, and recent evidence indicates their importance for cell survival (21, 22).

General Stress Regulator

One of the main biological challenges for bacterial cells occurs during logarithmic growth, when a complex and rapid activation of genes and protein synthesis occurs (19).

During exponential growth, DNA polymerase III catalyzes DNA replication and RNA polymerase is responsible for transcription. The RNA polymerase in *E. coli* is a very large holoenzyme composed of five protein subunits: two α subunits, one β subunit, one β´ subunit, and a σ chain (1). The RNA polymerase catalytic core is maintained under most conditions and consists of a tightly bound $\alpha_2\beta\beta'$ complex. The σ factor is the subunit that varies depending on the cell cycle, and its binding to the rest of the holoenzyme is relatively weak. The σ factor plays a central role in targeted transcription of genes and is responsible for recognizing promoter sequences to initiate the transcription of targeted genes (23). Bacteria have multiple σ factors that are activated under different conditions. As many as seven σ factors have been reported in *E. coli*, and recent genomic analyses of almost 1,000 genomes have confirmed the conservation of at least six of them (23, 24). In Gram-positive organisms such as *Bacillus subtilis*, more than 15 sigma factors have been identified (24).

$\sigma^{70}$is the main σ factor in *E. coli* directing the transcription of housekeeping genes under most conditions. σ^{70} is encoded by *rpoD*, and it is responsible for coordinating protein synthesis during the exponential growth phase (25). Rapidly growing *E. coli* cells expressing σ^{70} initiate the activation of an alternate sigma factor, σ^{S} the most important regulator of the general stress response when the cells are approaching stationary phase (26). σ^{S} coordinates cell survival under stressful conditions and regulates protein synthesis during subsequent growth (27). In some of the first reports, the *rpoS* gene was referred to as *katF* because its induction was linked to the production of a catalase (18). The full transcription of *rpoS* takes place only once the cells have reached stationary phase, and

the binding of σ^S to the RNA polymerase holoenzyme directs the transcription of multiple genes involved in metabolism and regulation (26, 28).

The extent of the influence of RpoS on *E. coli* metabolism is reflected in the fact that it regulates at least 10% of the genome, including over 85 genes or regulons with multiple metabolic or regulatory functions (29). Multiple loci encoding systems involved in stress responses, stationary-phase metabolism, and according to recent evidence even virulence factors are controlled by σ^S (24, 30). The genes controlled by σ^S are distributed across the entire *E. coli* genome, but there are some regions of higher concentration of RpoS-regulated operons. Weber et al. have classified all the RpoS-regulated genes into six major categories based on their functions: metabolism, regulation, transport and membrane function, adaptation to stress, protein processing, and unknown function (29). Despite the recent advances in genomic analysis, a relatively large proportion of all the functions of genes regulated by RpoS have yet to be characterized (29).

Multiple σ^S-regulated genes are part of the SOS global stress response system, and a network of specific stress response genes are involved in protecting the cells against osmotic, acid, and oxidative effects (31). An example of the interconnection between SOS and σ^S-dependent stress responses is the observation that an *rpoS* mutation caused a marked reduction in the concentration of the DNA polymerase Pol IV (32). This reduction in Pol IV levels is due to the reduction in σ^S-regulated transcription of *dinB*, which is required for *de novo* synthesis of Pol IV (18). RpoS is also involved in the oxidative stress response, as it regulates the expression of HPI and HPII, two catalases encoded by *katG* and *katE* (33). RpoS is also involved in osmoprotection via the regulation of the expression of *otsA* and *otsB*, whose products catalyze the synthesis of trehalose (34). In addition, the glutamate decarboxylase operon (*gadABC*, which protects *E. coli* and other bacteria from extreme acid conditions) is indirectly regulated by σ^S by means of *gadX* and

gadW (10, 29). These specific stress response systems are described in more detail below.

Because σ^S is crucial for cellular functions, its concentration is tightly regulated by a series of mechanisms involving both synthesis and degradation (Fig. 4.1) (26). The key signal that initiates *rpoS* transcription is a reduction in growth rate; however, a steady decline in growth is necessary to activate rapid transcription (26, 31). The regulation of *rpoS* transcription is dependent on several promoters and small molecules. The promoters *nldD*p1, *nlpD*p2, and *rpoS*p are located upstream of the *rpoS* coding region (28). When cells are replicating rapidly, the transcription of *rpoS* is largely repressed by a complex formed by the catabolite repression protein and cyclic AMP (29, 35). In contrast, one of the small molecules involved in activating *rpoS* mRNA synthesis is guanosine tetraphosphate (ppGpp) (26).

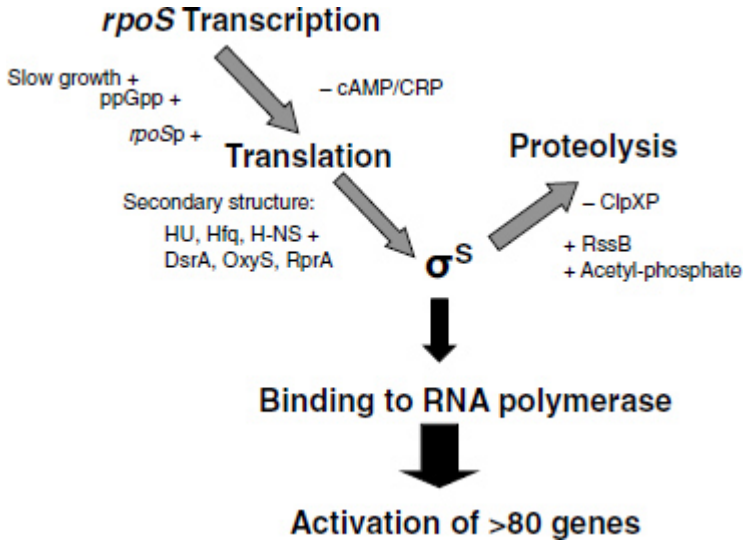

Figure 4.1 Diagram of σ^S regulation and some of the main factors involved in its activation (+) or inhibition (–). cAMP, cyclic AMP; CRP, cyclic AMP receptor protein.

The translation of *rpoS* mRNA is influenced by multiple external stimuli. Changes in aspects of the environment such as pH, osmolarity, temperature, and cell concentration enhance the rate of translation. However, a reduction of carbon source availability

during stationary phase strongly inhibits increases in σ^S concentration (26, 31). The development of secondary structures of *rpoS* mRNA that inhibit ribosome binding is another negative regulatory mechanism. External stress conditions cause the loss of those mRNA structures and then allow transcription. Additional *rpoS* mRNA regulators include a nucleoid protein (HU), the histone-like protein (HN-S), and the small regulatory RNAs DsrA, OxyS, and RprA (21, 22, 26). The σ^S concentration is also dependent on protein degradation pathways. The growth stage of bacterial cells influences the rate of σ^S protein hydrolysis, which has a half-life between 1 and 20 min (36). ClpXP is an ATP-dependent protease that is involved in σ^S proteolysis, but it needs a phosphorylated recognition factor, RssB, to be able to bind RpoS (26). Acetylphosphate is an indirect regulator of σ^S proteolysis because it is the preferred substrate for RssB phosphorylation (37).

The σ^S equivalent general stress regulator in Grampositive bacteria is known as σ^B (or SigB), and it has been reported in *Listeria*, *Bacillus*, and *Staphylococcus* (38, 39). More than 150 genes are regulated by σ^B. Multiple extrinsic and environmental conditions trigger the activation of σ^B, such as lack of carbon source, phosphate, and oxygen. Environmental stresses, including acidity, alkalinity, high solute concentrations, ethanol, and nitric oxide, also elicit enhanced synthesis of σ^B (38). All of the conditions that lead to σ^B induction can be classified into two types: energy limitations and environmental stresses (6). The SigB-dependent stress response regulation is not present in every Gram-positive bacterium. SigB stress responses have been observed in *Bacillus*, *Mycobacterium*, *Listeria*, *Streptomyces*, *Staphylococcus*, and *Ralstonia*, but other strictly anaerobic and facultative anaerobic Gram-positive bacteria, such as *Clostridium*, *Lactococcus*, and *Streptococcus*, entirely lack this critical general stress response (38). Because of the lack of SigB in anaerobic genera, it has been hypothesized that protection from oxidative stress could be the principal role for this sigma factor.

The relevance of sigma factors for the ability of foodborne pathogens to survive adverse conditions has been studied extensively, and one of the most important approaches to demonstrate their role has been through the use of mutant strains. In particular, the role of σ^S has been comprehensively investigated in *E. coli* O157:H7 and *Salmonella* (40, 41). Cheville et al. reported one of the first observations in which specific mutants were more sensitive to heat, salt, and acid than the wild-type strain (42). An *E. coli* O157:H7 *rpoS* mutant also had a diminished ability to colonize the gastrointestinal tract of cattle (43). Sigma factors may also be involved in virulence factor activation. In *L. monocytogenes*, σ^B regulates acid resistance proteins, but it is not involved in pathogenicity. In contrast, σ^S has an important role in regulating some virulence factors in *Salmonella enterica* serovar Typhimurium (7). In *Vibrio vulnificus*, σ^S was required for inducing an oxidative response, but heat tolerance was not influenced by *rpoS* (44). With the advent of genomic techniques, there is the opportunity to reevaluate the role of *rpoS* in survival of foodborne pathogens.

Other Global Stress Responses

Bacteria have multiple metabolic systems that sense their environment to enable them to respond to adverse conditions, and they use an array of sensory systems to monitor their environment in order to adapt to stressful conditions. Guanosine tetraphosphate and guanosine pentaphosphate (ppGpp and pppGpp) are nucleotidebased secondary messengers referred as alarmones (45, 46). Under adverse conditions, such as lack of amino acids and high temperature, the (p)ppGpp concentration increases, which causes an overall inhibition of all transcription and RNA synthesis. This general response is referred as the stringent response (18, 45). The stringent response has been extensively characterized since it was initially observed when bacterial cultures were transferred from rich to minimal media. The stringent response is critical for survival when nutrients are lacking and under stressful conditions, and its activation frequently occurs simultaneously with that of RpoS

during stationary-phase starvation (45). The stringent response is widely distributed among most bacterial phyla, as the enzymes responsible for (p)ppGpp synthesis are highly conserved in nature (47).

The stringent response is triggered by the lack of amino acids that leads to a buildup of "uncharged" tRNA. The (p)ppGpp-synthesizing enzyme, RelA, is then activated after binding to ribosomes containing these uncharged tRNAs (45). By binding to the RNA polymerase, (p)ppGpp then regulates transcription by directing the enzyme to different promoter regions. Despite the fact that the stringent response inhibits RNA synthesis, the absence of specific amino acids causes a selective activation of biosynthetic genes (18). As a global stress response, the stringent response regulates multiple cellular processes in addition to RNA synthesis, inhibiting translation and promoting proteolysis. While starvation is the main condition that activates the stringent response, different kinds of stress and conditions that inhibit growth can also enhance the response.

Many years ago, microbiologists observed that polyphosphate (polyP) accumulated in bacterial cells as "volutin granules," but its function was not clear (48). Nobel Prize winner Arthur Kornberg spent the last years of his career investigating the role of polyP, as he hypothesized that this family of compounds had a vital function in cells. His belief in the importance of polyP was partially based on the fact that over 100 bacterial species have two homologous enzymes, PPK-I and PPK-2, that are involved in polyP synthesis. The role of polyP in stress responses was discovered when *ppk1* mutants of a variety of Gram-positive and -negative bacteria were found to be more sensitive to stress factors than their wild-type counterparts (49, 50). The phosphokinases may also be involved in virulence regulation in addition to stress response, since *ppk1* mutants of *Salmonella*, *Shigella*, and *Vibrio cholerae* have diminished pathogenicity (48, 49)

Several studies have shown that polyP mutants display reduced tolerance to acids, oxidation, heat, and osmotic stresses (50, 51). In *Salmonella* cultures, the presence of a PPK-1 enzyme was critical for growth in the presence of organic acids and the ability to withstand heat in a mutant strain, in contrast to the wild type (51). PPK-1-deficient strains of *Shigella flexneri* and two *Salmonella* serovars were inactivated more rapidly at 55°C (52). In *V. cholerae*, deficiencies in PPK-1 synthesis resulted in acid-and oxidation-sensitive mutants, but toxin production, motility, and the ability to colonize the gastrointestinal tract were not affected (53).

As our understanding of stress response mechanisms has advanced, we have discovered that the individual global regulatory systems are tightly interconnected and interdependent. This regulatory stress response network spans many components of metabolism, including DNA replication, RNA transcription, protein translation, proteolysis, and small-molecule turnover. The interconnection of global, general, and specific stress responses allows bacteria to adapt and survive adverse conditions. In recent years, it has been recognized that not only do the regulatory mechanisms involve DNA-protein and protein-protein interactions, but also, transcription control is exerted by small RNA molecules (22). The rest of this chapter covers specific stress responses of relevant food bacteria (Fig. 4.2). However, it should be noted that apparently independent specific stress response mechanisms may in fact be subject to control by other interconnected regulators.

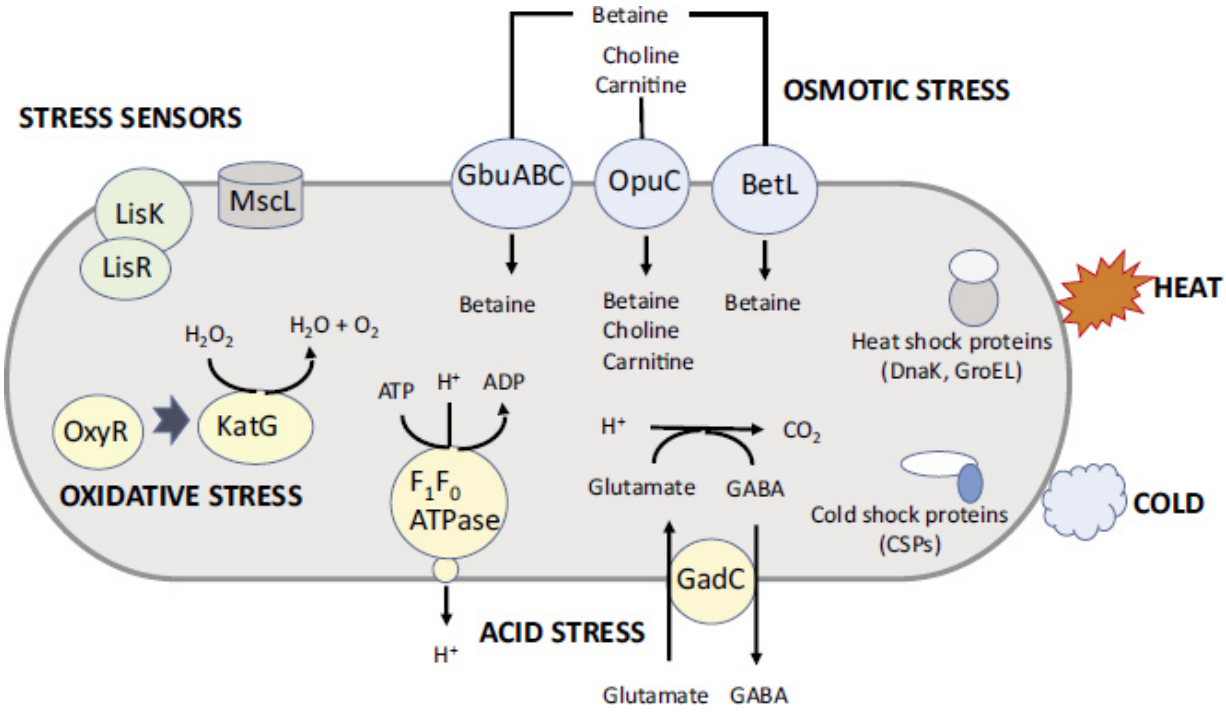

Figure 4.2 Hypothetical depiction of a bacterial cell with some of the most important specific stress response mechanisms reported in foodborne pathogenic bacteria. Illustration ideas were taken partially from reference 12.

ACID STRESS

The intracellular pH of most bacterial cells is tightly controlled within a relatively narrow range close to neutrality. Any changes in the cytoplasmic pH can affect multiple metabolic processes and can potentially cause serious damage to bacterial viability (54). Because an acid threat is a drastic attack, bacteria have evolved a complex and exquisite protective system of genetic and metabolic responses. The extent of success against an acid shock can be influenced by the bacterial species, individual strain differences, type of acid stress, growth phase, and the presence of external small molecules in the environment. The two acid stress response systems most thoroughly characterized among foodborne microorganisms are the acid tolerance responses (ATR) and acid resistance (AR).

Foster studied the ability of *Salmonella* to survive normally lethal acidic conditions when cells are pre-exposed to a mild pH condition and defined this response as the ATR (55). Cells can be adapted to acid when they are grown to stationary phase under mildly acidic conditions, similar to the acidity caused by acid production through fermentative pathways (56). This unique acid stress protection mechanism has been reported to enhance the survival of bacterial cells by a factor of more than 1,000 in comparison with noninduced cultures (10, 57). In addition to increased acid tolerance, cells previously adapted to mild acid have enhanced resistance to other external factors (osmotic, thermal, oxidative, and ethanol) (58). In several organisms, the ATR plays an important role in pathogenicity as a signal to induce virulence factors (56, 59).

While ATR can protect cells at mildly acidic pH values (3.5 to 4.5), this system is not sufficient to promote survival at lower pH levels. The stress response mechanisms that protect cells at extremely low pH values (less than 2.5) are referred to as acid resistance (AR) (10, 60, 61). Most of the AR response systems require the presence of an extracellular substrate, frequently an amino acid, in order to be metabolically active (60). The AR responses are remarkably stable once they have been induced and activated, since it has been reported that AR cells remain resistant during storage for long periods of time and at low temperatures (4°C) (60, 62).

The ability of pathogenic bacteria to cause disease is heavily dependent on survival under acidic conditions. First, foodborne pathogens may survive acidic and fermented foods for long periods thanks to their ATR and AR systems (63). Their ability to survive acidic conditions becomes even more critical when bacteria are ingested with the contaminated food. The pH of the gastric stomach can be less than 2.5, and this is often the first barrier that protects the human host. Bacterial pathogens with some of the smallest infectious doses have the most effective acid stress responses (60). In contrast, acid-sensitive bacteria often require larger numbers to overcome the loss of viability in order to cause disease. AR systems

allow a pathogen to survive the gastrointestinal tract, eventually colonize the intestine, and develop disease (58, 63).

In the remainder of this section, the acid stress responses of *E. coli*, *L. monocytogenes*, and *Salmonella* spp. are discussed as model systems. Note that, despite the detailed characterization of these systems, it is likely that they are more complicated than our current understanding reveals. In addition, published observations are based on a few strains, whereas a number of publications have suggested that there are variations depending on individual strains and experimental conditions (56).

E. coli

The optimal growth of *E. coli* occurs at near neutral pH, but it has been reported to be capable of growth at pH 4.4. Growth at a pH between 4.5 and 5.5 is a requirement to induce its acid resistance (60, 61). At pH values below 5.5, a complex collection of proteins involved in AR are synthesized (57). The AR stress response that protects *E. coli* has been extensively described. The specific stress responses that protect *E. coli* against acid exposure consist of four separate mechanisms. Three of those systems employ enzymes that decarboxylate specific amino acids: arginine, glutamate, and lysine (10). The fourth system is an oxidative response that does not require the presence of substrates and is repressed by glucose (57, 60). The induction of all four systems requires the onset of stationary phase during pre-exposure to mild acid (10, 64).

The σ^S protein is required to induce the glucoserepressed oxidative system, but it has a limited role in activating the arginine-and lysine-dependent decarboxylase responses (60, 65). The amino acid decarboxylase systems can be effective in maintaining cell viability only if the corresponding amino acid is present in the surrounding medium (54). The core components of the amino acid decarboxylase system are the enzyme catalyzing the decarboxylation and the antiporters that translocate both substrate and product simultaneously (Fig. 4.1). From glutamate, lysine, or arginine, the

decarboxylation reaction consumes a proton by producing CO_2 and gamma-aminobutyric acid, cadaverine, or agmatine, respectively, which are transported out of the cell in exchange for their substrate amino acid (65–67). This cytoplasmic neutralization process is maintained as long as there is a supply of substrate or the intracellular pH is stabilized near neutral (68, 69).

The AR system that protects *E. coli* by arginine decarboxylation involves an arginine decarboxylase and the arginine/agmatine antiporter. The operon that encodes the enzyme and transporter includes *adiA* and *adiC*, respectively (70). In addition, the arginine-dependent system involves *cysB* and *adiY*, regulatory genes that promote their expression (71). The activation mediated by AdiY requires its own overexpression. On the other hand, the activation of *adiAC* has a strict requirement of growth under anaerobic and acidic conditions in complex media (72). When the arginine-dependent acid response was studied in *E. coli* O157:H7, the conditions that elicited the greatest protection were growth of cells in rich medium under anaerobic conditions and a pH of less than 5.0 (10).

The second amino acid-dependent AR system is based on the ability of cells to transform lysine and produce cadaverine via decarboxylation. Similar to arginine, the two-component metabolic system involves lysine decarboxylase (*cadA*) and the lysine-cadaverine antiporter (*cadB*) (73). The full expression of the CadBA operon requires a low extracellular pH and high concentrations of lysine and involves two regulatory genes, *cadC* and *lysP* (73). *cadC* is located upstream of *cadBA*, and its expression is required for activation of *cadBA*. The periplasmic domain of CadC and the permease LysP are responsible for detecting extracellular conditions to induce the operon (74). The synthesis of CadA and CadB can also be repressed by intracellular accumulation of cadaverine, the product of lysine decarboxylation (69).

The third AR system that involves amino acid decarboxylation is the glutamate-dependent (GAD) system. The GAD system has been

extensively characterized and is not dependent on σ^S (10, 67). Similar to the other two decarboxylase AR systems, the GAD system has a transporter, the gamma-amino butyric acid antiporter (GadC), but in this case, two distinct glutamate decarboxylases, GadA and GadB, catalyze glutamate decarboxylation (60, 75). Both GadA and GadB are typically expressed during acid shock, but either one is sufficient to protect the cells at a pH above 2.5. However, when the extracellular pH is less than 2.5, the presence of both enzymes is required for survival (75, 76).

The GAD operon includes genes for three key regulator proteins capable of binding DNA: GadW, GadX, and GadY (77). While GadX is an activator for the entire operon, overexpression of the small RNA GadY causes high concentrations of the GadX transcriptional activator, which lead to induction of the glutamate decarboxylases GadA and GadB (77, 78). The interconnection of the specific GAD response system and the global regulators is illustrated by reports that despite the fact that the AR of *E. coli* is largely independent of σ^S, *gadX* is downregulated if σ^S becomes repressed (77). The GAD system appears to be widespread in multiple Gram-negative and Gram-positive organisms. Similar glutamate decarboxylase enzymes and antiporters have been identified in *L. monocytogenes*, *Bacteroides fragilis*, *Lactococcus* spp., *Lactobacillus lactis*, *Providencia alcalifaciens*, *Brucella abortus*, and *Enterococcus avium*, among others (79).

L. monocytogenes

In contrast to *E. coli*, *L. monocytogenes* is more sensitive to extreme acid exposure (less than 3.5) (56, 80). However, this bacterium has a number of mechanisms that allow it to survive the acid challenges that it encounters in nature, such as in the phagosome and the gastrointestinal tract (81). Among Gram-positive bacteria, *L. monocytogenes* has been reported to have an ATR system for protection against low pH (81). Pre-exposure to pH values of 5.0 to 5.5 has been consistently reported to enhance the survival rate more

than 100-fold and to induce its ATR (82). σ^B has an important role in regulating several of the ATR components, but *L. monocytogenes* also has several independent mechanisms (58).

As many as seven different metabolic components have been associated with the *L. monocytogenes* ATR (80). This complex network of protective mechanisms involves a σ^B-dependent general stress response, the two component system LisRK, a GAD component, the SOS response, changes in membrane fluidity, the FoF1 ATPase proton pump, and an arginine deiminase. The first σ^B dependent system is induced by acidic pH, is initially activated in rapidly growing cells, and is enhanced once they reach stationary phase (58). The two-component system LisRK was identified when it was observed that stationary-phase cultures of Δ*lisK* mutants were more acid resistant than those of wild-type cells (83). *lisRK* encodes a membrane-associated histidine kinase (K) and a cytoplasmic response regulator (R) that affects other genes (80). The role of the global regulator SOS has been evidenced with observations that Δ*recA* mutants were more sensitive to low pH (84). The critical role of the FoF1 ATPase proton pump in the ATR was reported by Cotter et al. (85), who observed that cells treated with the ATPase inhibitor *N,N′*-dicyclohexylcarbodiimide had a markedly reduced ability to survive pH 3.5. New ATR components have recently been identified using proteomic and transcriptomic approaches, but they are beyond the scope of this chapter (80).

The glutamate decarboxylase-based ATR is probably the best-characterized mechanism and the specific system that offers the greatest protection against an acid shock (80, 81). The GAD-based ATR system comprises three glutamate decarboxylase genes, i.e., *gadD1*, *gadD2*, and *gadD3*, and two genes for antiporters, i.e., *gadT1* and *gadT2* (86). In contrast to the *E. coli* genome structure, the *L. monocytogenes* GAD genes are distributed in three distinct operons: *gadD1T1*, *gadD2T2*, and g*adD3* (87). The GAD system appears to be the only ATR system that protects the cells at pHs below 3.5, and because of the common presence of glutamate in foods, it has been

suggested to be particularly essential for its survival in acidic foods (79, 88). *L. monocytogenes* possesses another amino acid-degrading pathway that is involved in acid resistance, the arginine deiminase (ADI) system, which catabolizes arginine to ornithine and consumes protons by ammonia production (89). The ADI metabolic components are arginine deiminase (ArcA), catabolic ornithine carbamoyltransferase (ArcB), carbamate kinase (ArcC), and membrane-bound arginine–ornithine antiporter (ArcD), which are regulated by ArgR, a transcriptional activator. The ADI is maximally expressed at low pH (5.0), in a lack of oxygen, and in the presence of arginine in the medium (80). The ADI system and other ATR mechanisms have also been reported to have a role in virulence factor regulation.

S. enterica serovar Typhimurium

Similar to other members of the family *Enterobacteriaceae*, *Salmonella* is capable of rapidly growing over a pH range of 5 to 9, but there have been reports that it can still grow at a pH of 4 (60, 90). The ATR of *S.* Typhimurium is typically activated at pH values between 4 and 5 (62). Exposure of *Salmonella* cells to a pH of 4.5 triggers the production of as many as 52 proteins (91). The protection of *Salmonella* cells against acid stress is conferred by at least three ATR systems, with different regulatory mechanisms (60, 92). The first ATR system comprises the general σ^S-dependent stress response and two pH-induced growth phase-dependent mechanisms (60). The pH-induced stationary-phase ATR and the pH-induced log-phase ATR are completely independent, and they have no common regulators (93). The logphase-dependent ATR is activated in exponentially growing cells when they are subjected to a low-pH environment, protecting them from a rapid change in pH. As many as 50 distinct proteins have been reported to be induced related to the log-phase mechanism (90). The two key regulatory components for the log-phase mechanism are encoded by *rpoS* and *fur* (90). The involvement of Fur in regulating ATR is independent of its role in the iron regulation network. A decrease in external pH

leads to increased Fur expression, which in turn activates the synthesis of unique acid shock proteins that do not require RpoS (90, 94).

A major difference between the stationary-phasedependent ATR and the log-phase-dependent ATR is that the former requires a longer exposure to low pH to be fully expressed (60, 93, 95). The stationary-phasedependent ATR is the predominant protection system under extremely acidic conditions (95). The stationaryphase ATR involves only 15 proteins, and it provides protection at pH 4 or less (55, 95). The stationary-phase ATR is not influenced by σ^S and Fur but is regulated by Omp. In response to an acidic environment, the regulator OmpR is synthesized, triggering the activation of genes that encode part of the OmpR-EnvZ regulatory system (94). OmpR is also involved in pathogenicity by upregulating *ssrAB*, encoding a virulence factor stimulated by acidic conditions. The general stress response and the stationary-phase ATR are largely responsible for protecting stationary-phase cells (90).

In addition to the general stress response and the growth-phase-specific systems, *S. enterica* serovars also have amino acid decarboxylase ATR systems that contribute to its survival at acidic pH (96). Similar to *E. coli*, *Salmonella* has arginine and lysine decarboxylase AR systems that protect cells from acid shock at about pH of 2.5 as long as there is a supply of the corresponding amino acid in the medium (97, 98). Unlike *E. coli*, *Salmonella* has no GAD system, but it has an ornithine decarboxylase ATR system (98). The inducible arginine, lysine, and ornithine decarboxylases are encoded by *adiA*, *cadA*, and *speF*, respectively. All three enzymes require anaerobic conditions for full expression, and they have different roles in protecting against acid and allowing growth at low pH (98). AdiA is known to be able to promote survival at pH as low as 2.3 but has no role at pH 4.5. CadA plays a role in both acid survival and growth promotion. SpeF is not involved in ATR but stimulates growth at moderately acidic pHs. These combinations of protection clearly show a relatively complex ATR response in *Salmonella*.

The advent of transcriptomics and proteomics approaches offers multiple opportunities to identify novel ATR and AR mechanisms not only in organisms that have been extensively characterized but also in bacteria that are not as economically relevant as those described above. Acidic foods will always be part of human diet, and it is critical to continue to understand the molecular basis for bacterial survival and growth under those conditions. Comparative genomics and metabolomics will likely contribute to elucidation of novel stress response networks.

OSMOTIC STRESS

All living cells, including bacterial cells, are surrounded by a semipermeable lipid bilayer membrane that contains all cellular contents and limits the exchange of compounds into and out of the cytoplasm (99). The environment surrounding bacteria exposes the cells to constantly changing chemical conditions that lead to changes in the amount of nutrients, water, and waste compounds in the cytoplasm. When the concentration of solutes in the extracellular environment changes drastically, it causes an abrupt movement of water and small-molecule solutes across the membrane. The rapid gain or loss of water and solutes leading to an osmotic shock is a life-threatening event for bacteria. Similar to other stress responses, bacteria have evolved and acquired multiple molecular mechanisms that protect them from potentially damaging osmotic changes (100).

Damage to DNA replication and cell division caused by an osmotic shock explains the loss of viability in susceptible bacterial cells (101). Bacteria have a system of sensors that detect osmolarity changes and trigger the activation and synthesis of enzymes and transport proteins. For the most part, many bacteria are protected from osmotic stress by global regulatory systems, but in some cases, species possess unique mechanisms, such as the accumulation of glutamate by an *S.* Typhimurium strain (102). Some variations of osmotic stress tolerance seem to be dependent on levels of osmotic

shock and temperature (103). This section describes the most relevant osmotic stress responses that have been described for key bacterial pathogens.

Signals and Primary Responses of Osmotic Stress

Changes in water content and cytoplasm solute concentrations are the signals that bacteria respond to and lead to shifts in cell volume (104). Regulation of cytoplasmic osmotic conditions is triggered by detecting drastic changes in osmotic pressure. The concentration changes that have been reported to trigger an osmotic stress response include those related to membrane damage, concentration of a given compound, lack of potassium, osmolality, and turgor pressure (100, 104). Transmembrane chemoreceptors in *E. coli* sense changes in solute concentrations and provide the first osmoprotective signal (105, 106). The transmembrane chemoreceptors in volve CheY, a response regulator phosphorylated by cytoplasmic kinase CheA. The flagellar motility complex is then affected by CheY, and this binding promotes the movement of bacterial cells away from high solute concentrations (106).

For over 20 years, the role of mechanosensitive (MS) channels in osmotic shock response has been observed in *E. coli* as well as in *L. monocytogenes* (107, 108). The MS channels MscL and MscS in *E. coli* have been described to be involved in sensing and responding to different osmotic conditions. In *Listeria*, the equivalent MS channel is encoded by *lmo2064*, which encodes a protein that is 43% identical to MscL (108). MscL and MscS are almost ubiquitous in most bacterial species, but MscL has also been reported in many eukaryotic organisms (109). These MS proteins appear to have a much wider role, since mutant strains have a diminished ability to grow (107). Recent evidence suggests that MS proteins play a very important role as “emergency release valves” that expel intracellular solutes rapidly (109). The discovery of novel bacterial sensing and signaling systems may offer new insights into stress responses.

Osmoprotectants are small-molecule compounds that are critical in the bacterial response to an osmotic shock. The activation of osmoprotectant transporters is one of the first metabolic changes triggered by osmotic stress. Adjusting the concentration of osmoprotectant solutes counteracts the increase in osmotic pressure and minimizes water efflux caused by simple osmosis (102, 110). Such osmoprotectants include trehalose, carnitine, glutamate, choline, glycine betaine, and proline, and they function by stabilizing the cytoplasm and minimizing the loss of enzymatic activity due to loss of protein tertiary structures (101, 102, 104). Glycine betaine is particularly protective for many bacterial species because it optimizes the amount of available water inside the cells (101, 110). The appropriate concentration of osmoprotectants is dependent on the induction of active transport systems.

Osmotic Response of Gram-Negative *Enterobacteriaceae*

E. coli and *S.* Typhimurium share the same osmotic response mechanism, which involves two steps. In the first step, an increase in the concentration of amino acids and potassium ions is attained by the activation of transport systems (111). The second step in their osmoregulation also involves the activation of transport systems for solutes that will balance the turgor pressure in the cell.

The transport of potassium ions is critical for the cell homeostasis of *E. coli* and *S.* Typhimurium, as it is involved in multiple cellular pathways. For osmoprotection, K^+ transport is largely regulated by Kdp, Trk, and Kup (104). The activity of Kdp is triggered by turgor pressure and the concentration of potassium responding to an osmotic shock (112). The presence of glycine betaine transporters (ProU and ProP) in *E. coli* is critical for its osmotic response. These transporters also have a dual specificity for proline (104). ProU is activated after the concentration increases and is vital during osmoadaptation, and *proU* is transcribed after an osmotic stress (104, 111). Conditions of high osmolarity cause full induction of the

proU operon. A common regulatory component may be responsible for also inducing both *kdp* and *proU* (111).

An increase in external solute concentration triggers the synthesis of a handful of proteins in *E. coli* (111). Genes involved in osmotic stress response are also regulated by RpoS (113, 114). Because osmotic shock can cause bacterial cells to slow their growth and enter stationary phase, the osmotic stress genes are regulated by σ^S (115). RpoS regulates the genes involved in trehalose synthesis, *otsA* and *otsB* (112, 114). The betaine transporters are regulated by several effectors. RpoS, catabolite repression protein, and Fis control ProP transcription, and synthesis of ProU is modulated by TopA, GyrAB, H-NS, and HU (114, 115). At the same time, RpoS is also responsible for releasing the repression of H-NS, a histone-like protein, during hyperosmotic conditions (113).

Another important stress response system is the two-component system OmpR-EnvZ in *Enterobacteriaceae* (112, 116). OmpR and EnvZ regulate the expression of the outer membrane porin proteins OmpC and OmpF, and they have been reported in multiple Gram-negative bacteria (117). EnvZ is a sensor protein kinase responsible for phosphorylating OmpR. Phosphorylated OmpR binds DNA and induces *ompF* when osmotic pressure is low but represses it at high osmolarity. OmpC synthesis, however, is diminished at low solute concentrations but stimulated with osmotic shocks (112, 116). *Salmonella* appears to regulate *ompC* and *ompF* differently than other *Enterobacteriaceae*, since stationary phase is the sole trigger of their activation (102). OmpR plays a role as a global regulator of other stress response mechanisms, and in its phosphorylated form it represses *flhDC*, the operon responsible for flagellum expression (116).

The complex osmotic response system in *E. coli* and *Salmonella* also involves PutP and PutA, which confer the capability of using proline as the sole carbon and nitrogen source (118, 119). PutP is a symporter that carries out the simultaneous uptake of sodium ions and proline, and PutA mediates the oxidation of proline (111). The

proteins encoded by the *bet* regulon (BetTIBA) of *E. coli* transport choline and catalyze its transformation to glycine betaine. BetI and ArcA are the regulators of the *bet* regulon.

Osmotic Stress Response of Gram-Positive Bacteria

Among foodborne pathogens, *L. monocytogenes* is particularly tolerant to high concentrations of solutes and salts. In *L. monocytogenes*, several proteins that are expressed as a result of high osmolarity have been reported (108, 120). The uptake of osmoprotectants is the stress response used by *L. monocytogenes*. The most relevant osmotic response genes are *betL*, *proBA*, *relA*, *clpC*, *clpP*, and *sigB*. $v^{s.}$ plays a particularly important role in surviving high-osmolarity conditions, since it induces the expression of *betL* and *opuC*. After stationary phase has been reached, σ^B-dependent induction allows the transport of osmoprotectants (120). σ^Balso induces the ABC carnitine transporter, peptidases, and antiosmotic stress transport systems (121).

In *L. monocytogenes*, BetL, a sodium-dependent transporter that is activated immediately after osmotic shock, mediates betaine uptake (108). When the osmotic stress is more prolonged, another transporter, GbuABC, that mediates betaine uptake is synthesized. Another osmoprotectant, carnitine, is transported into the cells by OpuC, which is also involved in virulence. The *proBA* operon encodes enzymes functionally similar to the glutamyl kinase and glutamylphosphate reductase that catalyze the synthesis of proline (122). Sleator et al. (108) reported that *proBA* mutants had a diminished ability to survive high concentrations of salt.

Gardan et al. (120) reported a unique protein, Ctc, that was induced by osmotic stress and by stationary phase. In the absence of glycine betaine and carnitine, Ctc became activated in protecting cells against osmotic shock. Ctc seems to also be involved in growth. Additional proteins protecting against osmotic stress have been reported in *Listeria* (108). These osmoregulated proteins include

OpuB, a carnitine transporter, and OppA, a protein that mediates the accumulation of peptides triggered by osmotic stress.

S. aureus has the ability to tolerate high concentrations of salt and relatively low levels of moisture for growth and survival. This pathogenic bacterium has been reported to grow at water activity levels of 0.9 and sodium chloride concentrations greater than 10% (101, 123). The osmotic tolerance of *S. aureus* may be due to increased levels of a pyruvate dehydrogenase during an osmotic shock (124). *S. aureus* is also protected from osmotic stress by two glycine betaine transporters with different affinities (125). The transporter with low affinity for glycine betaine may be more important for stress response, as it is induced by osmotic stress. In contrast, glycine betaine concentration is the inducer of the high affinity transporter.

Future Considerations

Food is a rich source of compatible solutes for bacteria, and therefore, knowing the solute-specific characteristics of a food is essential for choosing a method by which the available water will be limited in a food (121). Keeping this in mind, processors should take into consideration the rate at which organisms are able to recover after drastic internal pH changes by looking at solid and liquid media separately, as all foods should not be treated equally (31). Understanding the intricacies of the osmotic stress response can aid in the design of protocols and effective control measures which act to prevent the growth and survival of pathogens in foodstuffs with low water activity (119).

The challenge lies in the fact that the osmotic stress response of bacteria is a diverse system involving many external signals and coinciding mechanisms which, in large part, have yet to be elucidated (119). At the molecular level, the mechanisms of compatible solute function and their transport in various bacterial species, as well as the possible role of osmoprotectants in bacterial pathogenicity, are not fully understood (43, 119, 126). Additionally,

there is minimal information regarding possible osmoregulation of porins in Gram-negative species other than the enteric organisms (21). On a more holistic scale it is unknown whether osmoregulated operons, such as the OmpR-EnvZ and ProU operons of *E. coli*, possess common regulatory elements that might control these operons at a higher level (21). The facet of osmotic stress response and regulation will remain an area of interesting, and necessary, development for years to come.

OXIDATIVE STRESS

During evolution, successful life forms had to develop protective metabolism against oxygen, one of the most reactive elements in nature (127). It is largely believed that the earliest forms of life developed primitive photosynthetic capabilities which allowed them to transform light energy into chemical energy and at the same time produce oxygen as a by-product (1). As the earth's atmosphere changed to contain large amounts of oxygen, nonphotosynthetic living forms were forced to develop mechanisms to counteract highly reactive oxygen forms. As an ancient form of life, bacteria evolved multiple strategies to allow them to survive oxidative stresses.

ROS are the forms of oxygen that are most toxic for biological metabolism. The predominant forms of ROS are superoxide anion and hydrogen peroxide (33, 127). In order to dissipate the toxic effects of ROS, the key enzymes that bacteria developed are superoxide dismutases, catalases, and hydroperoxide reductases (128). Reacting ROS with cysteine residues provides one effective detection mechanism for their presence. *E. coli* responded to hydrogen peroxide exposure after 30 min by expressing several dozen proteins (129).

In *Enterobacteriaceae*, the OxyR regulon is one of the critical components for detoxifying hydrogen peroxide (128, 129). In Gram-negative bacteria, such as *E. coli*, sensing and detoxification of

hydrogen peroxide are controlled by the OxyR regulon (123, 130). The function of OxyR is not only regulatory; it also serves as the sensor for the presence of hydrogen peroxide. OxyR is activated when a cysteine residue (Cys-199) of one of its subunits is oxidized (127). After this initial oxidation step, Cys-199 reacts with Cys-208 from another subunit. Disulfide-containing OxyR then binds to promoters that will induce specific oxidative stress response genes. OxyR is extremely sensitive to hydrogen peroxide, since just nanomolar concentrations are sufficient for full activation. The OxyR basal state is restored to its inactive form by reduction steps catalyzed by glutathione reductase (GorA) and glutaredoxin 1 (GrxA) (129).

OxyR regulates a wide array of stress response proteins involved in the synthesis of reducing agents, hydrogen peroxide hydrolysis proteins, and other regulatory proteins (129). In *E. coli*, the detoxification of hydrogen peroxide and its free-radical by-products is catalyzed by catalase (KatG) and alkyl hydroxyperoxide reductases (AhpCF) (128). Other specific response components regulated by OxyR include thioredoxin 2 (*trxC*), Dps, and OxyS (22, 128). OxyR is also critical for iron uptake and metabolism. The ferric uptake repressor, Fur, is induced by OxyR, and the Fur regulon includes several proteins involved in iron, zinc, and hydrogen peroxide sensing (127). OxyR also regulates the Ohr regulon, which encodes proteins that mediate organic hydroperoxide detoxification.

In Gram-positive bacteria, such as *L. monocytogenes*, PerR, a stress response regulator equivalent to OxyR, has been reported (131). PerR-defective mutants had a reduced ability to tolerate hydrogen peroxide. PerR in Gram-positive organisms is a metalloregulatory protein with two metal-binding domains. Similar to OxyR, multiple oxidative stress response genes are also regulated by PerR (132). The expression of catalase (*kat*) was upregulated in Δ*perR* mutants, and as in *E. coli*, PerR was also involved in controlling the expression of Fur.

HIGH-TEMPERATURE STRESS

Changes in temperature are a threat that bacteria experience continually in the environment, and temperatures greater than room temperature often present the possibility of serious damage to cells. Microorganisms have evolved a series of protective pathways to allow them to survive high temperatures. The production of heat shock proteins (HSPs) is the most widely distributed heat stress response in bacteria. HSPs protect the cell components involved in protein synthesis, transport, folding, and degradation and can be synthesized at any temperature (126). A sudden increase in temperature enhances the expression of HSPs, and after about 10 min, the production of general HSPs ceases and growth stops (126, 133). At this point, bacteria upregulate several specific heat stress response genes.

Heat can cause severe and extensive damage to bacterial cells that can potentially lead to complete inactivation and death. Heating can cause the loss of tertiary protein structure, protein aggregation, disruption of the entire metabolism, enzyme inactivation, changes in protein phosphorylation, and disruption of cell and outer membranes (11, 126, 134). If bacteria are subjected to sublethal levels of heating, their ability to withstand higher temperatures is enhanced thanks to thermotolerance mechanisms (134). The thermotolerance mechanisms of several foodborne bacteria have been extensively studied, but this subsection is dedicated to two organisms whose mechanisms have been characterized more completely, *E. coli* and *Bacillus* spp. These two models represent not only Gram-negative and Gram-positive genera but also nonsporeformers and sporeformers.

Gram-Negative Bacteria

Several heat response systems have been reported in *E. coli* (135, 136). These systems have also been described in other Gram-negative organisms, and it appears that they are highly conserved. Approximately 400 genes are activated by increasing the incubation

temperature from 37 to 43°C (137). In *E. coli*, a large network of HSPs in combination with two sigma-dependent regulatory systems have been identified, the σ^E and σ^H heat stress regulators. Depending on the location and accumulation of misfolded proteins, activation of one or more of these systems is the primary response. The σ^E regulon is typically activated by damaged proteins in the cell's outer layers, and the transcription of σ^H is upregulated when unfolded proteins accumulate in the cytoplasm (135, 138, 139)

σ^E Regulon

Induction of the σ^E regulatory operon takes place only above 40°C (139). *rpoE* encodes σ^E, and it regulates the expression of at least 10 proteins and the transcription of over 43 genes. The *rpoE* operon includes *rseA* and *rseB*, which encode proteins that integrate into the cytoplasmic membrane and periplasm, respectively (135). Refolding and degradation of proteins are mediated by two proteins encoded by *htrA* and *fkpA* within this regulon (139). Several outer membrane proteins are activated after thermal shock, and their role is to repair DNA and membrane lipids. These outer membrane proteins also have a role in regulating the transcription of σ^E.σ^E is responsible for transcribing *rpoH*, which encodes the transcription factor σ^H (σ^{32}), the other major component of the heat response (126).

σ^H Regulon

The majority of the heat stress response genes are activated by σ^H (140). Transcription of *rpoH* is controlled by four promoters, referred to as P1, P3, P4, and P5, but when the temperature is more than 50°C, the only active promoter is P3 (139, 140). RpoH is inhibited by several heat shock proteins that include DnaK, DnaJ, and GrpE (140). The role of the latter proteins as well as GroEL is to function as chaperones, which are molecules that prevent the accumulation of misfolded or denatured proteins by proteolysis

(141, 142). Additional proteolytic proteins regulated by RpoH are Lon and the Clp proteins (ClpB, ClpP, and ClpX) (133, 135). In this regulon, the heat shock genes *htrC* and *htpY* are located upstream of the DnaK operon. The transcription of *htpY* induces only the *htrA* promoter in the σ^E regulon but activates both σ^H -and σ^E -dependent heat shock regulons, while *htrC* negatively regulates the response (135).

Table 4.1 Classes of heat shock genes in Gram-positive bacteria[a]

[b] Unidentified.

Gram-Positive Bacteria

The heat shock response of *Bacillus* has some similarities to that of *E. coli*, but in this case, most heat stressrelated genes are classified into four major groups (Table 4.1) (38, 133, 143). Each heat stress response class is distinguished by the regulatory systems that control expression of HSPs.

Class I

The *hrcA* and *groEL* operons are the main components of class I. The role of HrcA is to repress transcription of heat shock genes by binding to the controlling inverted repeat of chaperone expression *cis*-active sequence (130, 133, 144). The housekeeping sigma factor σ^A regulates the transcription of *groEL* (145).

Class II

The class II regulon is controlled by the σ^B stress factor and it is also referred to as the SigB regulon. More than 200 genes regulated by σ^B are upregulated within 3 minutes following heat exposure. The deactivation of these SigB-dependent genes occurs after 10 minutes, while the rest of the heat response genes remain expressed (130). The genes in this class may also be induced by other stresses, such as osmotic, low-oxygen, and high-pressure conditions (130, 133).

Class III

The class III heat stress response regulon has been reported in multiple low-G+C Gram-positive bacteria (133). The key regulator of this class is CtsR (class III stress gene repressor), which can be

regulated by σ^A and σ^B (127, 145). ClpC, ClpP, and ClpX (ClpX is in class IV) are stationary-phase proteins that are required for motility, sporulation, and growth at high temperatures (144). *Streptococcus* spp., *Clostridium* spp., and *Enterococcus* spp. have their own CtsR regulon, but their specific characterization has yet to be completed (133).

Class IV

Several stress response genes are placed in class IV because they are not regulated by CtsR or by σ^B (130, 133). The majority of these genes are components of transporter systems (130). In contrast to *B. subtilis*, *S. aureus* has only class I and III regulatory systems.

Although the regulation mechanisms of the heat stress response have been studied thoroughly in Gram-positive and Gram-negative bacteria via the model organisms *Bacillus* and *Escherichia*, respectively, additional research is recommended in order to fully understand the complex series of systems and responses that protect against heat stress. In many cases, it is still not fully understood how the bacterial cell initially senses a change in environmental temperature and how signals are transported into the cell to induce specific regulatory mechanisms (138, 141). In other foodborne pathogens, such as *Campylobacter*, the major regulators of the heat stress response have yet to be elucidated or confirmed.

LOW-TEMPERATURE STRESS

For many centuries, humans have relied on the use of low temperature for food preservation. Currently, cold storage and handling of foods continue to be one of the most effective technological approaches to minimize microbial growth and spoilage. Refrigeration is the use of low temperature above the freezing point of water (typically 0 to 7°C) to store foods, and freezing storage keeps foods at less than 0°C, normally at

approximately –15°C. Some bacteria associated with foods are capable of growing at refrigeration temperatures, but freezing completely inhibits allmicrobial growth. Low-temperature exposure of bacteria cells can cause serious damage to their metabolism and can lead to loss of survival ability.

The ability of bacteria to survive adverse low-temperature conditions depends on the presence of a response metabolism that counteracts cold shock. To complement the previous section, in which the stress responses to higher temperatures were discussed, this subsection covers the relevant molecular mechanisms that protect cells from low temperatures.

Drastic temperature changes from the mesophilic range (30 to 40°C) to less than 10°C affect bacterial cells by altering structure and metabolic functions as well as disturbing membrane fluidity and integrity (146). A sudden reduction in temperature inhibits the activity of most proteins and enzymes, and at the same time, it induces the synthesis of several cold shock proteins (CSPs). Low-temperature exposure of *E. coli* cells results in the synthesis of more than 25 proteins (146, 147). After cells are exposed to approximately 1 hour of low temperature, nine homologous CSPs, CspA to -I, are activated. In addition, several DNA-associated factors are also activated. Among the CSPs expressed are DNA gyrase (GyrA), RNA helicase (DeaD), a transcription factor (NusA), and a translation factor (InfB) (146).

CSPs have been characterized extensively, and they are some of the first stress responses for which molecular regulation was described. In general, CSPs are highly conserved among multiple bacteria, and they are small proteins, approximately 7.4 kDa (146). CSPs can bind to only single-stranded DNA or RNA, not doublestranded DNA. Among CSPs, CspC and CspE are also induced by changes to higher temperatures. Stationary phase and starvation can also be signals to induce CspD (146, 147). It was reported that two of the multiple CSPs of *L. monocytogenes*, Csp1 and Csp2, were upregulated after treatment with high-hydrostatic-pressure (HHP) processing (148).

The regulation of transcription is the main protective role of CSPs against low temperatures, because the chromatin-associated protein H-NS is associated with the cold shock response (147). CspA stimulates the expression of H-NS as a transcription activator binding the promoter region of *h-ns*. Similarly, GyrA synthesis is also stimulated by CspA. The majority of CSPs also protect the configuration of RNA tertiary and secondary structures. In addition to their roles as transcriptional activators, CSPs also have a regulatory function during translation, which is critical for cell survival (146). The first sign of CSP regulation is stabilization of mRNA, which includes its own RNA and rRNA (147). Because the low temperature increases the stability of bonds between DNA strands, the role in translation is to facilitate the continuous RNA synthesis of many household genes and minimize misfolded mRNA. Other cold-induced proteins, such as DeaD, are helicases involved in unwinding double-stranded nucleic acids.

HHP SURVIVAL

HHP is an effective technology for inactivating pathogens in multiple food types (149, 150). The damage inflicted by HHP on microorganisms is dependent on different variables related to treatment. The most important factors are the amount of pressure and the temperature. In addition, the type of food, the treatment time, and the bacterial characteristics influence the extent of inactivation. When mild pressure levels are used, the cell membrane is disrupted and metabolism is inhibited by increased permeability. The use of extremely high pressure intended to sterilize food stuffs causes irreversible damage to ribosomes, DNA, RNA, cell walls, and cell membranes (151). The growth of most microorganisms becomes inhibited at 20 to 130 MPa (152). Depending on the species, vegetative-cell death usually occurs between 130 to 800 MPa, but the inactivation of bacterial endospores often requires pressures above 1,200 MPa (151, 153). In general, stationary-phase cells are more resistant to HHP than

exponentially growing cells (149, 154). Overall, the effects of pressure on bacterial physiology and the genetic response elicited by organisms for survival to this stress are not well characterized. More studies are necessary in order to shed light on this facet of microbial stress response.

Exposure to pressure leads to expression of proteins in bacteria, and these proteins are the same as those induced by other stresses such as temperature shifts (155, 156). Similarly, when cells are exposed to thermal stress, acidity, or other stresses, they are often more tolerant of high pressure (149). The *E. coli* pressure stress response has been reported to be regulated by RpoS (157). Of the genes upregulated during stationary phase, as many as 55 are part of the protective mechanism against pressure. Several of these proteins were some of the key components of the temperature shift responses, but approximately 40 were found only in pressure-treated cells (158). High-pressure shocks have also been reported to induce the general stress response SOS, which is independent of RpoS (155). This SOS-dependent pressure response is regulated by RecA and LexA. These activators induce multiple genes, including *sulA* and *uvrA*. The reduction in outer membrane proteins (OmpC, OmpF, and OmpX) may also be due to SOS regulation (155). In *L. monocytogenes*, the general stress response, σ^B, is activated and two CSPs (Csp1 and Csp2) were transcribed as a result of high pressure (148, 159). Additional studies may be necessary to determine the cross-protective stress response to pressure and temperature.

STRESS RESPONSES AND VIRULENCE

The association between bacterial stress responses and pathogenicity has been extensively investigated in multiple foodborne pathogens (160). The main concern stemming from this possible linkage is whether exposure to sublethal stresses during food processing can lead to the presence of microorganisms with enhanced virulence. The hypothesis of this potential relationship was advanced originally by the realization that global regulators

such as sigma factors had such widespread influence on multiple regulons throughout the bacterial genome (12). In addition to the rationales that support the potential coregulation of stress responses and virulence factors, the environment of foods resembles to a certain extent the host's cellular components and defense mechanism.

One of the first connections between stress response and virulence regulation in a foodborne pathogen was reported by Fang et al. (161), when they showed that RpoS (KatF) mutant strains of *S.* Typhimurium had a reduced ability to cause infection in mice. The role of RpoS in systemic infection has also been demonstrated by observations that it is required for the persistence of *Salmonella* in liver and spleen (30). A direct link between RpoS and virulence is the expression of a hemolysin network in *Salmonella* (12). In *V. cholerae*, deficiencies in σ^S expression led to increased sensitivity to starvation and oxidative conditions, and it was found that it was required for efficient gastrointestinal tract colonization (162). Similarly, in *L. monocytogenes*, SigB mutants had a decreased ability to infect mice and guinea pigs, and this effect appeared to be mediated by the control of PrfA, a general virulence regulator, by SigB (12).

In addition to shared global regulators of stress response and virulence, some organisms have specific stress responses that are involved in pathogenicity. The link between osmotic response and virulence was observed when it was found that *opuC*-defective strains had a diminished ability to colonize the gastrointestinal tract of mice and cause systemic infection (12). OpuC is an osmoprotectant transporter in *Listeria.* Oxidative and acid response stress systems are two frequently studied systems with a clear link to the pathogenicity of foodborne bacteria. The low pH and strongly oxidative conditions that invasive pathogens encounter in phagosomes are the barriers that they need to overcome in order to cause infection. In *Salmonella*, OmpR-EnvZ is activated by acid shock, and it also induces the type III secretion system that enhances cellular replication (160). A recent report study linked the

requirements for the type III secretion system, *sopD*, and *sseD* to the ability of *Salmonella* to survive during desiccation (163). The acid resistance of *L. monocytogenes* mediated by arginine deimidase has also been reported to play an important role in promoting infection in a murine model (89). Recent bioinformatics and genomic advances are helping to elucidate the complex metabolic regulatory systems in bacterial pathogens (164). For two recent reviews on the relevance of stress responses and virulence of foodborne pathogens, see references 12 and 160.

SUMMARY

An advance in our knowledge of the molecular strategies for bacterial survival in foods is critical to understand the underlying principles that allow their presence and have deleterious effects, including spoilage and foodborne disease. A deeper understanding of the key components of each of these systems is essential to develop future strategies of control. Organisms such as *E. coli*, *Salmonella*, and *B. subtilis* have served as the model organisms for Gram-negative and Gram-positive bacteria to shed light on the intricacies of cellular responses to threatening conditions. Many of those systems have also been identified in other bacterial species, but many more species-specific stress regulators remain to be discovered. The advent of genomics-, proteomics-, and metabolomics-based techniques has accelerated our knowledge of the components involved in novel stress responses. In addition, the availability of an increasing number of fully sequenced bacterial genomes will also contribute to further advances in the field of bacterial stress responses.

Microbial Spoilage and Public Health Concerns

5
Milk and Dairy Products

Milk-associated microbes have long been of interest because of their impact on food safety and quality and their necessity for the production of fermented dairy products. The microbial ecology of milk and dairy products has primarily been studied by traditional, mainly culturedependent, microbiological approaches. These techniques have provided tremendous fundamental insights into the genetics, physiology, and ecology of microorganisms in dairy systems, including lactic acid bacteria, spoilage bacteria and fungi, and foodborne pathogens. This field has continued to evolve thanks to the rapid advancement in "-omics" technologies since 2000 (1–3). Genomics application in dairy products was marked by the genome sequence published for *Lactococcus* (*Lc.*) *lactis* IL1403, a dairy-associated strain most commonly used as a starter culture for cheese production (4). *Lc. lactis* IL1403 is also one of the first bacterial strains for which the genome sequence was available. Another significant genomics advancement was the discovery of clustered regularly interspaced short palindromic repeats (CRISPRs) and CRISPR-associated sequences (Cas) and their roles in immunity against bacteriophages of *Streptococcus thermophilus*, an organism routinely used in dairy fermentations (5). The development of high-throughput DNA sequencing methods provided metagenomics studies with unprecedented sampling depth, and these methods are currently pervasively used in exploring the microbial biodiversity of milk and dairy products, among other food commodities (6).

This chapter emphasizes current knowledge on dairy food microbiology from the perspective of cultureindependent microbiome research (Fig. 5.1). Because the majority of studies have relied on sequencing the DNA of selected marker genes, such as the variable regions of 16S rRNA genes in bacteria and internal transcribed spacer regions in fungi, this methodological approach is emphasized (Fig. 5.1). However, when possible, knowledge from metagenomics and other more comprehensive techniques is also discussed (Fig. 5.1). Findings from this emerging metagenomics field are complementary to and build upon prior dairy microbiology research (7, 8).

MILK MICROBIAL DIVERSITY AND ABUNDANCE

Bovine Milk

Around 180 million metric tons of bovine (*Bos taurus*) milk is consumed annually worldwide (9). Although bovine milk has long been studied by culture-dependent microbiological approaches, modern microbiological methods have provided new perspectives on its microbial composition and variation prior to and after pasteurization. It is now understood that bovine milk has a highly diverse microbial composition that fluctuates around a core microbiota consisting of a few key taxa.

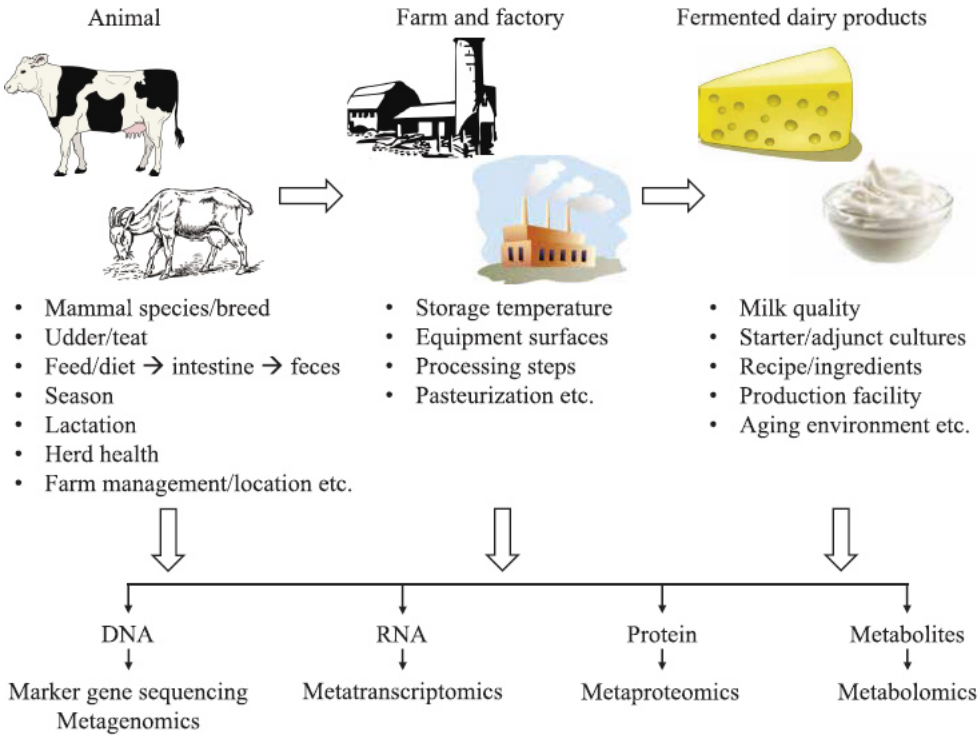

Figure 5.1 Sources and factors influencing milk and dairy product microbial composition, as well as genomics-based methods for determining microbiological variation in dairy products.

Bacteria in Unpasteurized Bovine Milk

The microbiota in milk originates from a variety of sources, such as the cow udder and teat, farm air, grass, dust, dirt, bedding, feed, feces, and equipment (Table 5.1) (10–15). The most direct passage of bacteria into milk is by the cow udder and teat. Verdier-Metz et al. surveyed microorganisms on teat skin and identified various bacterial taxa, including *Enterobacteriaceae*, *Enterococcus*, and *Staphylococcus*, which are also commonly found in raw milk (16). Unprepared teats can result in milk with significantly lower bacterial alpha diversity, which is likely due to the predominance of one or a few bacterial contaminants from the teat surface (17). Regardless of teat surface contamination, milk from the udders of healthy cows is not sterile. Transport of bacteria from the maternal large intestine to mammary glands by leukocytes in bloodstream might occur through an endogenous entero-mammary pathway (18, 19). Comparisons of 16S rRNA gene sequences from the milk, white blood cells, and feces of healthy cows resulted in the identification of operational taxonomic units assigned to *Ruminococcus*, *Bifidobacterium*, and *Peptostreptococcaceae* in all three sample types (20). Conversely, bacterial DNA was not recovered in white blood cells from cows that were the same age but not lactating or pregnant (20).

Bacteria found in milk are also subject to variation depending on cow breed, lactation stage, bovine health, cow, diet, farm location and practices, and season. The milk microbiota was found to differ according to the cow breed, thereby indicating a genetic component to milk microbiota composition (21). Bacterial composition was also found to show lactation stage dependency. Milk from early lactation harbored the highest proportions of *Lactobacillus* compared to milk from later lactation stages (22). *Bacteroides*, *Faecalibacterium*, *Campylobacter*, and *Rhodanobacter* were more abundant in raw milk during mid-lactation, whereas *Corynebacterium*, *Micrococcus*, *Arthrobacter*, and *Clostridium* were more prevalent in milk from late lactation (23). Milk from late lactation was also found to contain higher total numbers of bacteria as well as higher bacterial alpha diversities (22–24).

When a lactating cow is affected by mastitis (i.e., bacterial infection of the mammary gland), it has the potential to shed as many as 107 bacteria per ml into the milk, with increased proportions of

Acinetobacter, *Brevundimonas*, *Burkholderia*, *Dermacoccus*, *Enterococcaceae*, *Lactobacillus*, *Lactococcus*, *Pseudomonas*, *Ruminococcaceae*, *Sphingobacterium*, *Sphingomonas*, and *Stenotrophomonas* (21, 25–30). The enriched taxa can include potentially opportunistic pathogens as well as bacteria known to cause bovine mastitis, such as *Staphylococcus aureus*, *Streptococcus agalactiae*, *Streptococcus dysgalactiae*, and certain *Mycoplasma*, *Corynebacterium*, and *Enterobacteriaceae* species (21, 25). It is notable that the overall bacterial alpha diversity in milk was lower in mastitic than healthy cows (21, 25–30). The milk microbiota can also differ between teats on individual animals, depending on the extent of infection (25).

Cow diets influence milk quality and the associated microbiota. In a crossover feeding experiment comparing high-forage and high-grain diets, Zhang et al. showed that the high-grain diet, which is prone to induce subacute ruminal acidosis, increased the relative abundances of *Enterococcus*, *Brevundimonas*, *Lactococcus*, and *Stenotrophomonas*, while it reduced the proportions of *Clostridiales*, *Streptococcus*, *Sphingomonas*, and *Prevotella* and conferred a slight decrease in overall bacterial alpha diversity (31).

Farm location and practices are associated with differences in the bovine milk microbiota (21). Commensal and environmental microorganisms can be introduced and spread by handling personnel, bedding, and milking equipment. Additionally, animal housing conditions (indoor versus outdoor) can also result in variation in the raw milk microbiota. Cows raised in outdoor, pasturebased farms produced milk that harbored a more diverse microbiota (17).

Multiple studies have shown that the microbiota of raw milk varies depending on the season (17, 32, 33). In general, total bacterial cell numbers were estimated to be higher in the winter and spring than other seasons (24, 32). The diversity of bacteria was also greater in the spring (24, 32). *Corynebacterium* and *Acinetobacter* were more abundant in the spring; *Streptococcus* and *Staphylococcus* were more abundant in the summer; and *Turicibacter*, *Pseudomonas*, *Lachnospiraceae*, and *Enterococcus* were more abundant in the fall (32). These findings are likely influenced by variations in farming practices and environmental exposures that change depending on the time of year.

After collection, milk is stored under refrigeration (2 to 6°C) on the farm until transport for processing. Storage conditions can have different effects on the milk microbiota composition. When milk is stored at temperatures lower than 2°C, the microbiota composition stays largely unchanged (23). At higher temperatures (4 to 6°C), the total bacterial population increases, and specific psychrotrophic taxa, including *Streptococcus*, *Pseudomonas*, and *Acinetobacter*, have been found in increased proportions, whereas the quantities of *Staphylococcus*, *Rhodanobacter*, and *Ruminococcaceae* decreased (23, 34, 35). *Streptococcus*, *Pseudomonas*, and *Acinetobacter* are frequently associated with dairy product spoilage via either increased growth or the production of extracellular proteases, peptidases, and lipases (36). The milk microbiota can also fluctuate after transport and during storage or holding at dairy processing facilities. In one study, *Lactococcus*, *Streptococcus*, *Acinetobacter*, *Pseudomonas*, and *Mycoplasma* were enriched in milk kept in holding silos after transport from dairy farms (32).

Processed Fluid Milk

Milk is a nutrient-dense substrate for growth of a variety of bacteria, including foodborne pathogens. The U.S. Public Health Service's advocating the pasteurization of raw milk in 1939 was a landmark for public health which resulted in significant reductions in outbreaks of milk-borne illness (37). The current pasteurization treatment (high temperature, short time) required by the U.S. law is 72°C for 15 seconds. This method was previously designed to destroy *Mycobacterium tuberculosis* and is now used to eliminate *Coxiella burnetii*, the most heatresistant milk-borne pathogen (38, 39). Pasteurization also has a significant impact on the composition of milk microbiota. Overall, the bacterial alpha diversity of pasteurized milk is lower than that of raw milk (40). When specific members of bovine milk are compared pre-and postpasteurization, the relative abundances of *Enterobacteriaceae*, *Moraxellaceae*, *Pseudomonadaceae*, *Corynebacteriaceae*, and *Staphylococcus* are significantly decreased in

pasteurized milk, while the proportions of thermoduric bacteria, such as *Thermus*, and *Turicibacter*, are increased (40).

The addition of other processing methods further changes the milk microbiota composition. CO_2 addition by either modified atmosphere packaging or direct injection has been developed to lengthen the shelf life of raw and pasteurized milk (41). It was found that carbonized milk contained lowered proportions of *Pseudomonas*, *Serratia*, and *Erwinia* (42). These bacteria were likely inhibited because of their sensitivity to low O2 concentrations and reductions in pH resulting from CO_2 treatment (42).

Goat Milk

Goat (*Capra aegagrus*) milk has long been a source of human nutrition in countries in the Mediterranean, Eastern Europe, the Middle East, and South America (43, 44). Goat milk production constitutes about 2.1% of global milk production and increased by 39.2% from 2000 to 2012 (43, 45)

Table 5.2. is a compilation of abundant bacterial taxa that have been found in goat milk by recent efforts using DNA sequencing approaches. Like bovine milk, goat milk contains diverse bacterial populations that are affected by lactation stage. McInnis et al. showed that the microbiota of goat milk from late lactation was significantly different from that in milk from early lactation and mid-lactation (46). Specifically, *Pseudomonas* was the most abundant taxon during early and mid-lactation (about 50% of bacteria present). The relative abundance of *Pseudomonas* fell to approximately 2% during Late lactation, and the dominant taxon during late lactation was *Micrococcus*, constituting 68% of the bacterial population (46). McInnis et al. also collected raw milk from transgenic goats that can produce human lysozyme, and significant differences were observed only during late lactation, when *Bacillaceae*, *Alicyclobacillaceae*, *Clostridiaceae*, and *Halomonadaceae* were more abundant in the transgenic milk (46).

Milk from Other Mammals

Milk from other mammals, such as buffalo, donkey, water deer, and reindeer, is also consumed by various indigenous cultures and has been measured for microbial content by targeted 16S rRNA marker gene sequencing. Water buffalo (*Bubalus bubalis*) milk is consumed mainly in India, Pakistan, and southern China. It was shown that mastitic buffaloes produced milk with lower bacterial alpha diversities, which continued to decrease during refrigeration (1 to 4°C) (47, 48). In fresh, raw milk collected from healthy buffaloes, the bacterial community was dominated by *Streptococcus* (14%) and *Lactococcus* (8%) (47, 49). After 72 hours of refrigeration (1 to 4°C), *Pseudomonas* (51%) and *Acinetobacter* (11%) were predominant. After pasteurization, the microbiota of buffalo milk showed an abundance of *Lactococcus* (18%) and *Streptococcus* (7%). The pasteurized milk was stable for over 21 days at 1 to 4°C, after which the milk spoiled and was enriched in *Paenibacillus* (85%) (47, 49). Other abundant taxa (>1%) in buffalo milk include *Aerococcus*, *Corynebacterium*, *Clostridium*, *Enhydrobacter*, *Propionibacterium*, *Psychrobacter*, *Turicibacter*, and *Staphylococcus* (47, 48).

Table 5.2 The most prevalent bacteria in goat milk[a]

[a] Data adapted from references 46 and 53.

Donkey (*Equus asinus*) milk has progressively gained more interest for use as a replacement of bovine milk for children with cow milk protein allergies. Milk from donkeys also more closely resembles human milk in regard to essential amino acid and lactose concentrations (50, 51). The use of DNA sequencing to identify the bacteria in donkey milk demonstrated that *Pseudomonas*, *Sphingobacterium*, *Ralstonia*, *Acinetobacter*, and *Citrobacter* are the most abundant members of the microbiota (>1% of total relative abundance, in descending order) (52).

In a comparative study of milk from water deer (*Hydropotes inermis*), reindeer (*Rangifer tarandus*), and goats, Li et al. found that milk from water deer contained the highest bacterial alpha diversity, followed by reindeer and then goat milk, which contained the lowest diversity (53). Water deer milk harbored (>1% of total relative abundance, in descending order) *Pseudomonas*, *Acinetobacter*, *Chryseobacterium*, *Corynebacterium*, *Comamonas*, *Rhizobium*, *Rheinheimera*, *Microbacterium*, *Stenotrophomonas*, *Brevundimonas*, *Kocuria*, and *Sphingomonas*. Reindeer milk was found to contain (>1% of total relative abundance, in descending order) in *Hyphomicrobiaceae*, *Cyanobacteria*, *Halomonas*, *Ralstonia*, and *Propionibacterium* (53).

CHEESE

Cheese is an ancient fermented dairy food that has been a part of the human diet from as early as 5400 BCE (54). Cheese fermentations are prehistoric practices to preserve milk, improve flavors and textures, and increase the availability of nutrients for human consumption (54). It is estimated that there are now approximately 1,500 varieties of cheese produced around the world (55). These varieties are derived from milk of different ruminant animals exposed to coagulation agents (e.g., rennet, acid, heat, and/or crystallization), inoculated with ripening cultures (bacteria, yeasts, and molds), and incorporated with other ingredients (salt, spices, vinegar, smoke, coloring, etc.), as well as prepared using various processing and aging methods involving different factors (temperature, moisture, ripening time, etc.). A diagram of the most important steps in cheese manufacturing influencing the microbial populations is presented in Fig. 5.2.

The microbiotas of cheeses have been investigated since the early days of microbiology research (56). Microbes can be introduced into the cheese-making process in many ways, either intentionally or accidentally. However, knowledge on the ecological processes and molecular interactions that occur during cheese fermentation is incomplete. This is particularly evident because of the more recent applications of metagenomics methods to investigate this food. Table 5.3 is an extensive list of studies

that employed high-throughput DNA sequencing methods to elucidate the microbial communities of cheeses and cheese-related environments.

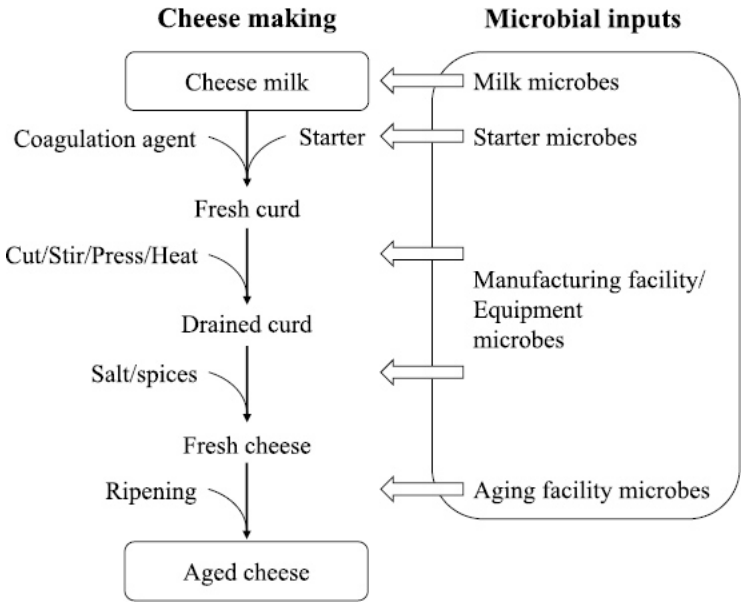

Figure 5.2 Steps in cheese manufacturing with the greatest influence on microbial populations.

Sources of Microorganisms in Cheese

Microbes can be introduced into cheese at nearly every step during processing (Fig. 5.2), leading to differences and variation in the cheese microbiota.

Milk

The process of cheese making typically starts with the standardization of milk to the desired composition in terms of fat, protein, calcium, and pH required for a specific type of cheese (57). Factors that influence the milk microbiota, such as animal species and lactation stage, are also important in cheese fermentations. The factors have implications for cheese quality and safety (22, 40). For example, cheese made from cow's milk contains the highest bacterial diversity, followed by goat's milk and then sheep's milk cheese (40).

The microbiota of raw-milk cheese is measurably different from that of cheese produced with pasteurized milk. Raw-milk cheeses tend to have a more complex and diverse microbiota than pasteurized-milk cheeses (40, 58, 59). Specifically, *Corynebacterium*, *Enterococcus*, *Halomonas*, *Helcococcus*, *Lactobacillus*, *Staphylococcus*, *Streptococcus*, *Tetragenococcus*, and *Vagococcus* are more frequently found in raw milk cheeses, whereas *Clostridium*, *Lactococcus*, *Pseudoalteromonas*, *Psychrobacter*, and *Vibrio* are more abundant in cheeses made using pasteurized milk (40, 58).

Starter and Adjunct Cultures

Starter cultures, derived from either traditional backslopping practices or selected strain(s), are added to milk to facilitate coagulation and jump-start the ripening process. Natural whey cultures are the most commonly used thermophilic starters derived from backslopping practices. These bacteria are in whey collected from a prior fermentation that is incubated at a high temperature (45 to 52°C) for 4 to 18 hours (60). Natural whey cultures contain high numbers of thermophilic lactic acid bacteria (LAB), such as *S. thermophilus*, *Lactobacillus* (*Lb.*) *delbrueckii*, and *Lactobacillus helveticus* (33, 49, 61, 62). In addition to thermophilic starters, mesophilic starter cultures are also widely used in cheese making. Traditional mesophilic starter cultures are naturally derived from self-coagulated milk. Strains of *Lc. lactis* (>90%) and *Leuconostoc* spp. (*Leuconostoc* [*Ln.*] *mesenteroides* and *Ln. pseudomesenteroides*)

with an optimal growth temperature around 30°C are common mesophilic starters (60, 63, 64). The addition of starter cultures reduces the bacterial alpha diversity, resulting in a temporary suppression of growth and activity of other microorganisms present (22, 33, 49, 65–67). For example, Masoud and colleagues found that the growth of pathogenic *Escherichia coli* in cheese was impaired by the reduction in milk pH as a result of starter culture bacterial activities (65).

High-throughput DNA sequencing has been applied in combination with culture-based and other molecular methods to determine the diversity of complex starter cultures in order to fully understand their genetic and functional potential in light of strain and lineage variations (63, 64, 68, 69). Significant intraspecific diversity was observed among lineages of bacterial species in starter cultures. Although a traditional Gouda-style mesophilic starter culture (known as Ur) was found to contain only two bacterial species (*Lc. lactis* and *Ln. mesenteroides*), when it was investigated in more detail using metagenomic methods, five lineages of *Lc. lactis* subsp. *cremoris*, two lineages of *Lc. lactis* subsp. *lactis*, and a single lineage of *Ln. mesenteroides* were identified (63).

In general, mixed-strain starter cultures are more robust and resilient to environmental perturbations than single-strain inoculants (70). Mixed-strain starters have these properties because of strain-specific differences in growth kinetics and metabolic pathways (e.g., citrate utilization and proteolytic activity). Metabolic complementation and cross-feeding between strains enable the bacteria to adapt to the dairy environment more quickly than when they are inoculated individually (63, 64, 71). Mixed-strain starters are also more resilient than singlestrain starters because of metabolic redundancy and compensation following exposure to environmental stress and bacteriophage attack. Because of the limited host range of bacteriophage, the populations of some but not allstrains within the starter culture are affected at any single time (63, 71). The stability of such mixedstrain starters is evidenced by the fact that after repeated back-slopping propagation cycles, species-level composition remains stable (62, 63, 71). To fully preserve the strain-level functionality, industrially important cheese starters are usually carefully maintained to minimize propagation cycles.

Adjunct cultures usually include nonstarter lactic acid bacteria (NSLAB), such as *Lactobacillus* spp., *Lactococcus* spp., and *Enterococcus* spp., as well as molds, such as *Penicillium* spp. (72). Adjunct cultures are vital for flavor development in cheese. The contributions of these microorganisms were shown in a meta-transcriptome study, which found that adjunct NSLAB gene transcripts for proteins required for proteolysis and lipolysis (flavor development) were enriched towards the end of cheese ripening (73). Adjunct cultures can also be added during the cheese-making process as probiotics for human health. Recent animal and human studies using cheese made with probiotic adjunct cultures showed that these bacteria remained viable in cheese and in the gastrointestinal tract (>103 CFU/g of fecal sample) without causing significant changes in the organoleptic properties of cheese (74, 75).

Table 5.3 High-throughput sequencing studies of cheese and cheese-related environments

Milk source	Study focus	Study description	Reference

Bacteriophages

Bacteriophages are notorious in milk because of their ubiquitous prevalence and ability to infect starter culture bacteria to result in delayed or even failed fermentations (60). Likely because of the coevolution of bacteria and bacteriophages in milk and dairy products, bacterial starter cultures often possess multiple viral resistance mechanisms. Resistance can occur by modification of phage receptors, resulting in the inhibition of phage adsorption, and also as a result of nucleic acid restriction/modification systems, abortive infection mechanisms (apoptosis), and CRISPR/Cas systems (76, 77). However, these mechanisms are only partially effective. To control phage populations during cheese manufacture, methods such as rotating starter culture use, intentional selection of bacteriophage-insensitive mutants, and mixed-strain starters are commonly used (78, 79).

Bacteriophages might also have important beneficial functions in some cheese fermentations. Cell killing by the viruses helps to prevent strain overgrowth and instead to maintain intra-and interspecies diversity. In this "kill-the-winner" model, phage proliferate in the most active bacterial strain (usually the most abundant strain) and thereby prevent it from using all of the available nutrients (80). In this regard, bacteriophage and prophage (targeting the most abundant bacterial species) sequences are frequently found in metagenomes of complex, functionally stable starter cultures (62, 63, 71, 81). DNA sequencing methods have also been developed for investigating the bacteriophages of dairy products. These methods provide a way to improve starter culture selection and bacteriophage control methods for milk and dairy products (81).

Enzymes and Other Added Ingredients

Citric acid is added to milk to achieve direct and fast acidification for curd formation, particularly for unripened cheese. The addition of citric acid (final pH of curd from 5.8 to 6) instead of starter culture bacteria to Mozzarella cheese processing was shown to result in a higher bacterial alpha diversity and higher proportions of psychrotrophic bacteria, such as *Aeromonas*, *Acinetobacter*, *Pseudomonadaceae*, and *Listeriaceae* (82, 83).

Rennet is often added to milk together with starter cultures. Rennet is traditionally extracted from calf stomach tissue but can also be produced from microbial fermentation and plants, such as fig and thistle (84). Recently, a study comparing commercial animal rennet and thistle rennet revealed that the source of rennet could have an impact on the microbiota of curd and fresh cheese (85). *Lactococcus* was more abundant in cheese made with animal rennet, while *Lactobacillus* and *Leuconostoc* were more abundant in thistle rennet cheese (85).

Physical and Environmental Conditions Used in Cheese Production

After fresh curd coagulates, whey is separated and removed by using different methods, including cutting, stirring, pressing, and cooking. The curd can then be shaped and flavored or brined. Brining of the curd in NaCl results in a strong selection against Gram-negative bacteria, with the exception of those that are halotolerant, such as *Pseudoalteromonas*, *Halomonas*, and *Vibrio casei* (86). The proportions of starter culture bacteria are also changed in response to brining. In Gouda cheese (brined in 19% [wt/vol] NaCl solution), the proportions of different *Lc. lactis* subsp. *cremoris* lineages changed rapidly after brining (87).

Cheese processing facilities and equipment surfaces harbor a diverse collection of microbial species (88) which could also be significant sources of microbes in cheese. These surfaces contain microbes that originate from the environment, personnel, milk, and cheese. The microbes are distributed throughout processing plants, as indicated by the large proportions of bacterial (87%) and fungal (50%) operational taxonomic units that were found to be shared between dairy plant swabs and cheeses (88). Spoilage bacteria, such as *Acinetobacter*, were found in high proportions (33% of the total bacterial proportions) in the vat containing milk to be curdled, and *Pseudomonas* populated the cheese molder and chopper (average, 50%) as well as the curd bench and curd tank (average, 30%) (88). In the same cheese facility, the fungal species *Yamadazyma triangularis* heavily populated (>90% of the fungal population) the Caciocavallo cheese hook, whereas the curd tank, curd bench, and knife were populated by *Trichosporon faecale* (88). In another study that sampled an Italian cheese fermentation site, bacteria known to contribute to cheese making, including *S. thermophilus*, were found in high proportions in the swab samples of the curd knife, brine tank, and drain tables (>35%) (89). NSLAB, including *Lactobacillus plantarum*, *Lactobacillus brevis*, and closely related species, were also found on the surfaces of the curd tank (89). Additionally, swabs from an American artisanal cheese plant showed that the curd-making and brining surfaces were predominantly populated by *Lactococcus* (~50% of the bacterial community), *Lactobacillus* (~10% of the bacterial community), and *Debaryomyces* (~40% of the fungal community) (86).

Surfaces that do not directly contact cheeses, such as floor drains, can also host a complex microbiota that is highly dependent on the products and processes carried out in the room (90). For instance,

Streptococcus and *Lactobacillus* were abundant in the floor drains of culture preparation room, *Pseudomonas* was found at high levels in both the smearing and ripening rooms, and *Psychrilyobacter* was abundant in the ripening room (90).

The accumulation of microbes on facility surfaces throughout the day might also cause quality and safety issues in the final cheese product. Within the same cheesemanufacturing facility, it was found that cheeses produced late in the day had more diverse microbial communities than cheeses made at earlier time points (91). *Acinetobacter*, *Clostridium*, *Lactobacillus*, *Pseudomonas*, and *Streptococcus* were more abundant in cheese made first after equipment cleaning, whereas *Brevibacterium*, *Corynebacterium*, and *Thermus* were more abundant in cheese produced 6 to 8 hours later (91).

Cheese Aging and Associated Environment

Most varieties of cheese undergo ripening, which can last for days to years, during which the microbial communities undergo drastic changes (57). The diversity of bacteria during cheese ripening has been reported to decline towards the end of the aging process (66, 91, 92). However, taxonomic changes are specific to the variety and site on the cheese (e.g., core versus rind). The surfaces of the cheese are more exposed to O_2, dry air, environmental contamination, and variation in temperatures than the centers. Because of these exposures, cheese rinds generally have a higher diversity of microorganisms than the cores (58, 93, 94). *Lactococcus*, *Leuconostoc*, *Lactobacillus*, *Bifidobacterium*, and *Ruminococcaceae* are commonly enriched in the core. *Brevibacterium*, *Brachybacterium*, *Corynebacterium*, *Hafnia/Serratia*, *Halomonas*, *Psychrobacter*, *Pseudomonas*, *Pseudoalteromonas*, *Staphylococcus*, *Streptococcus*, and *Thermus*, as well as yeasts and molds, have been frequently found on cheese rinds (40, 58, 59, 73, 91, 94).

Cheese Varieties

This section discusses recent findings on the examination of the microbial composition of different cheese varieties, emphasizing studies that have pursued systems biology, 16S rRNA gene and internal transcribed spacer marker gene sequencing, and metagenomics methods.

Hard Cheese

The Italian hard cheeses Parmigiano-Reggiano and Grana Padano are made by combining thermophilic natural whey starters, milk that is cooked at high temperatures (~55°C), and long ripening times (>2 years) (95). Bacterial diversity in Grana-style hard cheese was observed to decline during the first 6 months of ripening but then gradually increased again after 8 months (61). *Lactobacillus* species were present throughout the ripening process, and *Acinetobacter*, *Lc. lactis*, *Pseudomonas*, and *S. thermophilus* were also detected sporadically during ripening (61, 96). In Grana-style cheese, assessments of metabolic gene abundance indicated that *Lactobacillus fermentum* was the most active bacterium at the beginning of processing, and then *Lb. casei* and close relatives were the most prevalent, metabolically active group compared with other NSLAB during ripening (96).

Cotija cheese is a handmade artisanal cheese from raw cow's milk without an added starter culture that can be aged from months to years. After 3 months of ripening, over 500 genera were identified in the Cotija cheese metagenome, of which *Lb. plantarum*, *Ln. mesenteroides*, and *Weissella paramesenteroides* were the three most dominant species present, and *Aerococcus*, *Enterococcus*, *Lactococcus*, and *Staphylococcus* were detected in lower proportions (97). Genes coding for enzymes involved in flavor development were detected, including amino acid lyases and transferases as well as carboxylesterases (97). Genes coding for the production of antimicrobial bacteriocins were also detected, indicating the likelihood for the activation of bacterial defense strategies within the cheese (97).

Swiss-type cheeses (hard to semihard) have distinct gas pockets, or "eyes," which develop during ripening as a result of CO_2 production from lactate fermentation by *Propionibacterium freudenreichii* (95). *Lactobacillus* (>70%) and *Streptococcus* (>10%) populations dominated the bacterial community of this cheese type throughout the 2-month ripening period (91). Other bacteria were also present in

lower proportions during ripening, including *Lactococcus*, *Vibrio*, *Pseudomonas*, *Pseudoalteromonas*, and *Psychrobacter* (91). Cheese rinds harbored a more diverse microbiota than the cheese core at the beginning of ripening, but the core microbial diversity surpassed that of the rinds after 10 days (91).

Semihard Cheese

Gouda is a semihard cheese characterized by small eye holes that result from the production of CO_2 from citrate metabolism by *Lactococcus* and *Leuconostoc* (95). At 95% relative abundance, *Lc. lactis* subsp. *cremoris* dominated the Gouda cheese bacterial community during the beginning of ripening (87, 98). Bacterial diversity was then observed to increase during ripening (98). The metagenome of fresh Gouda was enriched in genes associated with bacteriophages, transport systems, and exopolysaccharide production (98). After aging for 3 months, genes for amino acid transport and catabolism, peptidases, monosaccharides, and organic acid utilization were more prevalent (98).

Caciocavallo-type cheese is a medium-aged pasta filata cheese made with raw cow's milk, and *S. thermophilus* or a natural whey starter is the primary starter culture. After 30 days of ripening, the cheese fermentation was driven by NSLAB, and the populations of *Lb. casei* and *Lactobacillus buchneri* increased consistently, whereas starter *S. thermophilus* numbers declined (66, 73). The metagenome of the Caciocavallo cheese also exhibited a spatial distribution. Genes required for amino acid and lipid metabolism were more abundant in the cheese center. The cheese rind was enriched in genes encoding genetic information processing, core cellular processes, and carbohydrate metabolism (73). Among carbohydrate metabolism pathways, metatranscriptome analysis showed that expression levels of lactose and galactose metabolism enzymes gradually declined during ripening (73).

Soft Cheese

Soft cheeses are higher in moisture content than semihard and hard cheeses and are generally aged for shorter periods of time. Mozzarella is one of the most popular soft cheeses consumed globally. Traditionally, it is made with unpasteurized water buffalo milk and natural whey cultures in southern Italy. During the 5 hours of fermentation required to make this cheese, *Lb. delbrueckii* and *Lb. helveticus* numbers increased, whereas *S. thermophilus* associated with the starter culture declined (49).

Pico cheese is a soft cheese traditionally made with unpasteurized cow's milk in the Pico islands of Portugal. A more diverse microbiota was observed in fresh Pico cheeses made with the traditional method than the industrial method, which involves milk pasteurization and the addition of starter bacteria (92). However, after a 3-week ripening period, the microorganisms in cheeses made using the traditional and those made using industrial methods became more similar. Both contained increased proportions of *Lactobacillus* and *Streptococcus* and reductions in *Acinetobacter* and *Stenotrophomonas* (92).

Bacterial Surface-Ripened Cheese

Bacterial surface-ripened cheese probably harbors the most heterogeneous microbiota among all cheese varieties due to its diverse surface bacterial communities (95). For instance, Livarot-style cheese is made by inoculating *Lc. lactis*, *Kluyveromyces lactis*, *Debaryomyces hansenii*, and *Geotrichum candidum* into milk and subsequently smearing (topical application) ripening bacteria (*Corynebacterium casei*, *Brevibacterium aurantiacum*, *Arthrobacter arilaitensis*, *Staphylococcus equorum*, and *Hafnia alvei*) onto the cheese surfaces. Dugat-Bony and colleagues found that, at the early stages of ripening (14 days), *Lc. lactis* (40%), *G. candidum* (30%), and *D. hansenii* (10%) were present in high proportions within the cheese metagenome but were gradually replaced by surface bacteria, primarily *C. casei* (71% of the total microbial metagenome at day 31) (99). Metatranscriptomes of this cheese showed that transcripts for amino acid and carbohydrate transport and metabolism, for protein translation, folding, sorting, and degradation, and for environmental signal transduction were highly diverse and abundant throughout the ripening process, suggesting that numerous metabolic pathways were active within the microbial community (99). It was notable that

the lactate produced by *Lc. lactis* and *K. lactis* was likely rapidly consumed by *D. hansenii* and *G. candidum*, as demonstrated by high levels of lactate dehydrogenase transcripts from these fungi (99). *G. candidum* was also linked to amino acid degradation, especially at the end of ripening, indicating that this species is important for neutralizing the pH and supporting the growth of flavor-enhancing, surface-associated bacteria in mature cheese (99).

Reblochon cheese is a French bacterial surface-ripened cheese. A Reblochon-style cheese made using pasteurized milk was examined for microbial and metatranscriptome composition during ripening. Transcripts in the cheese rind shifted from protein biosynthesis at the beginning of ripening to amino acid and lipid degradation at the time of maturity (93). Among the inoculated surface yeasts, *G. candidum* was the most active yeast at allripening times. *D. hansenii* showed increased activity towards the end of fermentation (93). It was also shown that although *B. aurantiacum* was inoculated as the ripening starter, the abundance and measurable metabolic activities were surprisingly low (2%) throughout the 35-day ripening period (93). Lactic acid starters (*S. thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus*), on the other hand, grew at the very beginning (5 days) of ripening but had limited metabolic activities during the rest of the fermentation period (93).

Mold Surface-Ripened Cheese

Camembert type cheese is a typical mold surfaceripened cheese with felt-like, bloomy white rinds. Camembert is traditionally made with unpasteurized milk and surface applications of the ripening culture consisting of *Penicillium camemberti*, *G. candidum*, and sometimes *K. lactis* and *Brevibacterium linens*. Camembert-style cheese is also commercially produced with pasteurized milk, and ripening starter is inoculated into milk directly, especially in North America (95). During ripening, *P. camemberti* and *G. candidum* were highly active in the cheese rinds according to metatranscriptome analysis (100). Transcripts related to energy metabolism from both fungi (glycolysis/gluconeogenesis pathways, pentose phosphate pathways, tricarboxylic acid cycle, and oxidative phosphorylation) were more abundant in the early stage than late stage of ripening. Proteolytic and lipolytic activities were also robust during the first 2 to 3 weeks of ripening, contributing to the flavor and texture development of Camembert cheese (100).

Sheep's Milk Cheese

Cheeses produced using sheep's milk are widely produced and consumed in Europe. In both hard and soft varieties, *Lactococcus* was found to be the dominant genus throughout ripening, and *Enterococcus*, *Lactobacillus*, *Leuconostoc*, *Staphylococcus*, and *Streptococcus* were also detected (40, 85, 101, 102). *Lactococcus* proportions generally declined over time, along with members of the *Enterobacteriaceae* family and *Staphylococcus* genus (85, 102). Canestrato Pugliese sheep's milk cheese was different, however, where *Lactococcus* proportions increased from 17.8% to 87.2% of the bacteria present. *Pseudomonas* and *Carnobacterium* decreased from 44.7% and 29.7%, respectively, to below 1% of the microbial contents during the 90-day ripening period (103).

KEFIR

Kefir is a viscous, acidic, self-carbonated and slightly alcoholic fermented milk beverage produced by adding kefir grains as starters into fresh or pasteurized milk. Kefir typically ferments for 1 day at 20 to 25°C (39, 104). Kefir grains are a white, spongy, symbiotic microbial consortium of LAB, yeasts, and acetic acid bacteria with an appearance similar to that of cottage cheese (104). The consumption of kefir has spread from its origin in the Caucasus Mountains to worldwide, in part due to the putative health benefits associated with this drink (105–108).

Kefir milk and grains studied with culture-based methods were found to be dominated by populations of LAB (*Lactobacillus*, *Lactococcus*, *Leuconostoc*, and *Streptococcus*) as well as lower numbers of acetic acid bacteria (*Acetobacter*) and yeasts (*Candida*, *Cryptococcus*, *Saccharomyces*, *Kluyveromyces*, and *Zygosaccharomyces*) (109–113). With the application of DNA sequencing methods, other genera not traditionally associated with kefir were also found, including *Bifidobacterium*, *Bacteroidaceae*, and

Pediococcus as well as the yeast genus *Dekkera* (114–116). Table 5.4 summarizes the abundant taxa (>1%) found in kefir.

Kefir milk and grains were found to have different bacterial and fungal populations (114, 115). The milk beverage bacterial communities are dominated by *Lactococcus* and occasionally *Lactobacillus* depending on the manufacturer (114–121). *Leuconostoc* proportions are also higher in the milk than grains (114, 115). In contrast, *Lactobacillus* species are the most abundant bacteria in the grains (114–121). The microorganisms are also not uniformly distributed throughout grains (115). *Leuconostoc*, *Clostridiaceae*, and *Enterobacteriaceae* were present at higher proportions in the center of the grains, whereas the surface harbored higher numbers of *Bacteroidaceae* (115).

Table 5.4 Abundant[a] microbes identified in kefir with high-throughput DNA sequencing methods

Group and organism	Source	Reference(s)
Lactic acid bacteria		
Lactobacillus	Kefir and grain	114-117, 119-121
Lactococcus	Kefir and grain	114-119
Leuconostoc	Kefir and grain	114-117, 120
Pediococcus	Grain	116
Streptococcus	Grain	117, 118

Bifidobacterium	Kefir and grain	114, 115, 120
Enterobacteriaceae	Kefir and grain	114, 119
Enterococcus	Grain	116
Propionibacterium	Grain	120
Ruminococcaceae	Kefir	114
Tetragenococcus	Grain	116
Yeasts		
Dekkera	Grain	115, 118
Hanseniaspora	Grain	118
Kazachstania/Naumovozyma/	Kefir and grain	115,118-120
Saccharomyces		
Kluyveromyces	Kefir and grain	115, 119

[a] Here, “abundant” is defined as being present in a relative proportion of > 1%.

Kefir and kefir grains collected from various geographic locations contained different microorganisms (115, 118). This difference could be partially explained by manufacturing practices. Korsak et al. found that the quantity of kefir grains used for inoculation led to differentiation in the microbiota of the beverage at the end of fermentation (119).

Throughout the 24-h kefir fermentation period, the microorganisms in kefir milk and grains undergo succession processes. Walsh et al. found that, from 0 to 8 hours of ripening of an Irish kefir, the microbiota of kefir milk shifted from a complex microbiota similar to that found in bovine milk to one

dominated by *Lactobacillus* (120). After 8 hours, *Lactobacillus* populations decreased and *Leuconostoc* and *Acetobacter* abundances increased (120). *Saccharomyces* and *Kazachstania* were the only abundant fungal genera throughout the fermentation of kefir milk (120). Concurrent with microbial community shifts, the kefir milk metagenome changed in a manner consistent with flavor development. Pathways associated with carbohydrate metabolism, carboxylate degradation, and unsaturated fatty acid biosynthesis were most abundant after 8 hours of ripening, and pathways for amino acid metabolism and 2,3-butanediol degradation were enriched at the end of fermentation (116, 120). Other genes found in the metagenome might have functions in the human intestine, including those coding for extracellular polysaccharide biosynthesis, bile salt transporters, adhesion and mucus-binding proteins, and the type III bacteriocins/bacteriolysins helveticin J and enterolysin A (120).

OTHER FERMENTED MILK BEVERAGES

A variety of fermented milk beverages are produced and consumed using traditional back-slopping methods or simply by natural fermentation relying on the microbes present in milk. It has been shown that artisanal fermented milks sourced from different mammals and regions have distinct microbiota, resulting in highly diverse products in terms of their organoleptic and nutritional properties (122–125). This section discusses several fermented milk beverages that have been studied using -omics approaches.

Fermented Cow Milk

Yogurt is the most popular fermented milk beverage around the world, with a long tradition of human consumption. Yogurt first appeared in historical records around 9000 BCE in the Middle East, India, and Northeast Africa, and it was used as a way to preserve milk and improve food safety. Yogurt fermentation is carried out by a starter culture composed of *Lb. delbrueckii* subsp. *bulgaricus* and *S. thermophilus* incubated in milk at 42°C to a final pH around 4.5 (126). Metatranscriptome and metabolome analyses confirmed previous findings on the symbiotic interactions between the yogurt starter bacteria (127). Specifically, *Lb. bulgaricus* was found to supply *S. thermophilus* with peptides and amino acids, and in return, *S. thermophilus* produces formic acid, folic acid, and fatty acids that stimulate the growth of *Lb. bulgaricus* (126, 128–131). Commercial yogurt often contains other added bacteria, including strains of *Bifidobacterium* as well as *Lactobacillus acidophilus*, *Lactobacillus rhamnosus*, *Lactobacillus paracasei*, and *Lb. casei* (126). These bacteria are typically added because of their probiotic properties, but they are also capable of adapting to the yogurt environment. Gene transcript analysis has shown that these bacteria are metabolically active in yogurt and express genes required for energy production and conversion (128).

Nunu is a viscous beverage resulting from the natural fermentation of raw cow's milk. It is usually fermented for 1 day at ambient temperatures and is widely consumed in rural parts of Ghana and other countries in west Africa (132). The bacterial populations of nunu are mostly composed of *Streptococcus infantarius*, *Lc. lactis*, *Enterococcus faecium*, and *Enterobacter cloacae* (>1%) (132). Unexpectedly, Shiga toxin-producing *E. coli* and pathogenic *Klebsiella pneumoniae* were also present in the nunu microbiota (132), indicating that heat treatment such as pasteurization might be necessary to ensure safe consumption.

Tarag is a yogurt-like beverage consumed in Mongolia, Russia, and northwestern China. It is produced by back-slopping fermentation of cow, sheep, or goat milk or a mixture thereof (133). Tarag is subsequently aged for at least 5 days at 10 to 25°C (134). As with other traditionally fermented dairy drinks, geographical variation in the microbiota of tarag was observed (134). However, *Lactobacillus* was consistently found to be the most abundant bacterial genus, followed by *Streptococcus*, *Lactococcus*, *Leuconostoc*, *Acinetobacter*, and *Acetobacter* (>1%) (123, 124, 134). The fungal populations of tarag consisted of mainly *Galactomyces*, *Saccharomyces*, *Trichosporon*, *Kluyveromyces*, *Pichia*, *Candida*, and *Vanderwaltozyma* (>1%) (124, 134).

Similar to tarag, matsoni (or also called matzoon) is also produced by back-slopping practices with mixtures of milk from cows, sheep, goats, and buffalo. This drink is produced in regions of Bulgaria,

Georgia, Armenia, and Russia. It is fermented at 35 to 42°C overnight, and the finished product is described as a mildly sour yogurt with a syrup-like viscosity (104, 125). Matsoni bacterial communities were found to have abundant proportions of *Lactobacillus* and *Streptococcus* with minor populations of *Lactococcus*, *Enterococcus*, *Pseudomonas*, *Rummeliibacillus*, *Enterobacteriaceae*, *Erwinia*, *Wautersiella*, and *Yersinia* (125). Yeast populations in matsoni are more heterogeneous, although *Kluyveromyces marxianus* and *Saccharomyces cerevisiae* were frequently detected (125).

Fermented Horse Milk

Koumiss, also known as airag, is an alcoholic fermented horse milk with a high vitamin content that has been consumed in central Asia since the 5th century BCE (104, 133, 135). Koumiss is fermented with a liquid starter culture and stirred for 1 to 2 hours before it is ripened at 6 to 8°C for around 3 days (104). *Lactobacillus* spp. such as *Lb. helveticus*, *Lactobacillus kefiranofaciens*, and *Lb. buchneri* are abundant in koumiss (>50% of bacteria present), and *Streptococcus*, *Lactococcus*, *Enterococcus*, and *Acetobacter* have also been detected (122, 123, 136). Koumiss metagenomes were found to have high proportions of lactose metabolism genes as well as pathways for amino acid transport and metabolism that are associated with flavor formation (e.g., casein-degrading proteinases, aminopeptidases, aminotransferases, and amino acid lyases) (136).

Fermented Yak Milk

Kurut is made by the spontaneous fermentation of yak milk and is a staple dairy product among nomadic populations inhabiting the Qinghai and Tibet highlands of China. Yak milk fermentation typically lasts for a week at 10 to 20°C (104, 137). The resulting kurut is a viscous, sour, alcoholic, white or ivory-colored beverage (104, 137). Without the addition of starter culture, the microbial composition of kurut is dependent on production practices and differences among yak herds (138). *Lactobacillus* was found to be the most abundant genus in kurut, followed by *Streptococcus* and *Lactococcus* (122, 138). The fungal communities of kurut had abundant *Saccharomyces* and *Galactomyces* populations, with subdominant genera (>1%) including *Vanderwaltozyma*, *Pichia*, and *Gibberella* (138).

CONCLUSIONS

Modern microbiological methods targeting nucleic acids (RNA and DNA), proteins, and metabolites have provided unprecedented levels of knowledge on microorganisms and their composition and functional relevance in dairy products (Fig. 5.1). High-throughput approaches are powerful tools to study dairy product defects (139, 140) and to test processing parameters and recipes that can lead to the development of new products (73). However, at present, -omics methods are inconsistently applied and standards are not yet available for dairy microbiome research. Additionally, there are technical limitations, such as the inability to detect cells and cellular contents that are present in low levels and difficulty with accurate species identification and molecular resolution. We expect that methodological standardization and sufficient technological and bioinformatics advancements will be achieved in the near future. We anticipate that these emerging methods will propel dairy microbiome research in ways that ultimately ensure dairy product safety and quality and provide fundamental knowledge on the ecology and molecular capacities of food-associated bacteria.

Meat and Poultry

Meat and poultry are important commodities in the United States and worldwide. Given the popularity of these commodities and their high consumption rate, it is critical to understand the sources of contamination and the means to prevent cross-contamination to protect public health. Contamination of meat and poultry by microorganisms occurs naturally as a result of procedures necessary to produce foods of animal origin. In general, most foodborne illnesses and outbreaks result due to undercooking or underprocessing of these products, cross-contamination, or improper handling of cooked meat and poultry. Because meat products are highly perishable commodities, particularly fresh meat and poultry, temperature controls are critical to prevent contamination. Given the broad spectrum of variables that can cause foodborne illnesses linked to meat and poultry products, this chapter discusses microbiological issues related to these commodities and their control measures.

FRESH MEAT

Traditional thinking that muscle of healthy animals destined for human consumption is sterile is still valid. However, evidence that some tissues and organs of healthy animals can contain zoonotic pathogens is being established. While the initial microflora of meat comprises microorganisms originating from the animal itself, either from the surfaces of the hide or from the intestinal contents, other sources include the processing environment and the personnel present during processing. A variety of Gram-negative and Gram-positive bacteria can make up the initial flora of meat, regardless of the animal species.

The populations and the composition of the initial microflora depend on the source of contamination, and this can vary from animal to animal or be normalized during processing if there is a risk of cross-contamination during processing. Further, the microbial populations on meat depend on the processing system utilized during slaughter and the specific unit operations used to harvest the animal. For example, the hides of beef cattle are removed subsequent to exsanguination, whereas in pork processing, the hide stays on the animal until after the carcass is chilled. Further, the unit operations specific to pork harvest, such as scalding, dehairing, and singeing, assist in significantly reducing the microbial load on the hide and exterior surface of the carcass. However, the risk of contamination of the carcass by microorganisms from the hide surface is significant in beef processing. In addition, the characteristics of the carcass surface influence the degree of efficacy of the antimicrobial interventions applied to the carcass and hence the type and cell populations of microorganisms on the carcass and, eventually, the meat.

Beef and Pork

General Ecology of Beef and Pork

The microbial types and the cell populations on carcasses during and subsequent to processing of beef and swine can be substantially different. As stated above, the major sources of microbial contamination of beef carcasses are the hide and the gastrointestinal (GI) tract. The types of microbes on the hide of beef cattle are dependent on the environment of the feedlot or the pasture, the microbes in the soil and water, and the beef ecosystem.

The types of microbes in feedlot air include several species of *Bacillus*, *Corynebacterium*, *Paenibacillus*, *Micrococcus*, and the molds *Alternaria*, *Cladosporium*, and *Penicillium* (1), with the populations ranging from 1 to 2 log CFU/liter and 1 to 4 log CFU/liter in upwind and downwind air, respectively, from beef cattle feedlots. These airborne microbes are largely from the soil of the feedlot environment, and the differences in microbial populations between the upwind and downwind air are attributed to the soil of the feedlot, which is the

source of the organisms. The types and populations of the microbes can be dependent on the weather and the season, with winter and rainy seasons usually resulting in higher populations than the dry, hot environment of the summer. In addition, there is evidence that the geographical location (latitude) of the feedlots has a significant role in the ecology of the foodborne pathogens *Escherichia coli* O157:H7 and other Shiga toxin-producing *E. coli* (STEC) types. The risk of hide contamination from soil during warm, dry periods is lower than that in rainy and humid periods due to formation of dung locks and the amount of mud or soil on the hide, because the microbes on the hides of cattle largely originate from the feedlot soil and the manure of the animals. The populations of *Salmonella* spp. and *E. coli* O157:H7 on cattle hides can increase following exposure to a dust cloud and during cattle load-out on trucks for transportation to the slaughter operation (2). The prevalence of *Salmonella* is usually greater in the wet season than in the dry season (3). Hence, the microflora from animal feces and that from the soil make up the microorganisms on cattle hides when cattle are transported to the slaughterhouse.

The GI tract of beef cattle is colonized by microorganisms that influence animal physiology, nutrition, health, and productivity (4). While the cattle intestinal microbiota has been well characterized using culture-based methods, the application of novel, genome-based methods is revealing greater diversity in these populations. The most common microbes in the beef cattle GI tract include the taxa *Bacteroidetes*, *Prevotella*, and *Bacteroides*; the *Firmicutes Faecalibacterium*, *Ruminococcus*, *Roseburia*, and *Clostridium*; and the proteobacterium *Succinivibrio* (5). Also, the type of cattle (dairy versus beef) influences the microbial diversity in the animal gut, with higher populations of *Arthrobacter*, *Asteroleplasma*, *Bifidobacterium*, *Collinsella*, *Delftia*, *Eggerthella*, *Lactobacillus*, *Mitsuokella*, *Olsenella*, and *Propionibacterium* in beef cattle than in dairy cattle. While a diverse microbial community can contaminate beef cattle during slaughter, the microbes that can grow and cause meat spoilage depend on their ability to survive subsequent antimicrobial interventions and grow in the meat during subsequent packaging, storage, and distribution processes.

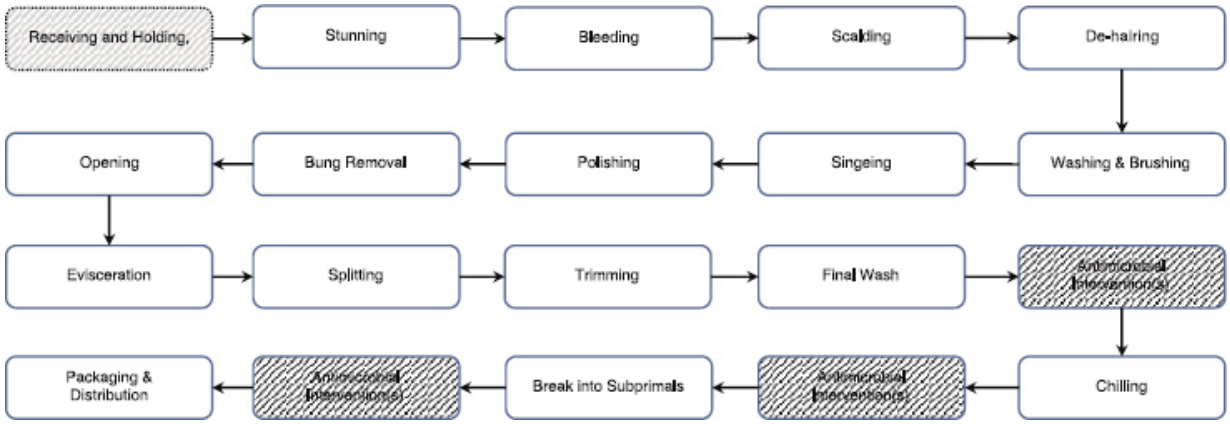

Figure 6.1 Unit operations for pork slaughter.

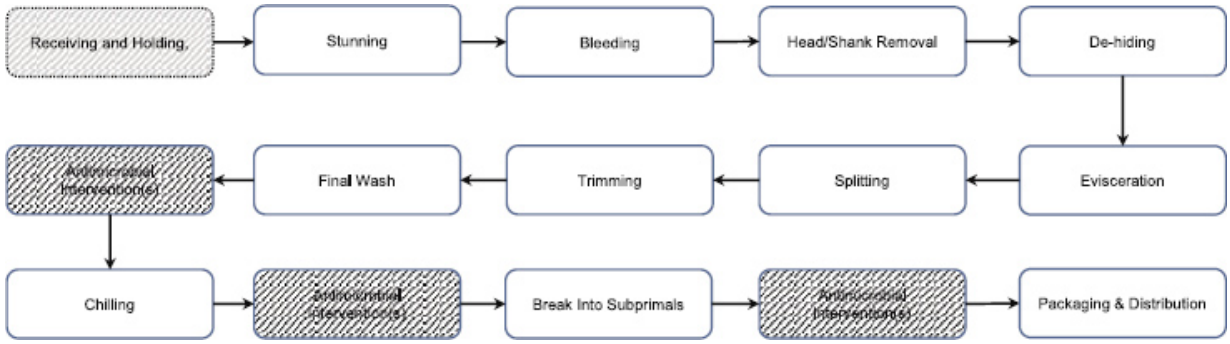

Figure 6.2 Unit operations for beef slaughter.

Beef and Pork Harvest and Slaughter

The main purpose of the cattle and swine harvest processes is to convert the animal to meat. While the major unit operations, such as stunning, exsanguination, bunging, evisceration, splitting, and carcass chilling, are similar between the species, there are significant differences in additional unit operations applied during the harvest process (Fig. 6.1 and 6.2). For example, swine carcasses go through scalding, dehairing, and singeing operations that beef carcasses are not subjected to. Also, characteristics of the hide (presence or absence of hair, mud, and dung balls [for cattle], smoothness of the hide or skin, etc.) and the fact that the hide is left on the carcass in most swine harvest operations until after chilling have a significant influence on the microbial populations of the carcass prior to and subsequent to chilling.

In beef processing, the hide is removed after exsanguination and the hide is pulled while it is being rolled down from the carcass to expose the carcass tissue surface underneath. This processing step can create aerosols if the hide is wet so that microorganisms can be deposited on the equipment or on the freshly dehided carcass itself (Fig. 6.3).

Subsequent to the implementation of the Pathogen Reduction; Hazard Analysis and Critical Control Points rule, beef processors have implemented many antimicrobial interventions at various locations in their processing facilities utilizing a variety of antimicrobial agents and treatments based on processing plant experience and in-plant microbiological evaluations. These antimicrobial interventions are discussed further below.

Contamination of Beef and Pork during Harvest and Slaughter

Sources of contamination

The primary sources of microbial contamination of carcasses, regardless of the species, are the hide and the GI tract of the animal. The secondary sources of contamination include the environment and personnel that handle the carcasses, as these harvest and slaughter operations are labor-intensive. The microbial load on the hide for beef cattle can be 8 to 10 log CFU/100 cm^2 for total plate counts, 6 to 8 log CFU/100 cm^2 for total coliform counts, and 5.0 to 7.5 log CFU/cm^2 for *E. coli* counts (6). These numbers can vary substantially depending on the processing operation, source of the cattle, season of harvest, geographical location of the feedlot or pasture, and the transportation and lairage conditions at the processing operation. While the source of contamination can be the same for swine as well, hogs are purchased through long-term contracts and are reared indoors in large barns for most large swine-processing operations. As such, the hogs are not exposed to the environment and soil, although they are exposed to manure at the growing facility, during transportation, and at the lairage of the processing facility. Regardless, most swine are not dehided prior to evisceration, and hence, the unit operations have the capability of substantially reducing the microbial populations on the hide prior to evisceration; thus, the main source of contamination

remains the GI contents and the feces during or immediately before evisceration.

The harvest process influences which of the two sources—hide or the GI contents and feces—constitutes the predominant source of the organisms and consequently the proportions of the microbes on the carcass surface.

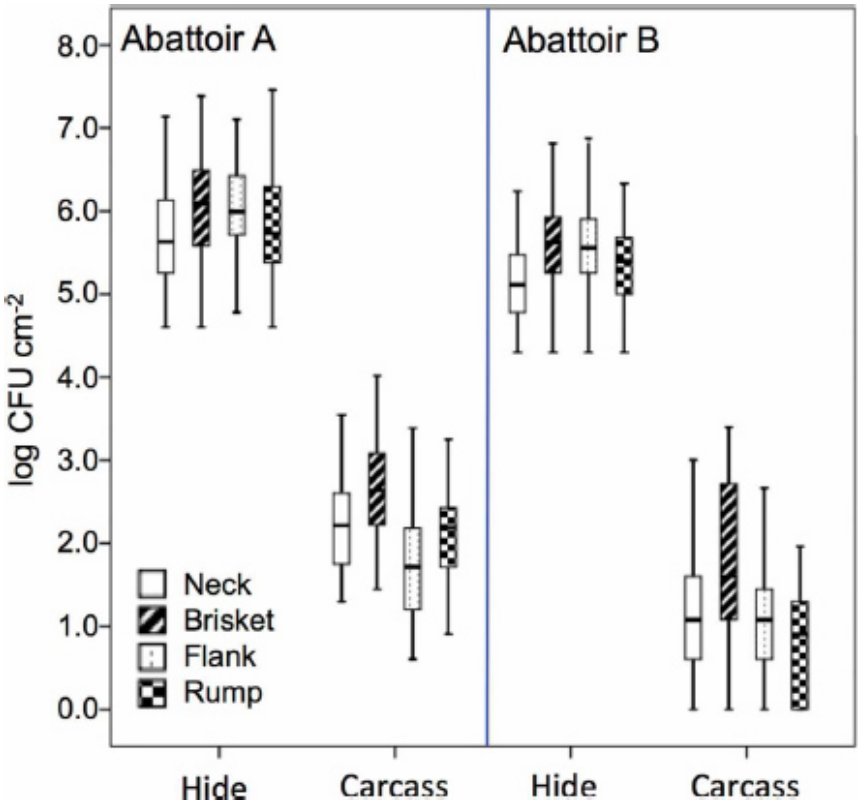

Figure 6.3 APCs on beef cattle hides and freshly dehided carcasses. Reprinted from reference 303.

Microbial loads on carcasses at different stages of slaughter

Using swine slaughter as the example, hogs are moved from lairage to processing chutes and undergo stunning either by electrical means or by a controlled atmosphere and cut by incision in the jugular vein to allow bleeding. After the bleeding, the carcasses go through scalding and singeing steps, which can cause some reductions in microbial populations on the hides of the carcasses (Table 6.1). The scalding process involves immersion of swine carcasses in hot water (61°C) for 8 to 10 min after bleeding and before the dehairing process. In some

instances, the scald water is infused with surfactants to reduce the surface tension of the water and/or pH-modulating agents to enhance loosening of the hair follicles to increase the ease of hair removal. Often, these agents result in higher pH values (>10) in the scald water and, with relatively higher temperatures and the use of surfactants, the scalding process can substantially reduce the microbial load on the skin of swine carcasses, often by more than 3.0 log CFU/cm^2 (7). The subsequent process of dehairing allows recontamination of the carcass from residual hair in the dehairing equipment which has lodged throughout the day of production, with an increase of the microbial load during the production day, often an increase of 2.0 to 3.0 log CFU/cm^2. The subsequent process, singeing, involves flaming (1,200°C for 15 s) the surface of the skin to remove any residual hair on the carcass. This process can achieve substantial reductions of microbial populations on the carcass hide, which is still intact. Following singeing, the carcasses are sprayed with water while brushes remove any singed hair from the hide surface (polishing), which may result in an increase in microbial populations, as the brushes are not exposed to any antimicrobials throughout the processing day. Subsequent to polishing, the carcasses go through several steps during the evisceration process, and carcass contamination can occur at this stage from the fecal material during the bung (distal colon and rectum) removal process or from the GI contents in subsequent steps. Carcass chilling can have a major impact on the microbial load of a carcass, as the carcasses are placed in a chiller for 18 to 24 h, depending on slaughter volume, carcass size, and cooler capacity. With expanding production volumes and minimal increases in cooler and refrigeration capacities, swine carcasses are frequently placed in the cooler in close proximity, often touching each other. This can be detrimental to the microbial quality of the carcass, as cooling of the carcass surfaces that touch each other as well as the exterior hide surface and the proximate internal cavity of the adjacent carcass is slower, resulting in growth of microbes in areas of the carcass that survived the process or recontaminated the carcass during or after evisceration.

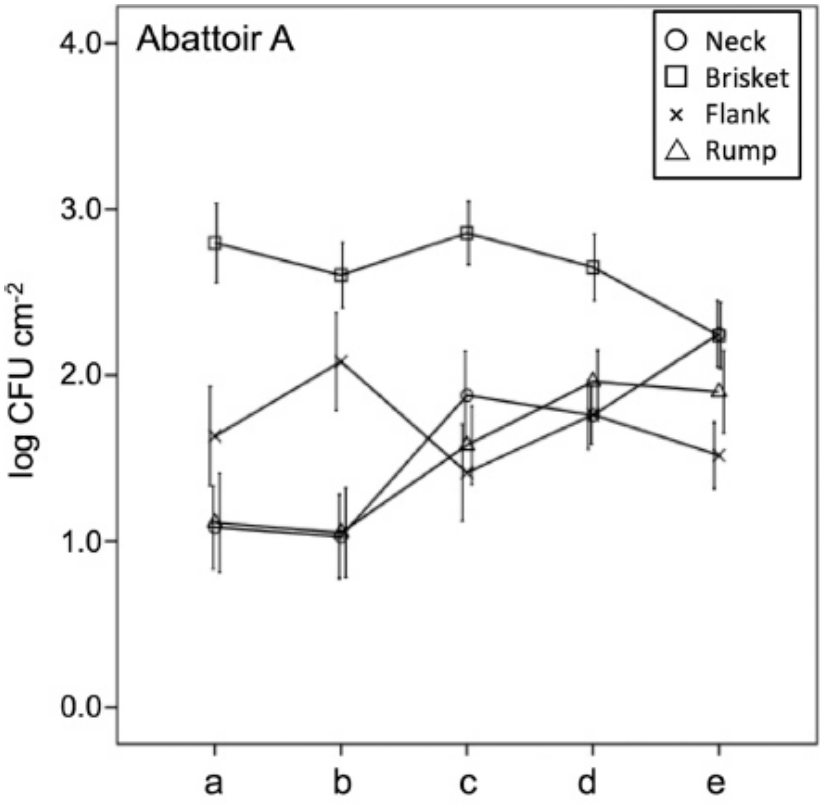
Table 6.1 APCs, total coliform counts, and *Salmonella* prevalence on swine carcasses at different stages of harvest[a]

Stage	APC (log CFU/cm²)	TCC (log CFU/cm²)	*Salmonella* prevalence (%)
Bleeding	6.41	6.17	31
Scalding	2.65	2.42	1
Dehairing	4.75	3.64	7
Singeing	2.20	1.03	0
Polishing	3.31	2.58	0
Evisceration	3.05	3.05	7
Chilling	3.19	2.96	ND

[a] Adapted from reference 7. ND, not detected.

Several swine processors have incorporated antimicrobial interventions throughout the slaughter process to reduce *Salmonella* contamination of the carcasses. Examples of these antimicrobial interventions include steam vacuum systems and organic acid sprays applied before and after chilling and at other steps of processing.

The current U.S. Department of Agriculture Food Safety Inspection Service (FSIS) performance standards for swine processing are based on the prevalence of *Salmonella* on carcasses after chilling. In the most recent nationwide survey of microbial contamination of swine processing operations, the FSIS reported the aerobic plate counts (APCs), *Enterobacteriaceae* populations, total coliform numbers, and *E. coli* populations to be 5.81, 3.01, 2.92, and 2.78 log CFU/cm² and 2.02, 076, 0.73, and 0.67 log CFU/cm² after evisceration and chilling, respectively. In addition, the report indicated there was a reduction in *Salmonella* prevalence from 69.6% (at evisceration) to 2.7% (at chilling), indicating that there was a major reduction of *Salmonella* contamination between the evisceration step and carcass chilling resulting from the application of antimicrobial interventions.



There is minimal information regarding the microbial load on beef carcasses at different stages of the slaughter continuum. However, the

main sources of contamination during the slaughter of beef cattle are the dehiding and evisceration processes. The hide is the primary source of contamination of the beef carcass during slaughter. Microbial populations on hides can vary substantially based on the geographical location of the feedlot, whether the cattle were fed or pasture raised, seasonality, and conditions in the feedlot soil, transportation, and lairage prior to slaughter. Microorganisms on the hides of cattle can be aerosolized in the processing plant, depending on whether mechanized or manual hide removal is practiced, and thereby be deposited on the freshly dehided carcass. Once the microorganisms are deposited, their removal, and more importantly elimination of the foodborne pathogens *E. coli* O157:H7 and other STEC types, is extremely difficult if not impossible. It is reasonable to assume that the carcass surface (interior of the hide prior to dehiding) is sterile or close to being free of microorganisms prior to the dehiding process. Any microbial load on the freshly dehided carcass is most likely the result of contamination through either aerosolization and deposition of the microorganisms on the hide or handling of the carcass by personnel. While the hide can harbor up to 7 log CFU/cm^{2}of microbes, a freshly dehided carcass surface typically has 2.0 log CFU/cm^2 or more microbes, most likely resulting from post-hide-removal contamination (Fig. 6.3).

The evisceration step may further increase the microbial load on the carcass, depending on the hygienic procedures applied. The total microbial populations on the carcass at each stage of the slaughter operation, i.e., on the hide and on carcasses before evisceration, after evisceration, after intervention, and after chilling, were 8.3, 3.8, 3.7, 1.2, and 1.4 log CFU/100 cm^2, respectively, indicating that there was substantial contamination of the carcass from the dehiding step (as represented by the microbial population at the pre-evisceration step) (Fig. 6.4), with minimal change in the cell populations after evisceration; hence, good hygienic practices were in place (8). A substantial reduction in microbial load can be achieved by treatment with effective antimicrobial interventions (in this case, the carcasses were passed through a hot water spray cabinet [90°C] and a peroxyacetic acid [PAA] spray, followed by passage through a steam

pasteurization cabinet). It should be noted that not all beef slaughter operations employ this sequence of antimicrobial interventions; rather, the specific interventions incorporated into the process are plant specific and are based on a variety of factors, such as availability of space on the processing floor, capital investment required, and cost of operation of the antimicrobial treatment, among others.

After the antimicrobial intervention is applied, chilling does not reduce the microbial population. Most beef slaughter operations in the United States chill the beef carcasses in “hot boxes,” whereas some operations in Europe use air blast chilling, in which the carcasses are exposed to a blast of cold air, often at temperatures below 0°C. For swine carcasses, the dynamics of changes in microbial populations on the carcasses during chilling depend on the carcass spacing, ambient temperature, and air movement during the process to enable rapid chilling of the carcass surface. In addition, dehydration of the carcass surface may play a role in minimizing microbial growth during the chilling process. In some beef harvest operations in the United States, the carcasses are spray chilled by applying chilled water to prevent surface drying and to assist in rapid chilling of the carcasses. Many processors are increasingly incorporating antimicrobial chemicals in the water used in spray chill systems to prevent microbial growth on carcass surfaces.

Intact and nonintact products

Most meat from beef and swine carcasses is consumed as intact cuts, such as steaks, roasts, or chops. However, the palatability of such products can vary greatly, depending on the animal from which the meat is harvested. During beef processing, the carcasses are graded based on several factors, of which intramuscular fat is a major criterion, as it determines the juiciness of the cut. In addition, other factors, including the age of the animal, can play a significant role, with steaks and roasts from older aged animals being chewy and less tender, which can easily be detected by the consumer. Thus, processors or purveyors use a variety of methods to tenderize the sub primals (a portion of meat smaller than a side of a carcass) to achieve consistency in tenderness and eating quality of the cooked steaks and roasts.

Traditionally, food preparers cooked pork to higher temperatures to ensure destruction of the parasite *Trichinella spiralis*, resulting in a loss of moisture and a dry product. To enhance moisture retention, pork processors marinate the meat through mechanical means, such as injection with ingredients such as salt and phosphates, to improve juiciness and palatability of the product. The microbiology and food safety risks of such nonintact meat can be substantially different from those of the intact meat products.

A large proportion of beef products (up to 18%) retailed in the United States have been mechanically tenderized or injected with solutions to enhance tenderness and/or flavor of the meat (9). Beef steaks and roasts available at retail in North America may be blade tenderized at central cutting or retail store facilities (10) and may not be recognized as such at the time of purchase or subsequent cooking.

Nonintact beef products have been involved in recalls (12) and several outbreaks of foodborne illness in the United States (13–16) due to contamination with *E. coli* O157: H7 (17). Most beefsteak purchasers

may not notice that certain beefsteaks have been tenderized, or even though they recognize that steaks are tenderized, they may not know of the potential for internal contamination with *E. coli* O157:H7.

A portion of the U.S. population prefer steaks cooked to rare (cooked to an internal temperature of 60°C) or medium rare (cooked to an internal temperature of 65°C) degrees of doneness; in these cases, it is possible that the internalized foodborne pathogens may survive and cause foodborne illness (18, 19). Due to this increased food safety risk, the FSIS declared that nonintact beef products or intact products that are intended for production of nonintact products (such as mechanical tenderization or grinding) are considered adulterated if they contain *E. coli* O157:H7 (20).

Intact meats. Intact meats or cuts are those prepared from larger pieces of meat, such as subprimals (beef or pork), and have not been subjected to further handling or treatment, which would introduce the surface microflora to the interior of the meat cut. Processes such as mechanical tenderization, injection with marinade solutions, and marination with applied vacuum can translocate the microorganisms from the meat surface to the interior of the meat. In the case of intact meat, the microbes are largely on the surface of the product, and hence cooking, which provides higher temperatures at the surface of the meat and for longer periods of time, results in greater lethality at the meat's surface than in the interior. Therefore, cooking to lower degrees of doneness, such as rare, should achieve a lethality adequate to render the meat (steak or chop) safe for consumption. Thus, cooking of intact meat should achieve adequate inactivation of surface microorganisms and lethality, regardless of the cooking method employed.

Nonintact meats. Nonintact meat products can be broadly classified as (i) those that are visually intact subsequent to the processes such as mechanical tenderization, injection, vacuum tumbling with a marinade, tenderizing using proteolytic enzymes, etc., and (ii) those that are chunked and reformed or restructured, ground, chopped, flaked, minced, etc., and do not retain the appearance of intact products. The second category of products are typically cooked to

higher internal temperatures (such as 71.1°C for ground beef) to achieve adequate lethality for *Salmonella* and *E. coli* O157:H7.

The processes that produce nonintact meat cuts translocate surface microbes regardless of the type of microorganism; however, the food safety risk is primarily due to translocation of foodborne pathogens such as *E. coli* O157:H7, STEC, and *Salmonella*. Sporing (21) and Thippareddi et al. (22) were the first to report extensively on the food safety risks of mechanical tenderization, determining that 3 to 4% of the surface microorganisms (*E. coli* O157:H7) can be translocated to the center of the steak when subprimals are mechanically (blade) tenderized before being portioned into steaks.

Numerous studies have revealed the conditions for inactivating *E. coli* O157:H7, STEC, and *Salmonella* during the cooking of nonintact beef and pork products. Inactivation of these microorganisms in such products is dependent on the surface populations of these microbes, the type and thickness of the meat cut (steak or chop), the internal temperature to which the product is heated, the temperature and relative humidity of cooking, the uniformity of temperature during cooking (e.g., cooking on a heated surface such as a flat grill, two surfaces such as on a clamshell grill, in a kitchen oven, etc.), and other factors. Sporing (21) reported that of three cooking methods (i.e., on a gas grill, in an electric skillet, and under an oven broiler), oven broiling provided the most consistent inactivation of *E. coli* O157:H7 on intact and nonintact steaks, regardless of the thickness of the steaks and the target end point cooking temperature. The reductions of *E. coli* O157:H7 in intact and nonintact steaks upon cooking to internal temperatures of ≥ 60°C were similar, indicating that the integrated lethality achieved was adequate to inactivate microbes that translocated to the geometric center of the steak during blade tenderization of the beef rounds. However, using other cooking apparatus, such as a gas grill or electric skillet, that do not uniformly heat the steak surfaces may result in greater differences in pathogen reduction and hence a greater risk of pathogen survival.

A quantitative microbial risk assessment conducted by the FSIS revealed that the probability of *E. coli* O157:H7 surviving typical

cooking practices in either tenderized (mechanical, or blade, tenderized) or nontenderized steaks is minimal. Further, it was reported that 2.6 of every 10 million servings of steaks that are intact (nontenderized) contain one or more *E. coli* O157:H7 organisms, compared to 3.7 of every 10 million servings of mechanically tenderized steaks (23).

Regardless of the conclusions of the risk assessment, the FSIS considers *E. coli* O157:H7 and other STEC types adulterants in nonintact beef. The industry has applied numerous antimicrobial interventions to subprimals that are destined for nonintact beef products to minimize the risk. The efficacy of these interventions to reduce such risk needs to be evaluated and quantified through a quantitative risk assessment. Other measures adopted by the industry include proper chilling of meat and decontamination of injection solutions during reuse, use of antimicrobials in injection brines, effective sanitation and temperature controls, and effective cooking procedures that are based on product characteristics. In addition, manufacturers should follow industry-recommended best practices (24, 25).

General Spoilage of Beef and Pork

Spoilage of food products, specifically meat and poultry products, refers to chemical, enzymatic, and microbial activities that result in visual or olfactory changes in the product. In most cases, spoilage is caused by microbial activity or growth by nonpathogenic microbes in response to the prevailing extrinsic conditions during processing, distribution, and storage of the products. Spoiled food is considered an economic loss, as it is not necessarily unsafe if foodborne pathogens are absent. A report by the Food and Agricultural Organization of the United Nations on global food losses and food waste revealed that an estimated 3.5%, 1.0%, 5.0%, 4.0%, and 11.0% of food is wasted during production, postharvest handling and storage, processing and packaging, distribution (supermarket and retail), and consumption, respectively, in North America (United States and Canada) and Oceania (Australia and New Zealand) (26). While food losses or waste at these stages in the food chain cannot be thought to be due to

spoilage, most of the losses or waste at distribution and consumption are due to spoilage.

During the harvest and further processing of cattle, swine, or poultry into meat, the inherent barriers, both active (immune responses) and passive (e.g., skin, hide, scales, etc.), break down, and the interior is exposed to the environment, resulting in microbial contamination. The degree of processing and the steps involved dictate the type and number of microorganisms on the product and eventually determine the type of spoilage. The degree of processing required as well as the hygiene employed during processing also affects the type of microorganisms and the cell populations of those microbes and hence determines the types of spoilage observed during distribution and storage at the consumer level. Meat and poultry processors have incorporated many antimicrobial interventions that utilize various antimicrobial mechanisms, such as low or high pH, oxidation, high or low temperatures, antimicrobial chemicals, and packaging atmospheres (modified atmospheres such as CO_2 or $N_2$with high or low oxygen), that dictate the types and the growth rates of spoilage microbes and hence the shelf life of the products. In general, only a few microbial types dominate during storage, based mostly on storage temperature and the gaseous composition of the surroundings (27). Aerobic or facultatively anaerobic Gram-negative bacteria such as pseudomonads dominate under cold aerobic conditions, whereas the dominant microflora consists largely of lactic acid bacteria (LAB) in vacuum-packaged products (27, 28).

Most of the microbes present in meat at the time of packaging are a result of contamination during harvest operations and further processing, with the sources being the hide, GI tract, personnel involved in processing, and the processing environment (e.g., surfaces of equipment and air). The types and numbers and hence the proportions of the microorganisms at packaging determine which microbes grow and predominate at the end of the shelf life of the product (Table 6.2). However, microbial growth and the types of microbes that grow in these products are influenced by intrinsic (pH, water activity [a_w], competitive flora, nutrient composition, oxidation reduction potential, etc.) and extrinsic (temperature of storage and

environmental exposure throughout the cold chain, packaging type, gaseous atmosphere, antimicrobial ingredients, and other meat ingredients) properties of the meat.

With the advances in and availability of molecular methods for detection and identification of microorganisms, it is increasingly possible to identify microbes that have evaded detection by traditional cultural methods for foods. While *Pseudomonas* spp., *Carnobacterium divergens*, *Brochothrix thermosphacta*, *Rahnella* spp., and *Serratia grimesii*, or closely related species, are largely detected in fresh beef, *Photobacterium* spp. are largely detected in meat samples stored in air or in vacuum packages (29). Interestingly, testing by microbial culturing of meat specimens has enabled the detection of microbial species (e.g., several species of *Serratia* or *Rahnella* and *Leuconostoc*) that are not detected by analysis of DNA extracted directly from meat (29). Ercolini et al. (30) used random amplified polymorphic DNA-PCR and 16S rRNA gene sequencing and identified 50 mesophilic and 29 psychrotrophic isolates in beef. The most frequently detected species of both the mesophilic and psychrotrophic populations were *Carnobacterium maltaromaticum* and *C. divergens*, whereas *Acinetobacter baumannii*, *Buttiauxella* spp., and *Serratia* spp. were identified among the mesophiles, and *Pseudomonas* spp. were common among psychrotrophs. Doulgeraki et al. (31) isolated 266 LAB from minced beef stored at 0, 5, 10, and 15°C aerobically or in modified-atmosphere packaging (MAP) with an atmosphere consisting of 40% CO_2–30% O_2–30% N_2in the presence or absence of oregano essential oil. *Leuconostoc* was the predominant bacterium isolated during aerobic storage at 5, 10, and 15°C, as well as during MAP storage at 10 and 15°C, whereas *Lactobacillus sakei* predominated during aerobic storage at 0°C, as well as during MAP storage at 0 and 5°C. Other bacteria, i.e., *Leuconostoc mesenteroides*, *Weissella viridescens*, *Lactobacillus casei*, and *Lactobacillus curvatus*, were isolated sporadically. Hence, different microbial species dominate in different environments and contribute to muscle food spoilage as they release different volatile compounds (28).

Spoilage of Fresh Meat

Even with significant improvements and availability of packaging systems, most intact and nonintact fresh meat packaged at retail is packaged aerobically on a tray pack with a plastic film wrap; however, a small portion is also packaged under anaerobic conditions, such as by vacuum packaging. However, most fresh meat packaged at a processing plant is packaged under a modified atmosphere, with vacuum, high oxygen, or low oxygen (the atmospheric composition mainly consisting of carbon dioxide and/or nitrogen). High-oxygen packaging is mainly used for intact meat as well as ground beef products to enhance the bright red color of oxymyoglobin, the meat pigment responsible for the color.

Based on the packaging system used, the predominant bacteria when fresh meat is stored under refrigeration are either *Pseudomonas* spp. (when meat is packaged under aerobic conditions) or LAB (when meat is packaged under vacuum or other MAP conditions) (28) (Table 6.3). However, when the meat pH is affected by stress on the animal (producing dark, firm, dry [DFD] or pale, soft, exudative [PSE] meat), glycolytic reserves, and the rate of cooling of these carcasses, these parameters dictate the type and rate of microbial growth regardless of the type of packaging system and chilled storage method used. The ultimate pH of the DFD and PSE muscles is typically >6.0 and <5.3, respectively, whereas the pH of normal muscle is 5.5 (32). These are significant differences in pH values, and thus, the rates of microbial growth and spoilage are different in these meats regardless of other storage conditions, such as packaging atmosphere and storage temperature.

In the absence of glucose, higher pH values of meat allow more rapid degradation of amino acids by pseudomonads and detection of spoilage at lower bacterial cell densities (6 log CFU) than in normal meat (33). Under vacuum packaging or other MAP conditions, DFD meat spoils rapidly by developing green discolorations due to growth of *Serratia liquefaciens* and *Shewanella putrefaciens*, which outgrow LAB at the higher pH and in the absence of glucose and glucose-6-phosphate (34). The green discoloration is associated with formation of hydrogen sulfide from cysteine or glutathione by *S. putrefaciens*; hydrogen sulfide reacts with myoglobin to form green sulfmyoglobin.

S. liquefaciens, even at low populations, produces small amounts of hydrogen sulfide that are associated with DFD meat spoilage (34). However, for normal and PSE meats, the spoilage is dictated by the storage temperature and the packaging system used, with pseudomonads (for aerobically stored products) and LAB (for anaerobically stored products) being the predominant spoilage organisms.

[b] +, positive; −, negative.

[c] X, known to occur; XX, most frequently isolated.

Comminuted products, including ground meat, spoil faster than externally contaminated intact meat cuts because of higher levels of initial contamination present in trimmings from beef that had large surface areas exposed to contamination, cross-contamination among trimmings, microbial spreading during grinding, and the release of fluids and nutrients from cells ruptured due to grinding (28, 35, 36). The types of dominating microorganisms and spoilage defects are similar in intact and comminuted products of the same origin. Dominant microflora members in aerobically stored comminuted products include *Pseudomonas*, *Acinetobacter*, and *Moraxella*, whereas LAB dominate in the interior due to oxygen limitation. *Enterobacteriaceae* are more frequently present in comminuted than in intact products. Spoilage microbes dominating in spoiled refrigerated fresh sausage are similar to those present in other fresh meats but may also include *B. thermosphacta* (28).

Meat Spoilage by Psychrotrophic Clostridia

While certain species of clostridia are well recognized as major food safety concerns due to toxin production, others, known in general as psychrotolerant clostridia, cause spoilage in vacuum-packaged meats such as deep tissue or bone taint spoilage. Some clostridia also cause surface spoilage and blown-pack spoilage (37). These unusual types of spoilage of vacuum-packaged refrigerated fresh and cooked meat and poultry products are caused by psychrophilic, psychrotrophic, or psychrotolerant clostridia, such as the generally closely related species *Clostridium laramie*, *C. beijerinckii*, *C. lituseburense*, *C. algidicarnis*, *C. algidixylanolyticum*, *C. estertheticum*, *C. frigidicarnis*, and *C.*

gasigenes, which can germinate, grow, and sporulate at 2°C or lower (0°C) in meat at a normal pH (38, 39). As the meat undergoes proteolysis,

[a] Adapted from reference 147.

[b] An "X" indicates the occurrence of the microorganism under the specified storage conditions. A microorganism is considered to occur if, according to the literature, it was identified at least once under the specified conditions regardless of the time of storage.

[c] Nisin-activated antimicrobial packaging (11, 304); in other works on antimicrobial packaging, species identifications were not performed.

the spoilage is characterized by muscle softening, excessive production of hydrogen sulfide ((blown pack, especially by *C. estertheticum* and *C. gasigenes*), associated offensive odors, and release of purge or exudate, while the color of the purge changes from an initial pinkish

red to green (38, 40, 41). Such spoilage has occurred in the United States, Europe, South Africa, and New Zealand. The microbes involved are not considered pathogenic, but the meat is organoleptically unacceptable.

Blown-pack spoilage (where the packaging material of vacuum-packaged meat is distended by massive gas formation during refrigerated storage) has been reported for beef primal cuts, lamb, venison, cooked hot dogs, precooked turkey, roast beef, and sous vide products, resulting in major financial losses, as the meat is unacceptable for consumption. Initially, contaminated product spoils on the surface, with little gas accumulation (surface spoilage), and the bacteria are found in the purge or by swabbing the meat surface. Blown-pack spoilage occurs sporadically and in only a fraction of the product in a consignment. This indicates that contamination with spores is sporadic and that there is a need for specific conditions that allow spore germination and growth (37, 42). While postpackaging heat-shrink treatments of vacuum packaged meats have been reported to accelerate the onset of clostridial blown-pack spoilage (37), this is debatable, because the temperature on the meat surface in contact with the film does not increase significantly, as the meat is at very low temperatures. Prediction or prevention of this type of spoilage is still difficult. Good management practices during meat processing are not always sufficient for its prevention, as some believe that the source of the organism is the feedlot or pasture soil that is carried to the processing operation on the cattle hide. Avoiding higher temperatures (90°C for 3 s or 70°C for 10 s) during heat shrinking of packages, which could stimulate spore germination, and storing vacuum-packaged meats at lower temperatures (e.g., –1.5°C) have been recommended to minimize the risk (40, 41).

Spoilage of Processed Meats

Spoilage defects of processed meats, including frankfurters, bologna, cooked or fermented sausage, and luncheon meats, include slime, souring, and greening. Slime is usually confined to the surface of the product and is associated with growth of yeasts, *Lactobacillus*, *Enterococcus*, and *B. thermosphacta* in the presence of moisture (28).

These microbes metabolize sugars to produce organic acids that result in souring on product surfaces under casings or packaging films. While greening of fresh meats may be due to hydrogen sulfide production, greening of nitrite-cured meat products may develop in the presence of hydrogen peroxide. The reaction product, which is formed during growth of catalase-negative bacteria when surfaces of vacuum-packaged or MAP products are exposed to air, reacts with nitrosohemochrome to produce green choleglobin. This is possible because muscle catalase, which breaks down hydrogen peroxide, is inactivated during cooking. The most common causative agents of such greening are *W. viridescens* and species of *Streptococcus* and *Leuconostoc*, which may be introduced into the product before or after processing (28).

Putrid spoilage of cured meats by Gram-negative psychrotrophic bacteria under refrigeration is inhibited by reduced a_w (43). These products, however, are spoiled by lower-a_w-tolerating lactobacilli or micrococci. While lactobacilli predominate in spoiled vacuum-packaged or MAP products, aerobic micrococci predominate on cured meats stored aerobically. Inclusion of glucose in cured meats allows the formation of a slimy dextran layer by *Leuconostoc* species or other bacteria, including *B. thermosphacta*. Dry-cured products are spoiled mostly by yeasts and molds, because the low a_w, presence of nitrite, and exposure to smoke suppress bacterial growth (44). Growth of spoilage fungi in these products may be inhibited by the addition of antifungal agents. Drycured meats may also be spoiled by microbial growth which occurred before proper and adequate salt penetration, curing, and drying, whereas when properly prepared and stored, dried meat products remain stable. Xerotolerant molds are inhibited at moisture contents of about 15% and below (28).

Foodborne Pathogens

The microbial pathogens of greatest concern in beef and pork meat include *E. coli* O157:H7, non-O157 STEC, *Salmonella*, *Campylobacter*, *Yersinia enterocolitica*, and *Listeria monocytogenes*. While other bacteria, such as *Staphylococcus aureus*, *Clostridium perfringens*,

Bacillus cereus, other *Bacillus* spp., *Clostridium botulinum*, *Aeromonas*, *Arcobacter*, *Brucella*, *Shigella*, *Enterobacter*, *Plesiomonas shigelloides*, *Helicobacter*, and potentially *Mycobacterium* and *Clostridioides* (formerly *Clostridium*) *difficile* (45–47), may be associated with and isolated from meat and meat products, they are not among the majority that have caused foodborne illnesses. Swine can transmit the parasitic agents of trichinosis (*T. spiralis*), sarcocystosis (*Sarcocystis* spp.), and toxoplasmosis (*Toxoplasma gondii*), and beef cattle can transmit tapeworms (*Taenia* spp.), *Sarcocystis* spp., and, especially through fecally contaminated water, *Cryptosporidium parvum* (cryptosporidiosis). Viral agents, such as norovirus, hepatitis A virus, and enteroviruses, cause most foodborne disease cases in the United States, more than bacteria or fungi, but their transmission is mostly associated with poor sanitation, cross-contamination from infected food handlers during preparation and serving, or inadequate cooking (35, 36, 48–50).

According to the U.S. Centers for Disease Control and Prevention (CDC), the pathogens (and some associated foods) responsible for most foodborne illness are *Campylobacter* (poultry), *E. coli* O157:H7 (ground beef, leafy greens, and raw milk), *L. monocytogenes* (deli meats, unpasteurized soft cheeses, and produce), *Salmonella* (eggs, poultry, meat, and produce), *Vibrio* (raw oysters), norovirus (many foods; e.g., sandwiches and salads), and *Toxoplasma* (meats). Viral pathogens are of major concern in food service (largely from contamination by food handlers), whereas bacterial pathogens such as *E. coli* O157:H7 and other STEC types, *Salmonella*, and *Campylobacter* continue to be of importance in the safety of raw meat and poultry, as does *L. monocytogenes* in ready-to-eat (RTE) processed meat and poultry products (www.cdc.gov/foodsafety).

Muscle food safety challenges may be associated with changes in food animal production and product processing and distribution practices, including aquaculture; increased international food trade; changing consumer needs and preference for minimally processed products; increased worldwide muscle food consumption; large numbers of consumers at risk for infection; emerging pathogens and pathogen changes that may be associated with increased virulence and

resistance to control or clinical treatment; advances in microbial detection methods; inadequate food handler and consumer education and training in proper food handling; and increased interest, awareness, and scrutiny by consumers, the news media, and consumer activist groups (50–53).

The presence of biogenic amines, such as histamine, putrescine, spermidine, and spermine, can also be a hazard associated with consumption of stored muscle food products. Amines found in fresh meat and fish products (primarily scombroid species such as tuna, mahi-mahi, and mackerel) in aerobic, vacuum, or MAP storage may lead to scombroid poisoning, a severe, and sometimes fatal, allergic reaction. Biogenic amine formation in some products has been attributed to *Enterobacteriaceae*; however, tyramine can also be formed by some strains of *Lactobacillus* (28). Proper sanitation and storage temperature and time should minimize human health problems associated with biogenic amines in muscle foods (54).

Antimicrobial Interventions

Most beef and pork processing operations in the United States have incorporated, as a result of implementing hazard analysis and critical control point (HACCP) systems, interventions to reduce the prevalence and concentrations of food safety hazards, which in most cases are foodborne pathogens that are "reasonably likely to occur." The microbiological food safety hazards addressed in HACCP plans include *E. coli* O157:H7, STEC, *Salmonella*, and *Campylobacter*. While some antimicrobial interventions may have been in place prior to implementation of an HACCP system, there has been a major increase in adopting antimicrobial interventions, with as many as a series of three to five treatments applied at different stages of production or processing. This is termed a multiple-hurdle approach and includes total or partial external animal washing or hair removal or hideon washes after exsanguination, followed by decontamination techniques applied to carcasses immediately after hide removal but before evisceration, as well as at the end of the dressing process or before and during carcass chilling. Beef processors have incorporated these treatments in spray chilling systems as well as on chilled carcasses

before boning and on meat cuts and trimmings prior to packaging or before grinding or processing into nonintact products (50, 55). These antimicrobial interventions include those applied on the hide (acid, alkaline sprays, or hypobromous acid), those used pre-or postevisceration (e.g., hot water, saturated steam, organic acids, and combinations with mineral acids and oxidizers such as acidified sodium hypochlorite, hypobromous acid, or PAA), and those used on chilled carcasses, subprimals, and/or trimmings destined for grinding into ground or comminuted products (e.g., organic acids such as lactic, citric or some combinations with mineral acids, acidified sodium hypochlorite, PAA, and lauric arginate). While several others, such as chlorine or chlorine dioxide, trisodium phosphate (TSP), hydrogen peroxide, ozone, and lactoferrin, have been evaluated, they are not currently being used.

The effectiveness of these treatments in reducing microbial contamination is affected by factors such as water pressure, temperature, the chemicals and their concentrations used, duration of exposure, method of application, and time or stage of application during processing (55). Decontamination interventions, such as hot water, steam, acetic acid, or lactic acid, reduce bacterial cell populations by 1 to 3 log CFU on carcasses. Importantly, decontamination must be implemented as part of an integrated food hygiene system and should be based on the use of multiple sequential interventions at different points during slaughter (55–62).

According to the FSIS, decontamination agents may be approved for use if they (i) are generally recognized as safe, (ii) do not result in adulterated product, (iii) do not create a need for labeling (i.e., added ingredients), and (iv) can be documented with scientific studies as being effective (55, 63). EU regulations, in principle, allow application of water, including hot water, and chemical solutions for decontamination of carcasses. However, each proposed application needs to be individually approved, and chemical decontamination should be followed by a water treatment to remove residues in order to avoid the need for labeling (35, 64–66). The following are issues that should be addressed when decontaminating agents are being selected, approved, and used: (i) the safety of the application relative

to workers, the environment, and consumers; (ii) potential undesirable effects on product quality; (iii) the potential for spreading and redistributing bacterial cells over the carcass surface or their penetration into the tissue; and (iv) the potential development of stress-resistant pathogenic bacteria (28, 55, 67).

Poultry

Consumption of poultry meat is steadily increasing worldwide, with trends suggesting a shift from whole chickens to further processed (not RTE) products such as parts, i.e., skin-on and skinless products. With further handling of poultry meat, there are increased risks of contamination; thus, such processing requires additional controls to prevent cross-contamination and ensure the microbial safety of poultry meat products.

General Ecology of Poultry

Live poultry naturally harbors microorganisms that are native to their skin, feathers, and feet, as well as other microflora obtained through contact with litter and feces during grow out. The chances for microbial carriage to the slaughterhouse are high, due to cross-contamination in live handling and transportation. This initial microbial load can be concerning for poultry producers, as large numbers of bacteria can decrease the effectiveness of antimicrobial interventions implemented in the processing plant. Most of the microflora present in birds upon slaughter causes meat spoilage and overall quality loss. However, pathogenic bacteria of public health concern are also commonly found in poultry and can persist from farm to processing. The most prevalent foodborne pathogens associated with the consumption of poultry meat are *Salmonella* spp. and *Campylobacter* spp., followed by *S. aureus*, *C. perfringens*, and *L. monocytogenes* (68). The latter is present most frequently in RTE products that have been contaminated during or postprocessing. In recent years, *Aeromonas* spp. have emerged as human pathogenic bacteria isolated from poultry meat products (69).

Poultry Harvest and Slaughter The goals of poultry processing are to ensure the microbiological safety of carcasses while maximizing product yield and nutritional and sensory quality. Poultry processing is an extremely complex and fast-paced operation, where production efficiencies are complemented by good manufacturing practices (GMPs) and other food safety programs to ensure safety and quality of processed poultry. Figure 6.5 shows the primary steps involved in slaughter of poultry. Spoilage and pathogenic bacteria enter the processing plant mainly through live birds that have been contaminated at the farm or during transport. As birds move through each step of the processing system, every effort is made to prevent cross-contamination with or reduce the prevalence of spoilage and pathogenic microorganisms. The success of eliminating bacteria from carcasses or preventing their transfer from carcass to carcass depends on the specific conditions used in each stage of processing.

Transportation and unloading

Processing begins with capture of live birds at the farm and transport to the plant. Birds are loaded into transport units, such as plastic crates or steel cages, and then loaded onto trucks for hauling to the processing plant. These transport units can be an important source of contamination before arrival at the plant. Containers can quickly become contaminated by fecal matter containing high populations of pathogens, such as *Campylobacter*, *Salmonella*, and *E. coli* (70–73). These pathogens can be spread to other birds held in the same or adjacent crates (74, 75). To prevent such contamination, birds should be transported in clean crates lined with single-use paper liners (76). To ensure cleanliness, crates should be cleaned and disinfected between uses. A two-stage approach that first cleans and then disinfects crates is best. Ramesh et al. (77) determined that manually cleaning crates with a high-pressure jet spray of disinfectant solution alone did not substantially reduce coliform levels. However, subsequent immersion of precleaned crates in hot water (60 or 70°C) or sodium hypochlorite (1,000 ppm) did significantly reduce coliform levels. Similarly, Allen et al. (78) determined that the most effective treatment to remove *Campylobacter* from transport crates was the

combination of soaking, brushing, and washing followed by application of disinfectant. However, studies have revealed that some pathogens can survive cleaning and disinfecting of crates (75, 79–81).

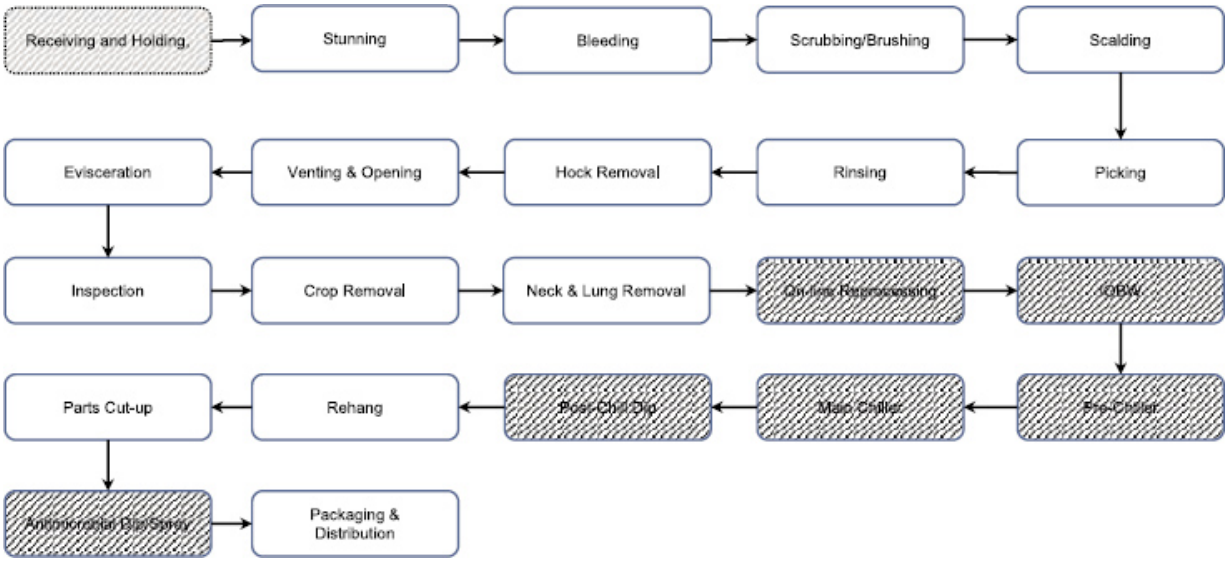

Figure 6.5 Unit operations for primary processing of poultry. IOBW, inside-out bird washer.

Once the birds arrive at the plant, they are unloaded and hung on shackles. High levels of bacteria on birds at this stage of processing can overwhelm plant interventions and be carried to subsequent stages of processing (72, 82). Birds are “dumped” from transport crates onto conveyors where they can become contaminated by aerosols or condensation from equipment or the ceiling (64). Controlling air flow from inside to outside the facility may help avoid condensation as well as prevent cross-contamination (76). Additionally, employee interventions, such as training, changing clothes and boots upon arrival, separate facilities for “dirty” and “clean” employees, and restricting employee movement, can limit cross-contamination (76).

Stunning

Stunning renders birds unconscious prior to killing. The most common method for this is electrical stunning in a water bath containing saline. Electrical stunning renders birds unconscious for 60 to 90 seconds, during which time the neck is cut, allowing them to

bleed out. Other methods of stunning have been developed. One such method is gas stunning, or controlled-atmosphere stunning. These methods lead to a gradual unconsciousness instead of immediate unconsciousness. Different gas combinations are used, including carbon dioxide alone or carbon dioxide in combination with inert gases, i.e., argon, nitrogen, or both. Another method is a low-atmosphere pressure system, which removes air from a sealed chamber gradually, rendering the birds unconscious (83). Wing flapping and quivering can occur during electrical stunning as well as controlled-atmosphere stunning, which may lead to transfer of bacteria from the inside to the outside of birds, to nearby birds, and to equipment.

Scalding

Scalding prepares carcasses for defeathering by opening feather follicles. Carcasses move through one or more scalding tanks filled with hot water. “Soft” scalding occurs at 53.35°C for 120 s, while “hard” scalding occurs at 62 to 64°C for 45 s. This is the first location where birds are exposed to a common bath, which can allow transfer of bacteria from carcass to carcass (84). Due to the high level of organic load in the scalders, including fecal matter, the scalding step can be a major source of cross-contamination, with limited opportunities to use any antimicrobials due to the high temperature of the scalder water.

Defeathering

In the defeathering process, high-speed rotating metal discs with rubber fingers operate to remove the feathers, which have been loosened by scalding. Abrasion by the rubber fingers against the carcass pulls outloose feathers, exposing the feather follicles. Berrang and Dickens (85) reported that this is the only processing step during which *Campylobacter* spp. populations increase; this can be attributed to either cross-contamination from rubber fingers or exposure of the feather follicles.

Evisceration

At the evisceration stage of processing, the edible and inedible viscera are removed from the carcass. This is a highly automated unit operation in modern poultry processing, and its success is strongly dependent upon uniformity of the size of the carcasses. At this stage, if the GI tract is exposed, fecal contamination of the carcasses can occur. Other sources of cross-contamination at this step include the equipment and employees, and the proportion of *Salmonella*-positive carcasses can increase at this stage (86).

Chilling

The goal of the chilling stage is to reduce the temperature of the carcass to below 4.4°C, and this is typically a critical control point in the overall HACCP plans of processing plants. Chilling is the final important step for initial processing of whole-carcass broilers; it is designed to bring the product temperature below 4°C to prevent the growth of microorganisms. The FSIS recommends that the time required to reach 40°F (4.4°C) should not exceed 4 h for birds weighing <4 lb, 6 h for birds weighing 4 to 8 lb, and 8 h for birds weighing >8 lb (87).

Immersion chilling and air chilling are two methods used for this process, with the former being used most commonly in the United States and the latter being commonly used in Europe. The two chilling systems significantly determine the microbial quality and safety of poultry carcasses. Due to the extensive bird-to-bird contact in a water immersion chilling system, there is a greater potential for cross-contamination between carcasses than during air chilling, where carcass-to-carcass contamination is less likely.

General Spoilage of Poultry

Food spoilage is an important economic issue, with an estimated one-third of global food products being wasted annually (88), and it has been estimated that microbial spoilage causes 25% of allpostharvest food loss (89). Given this massive problem, it is important to study the underlying mechanisms of spoilage to facilitate development of novel technologies and techniques for improved food preservation and mitigation of postharvest losses. Poultry meat, especially parts

containing skin, is known to have a higher microbial contamination rate than beef and pork, thus making poultry meat highly perishable, even under refrigeration (90).

Meat spoilage is a natural process of decomposition that is caused by endogenous enzymatic activity in the muscle and by growing microorganisms that metabolize organic molecules in the muscle tissue (91). This process of food degradation results in the production of organic molecules, such as amines, sulfides, alcohols, aldehydes, ketones, and organic acids, which impart undesirable organoleptic characteristics (89, 92). Examples of characteristics that are affected by spoilage include color, odor, texture, and flavor, as well as any other feature that contributes to consumer acceptability of a food product (89). Although spoilage generally encompasses these characteristics, consumer acceptability is influenced by cultural and individual tastes and by economic factors; thus, the definition of spoilage is subjective to some degree (92).

Mechanisms of Meat Spoilage

Microbes that cause spoilage can be introduced to the product from many different sources, but the main source is the animals themselves at the time of slaughter. The intestines, skin, and feathers of birds harbor spoilage bacteria, which are readily introduced into the product during processing steps such as scalding, defeathering, crop removal, evisceration, and chilling (93). Minimally processed meat products provide ideal environmental conditions for microorganisms and spoil quickly unless they are modified or stored in a manner to prevent microbial growth (92). Characteristics of fresh meat products that contribute favorably to microbial growth include a high a_w of 0.99 and a pH range of 5.5 to 6.5, and these products contain numerous energy sources, such as sugars, amino acids, and nucleosides, in addition to many vitamins and minerals (91). The most common microbes associated with spoilage include *Pseudomonas* spp., *Enterobacteriaceae*, *B. thermosphacta*, and LAB, which are collectively referred to as ephemeral spoilage organisms (ESO) (29). Oxygen availability is an important factor for ESO metabolism; therefore,

vacuum packaging can be useful for limiting ESO growth and lengthening the shelf life of poultry products (94).

Foodborne Pathogens

Salmonella

Salmonella belongs to the family *Enterobacteriaceae* and is classified as a Gram-negative, facultatively anaerobic, motile rod. Salmonellae are mesophilic and grow optimally at 35 to 37°C but can adapt to diverse niches and environmental conditions (95). The genus *Salmonella* comprises the species *Salmonella enterica* and *Salmonella bongori*. The former, being the species most commonly associated with human disease, has more than 2,500 serovars according to estimations from the CDC (96). Serovars of *S. enterica* can be further classified as typhoidal or nontyphoidal, according to their diseaseinducing nature in humans. The typhoidal *Salmonella* serovars, *S. enterica* serovars Typhi and Paratyphi, cause enteric fever, whereas nontyphoidal serovars are responsible for the gastroenteric disease referred to as salmonellosis. The most common causative agents of nontyphoidal salmonellosis in the United States are *S. enterica* serovars Enteritidis, Typhimurium, Newport, and Heidelberg (97). Surveillance reports from the FSIS highlight the prevalence of *Salmonella* serovars in poultry products, with *S. enterica* serovars Kentucky, Enteritidis, Typhimurium, and Infantis being the most commonly found in broilers (98). Human infections caused by nontyphoidal *Salmonella* result in acute gastroenteritis characterized by nausea, vomiting, abdominal cramps, diarrhea, and fever. An illness onset time ranging from 4 to 72 hours after contaminated food or water is consumed is typical. The illness can last up to 7 days if it is noninvasive, but cases of septicemia in highly susceptible patients have been reported (99, 100). While common in nature, *Salmonella* has its main reservoir in the GI tracts of animals, including poultry.

Thus, consumption of contaminated poultry meat and eggs has continuously been an important route of *Salmonella* transmission to humans and source of salmonellosis outbreaks (101). With the global consumption of poultry and globalization of poultry meat trade

increasing (102), the industry faces major challenges in the control of *Salmonella*. Traditionally, regulatory efforts to reduce the prevalence of *Salmonella* in poultry have been heavily focused on processing; however, a preharvest approach has been implemented in recent years in hopes of reducing the persistence of the pathogen (76, 103).

Campylobacter

Campylobacter is a foodborne pathogen belonging to the family *Enterobacteriaceae*. It is characterized as a Gram-negative, mesophilic, spiral rod that requires microaerophilic conditions to grow. While susceptible to numerous environmental conditions, *Campylobacter* spp. can easily multiply inside their hosts (104). In particular, the GI tract of poultry is considered a major reservoir for *Campylobacter* (65). In 2012, the World Health Organization reported *Campylobacter* to be the leading causative agent of bacterial gastroenteritis worldwide (105). Humans develop campylobacter enteritis through consumption of contaminated foods or water and experience symptoms of disease after 24 to 72 hours (106). The disease is a self-limiting gastroenteritis, characterized by diarrhea, cramps, and fever, with an infectious dose as low as 800 CFU (107). Serious sequelae of *Campylobacter* infections include the autoimmune disorder Guillain-Barré syndrome. An estimated 20 to 40% of Guillain-Barré syndrome cases are derived from *Campylobacter* infections, substantially increasing the total economic burden of *Campylobacter* infections (108).

According to the CDC and the European Food Safety Authority, there is sufficient evidence to consider *Campylobacter* a foodborne safety hazard linked to poultry meat, with the most prevalent species being *Campylobacter jejuni* and *Campylobacter coli* (97, 109). Vertical transmission of *Campylobacter* in poultry is uncommon, with flocks becoming positive after 2 weeks of age. This foodborne pathogen, however, can spread quickly and colonize flocks through horizontal transmission and persist through transport to the processing plant (85, 110). Higher loads of *Campylobacter* in incoming birds increase the risk of cross-contamination during processing; additionally, the known persistence of the pathogen in carcass skin is of concern.

Hence, preharvest interventions and improvement of pathogen reduction interventions during transport and slaughter are needed.

Staphylococcus aureus

S. aureus is a Gram-positive, aerobic coccus that is a commensal bacterium on the skin and mucosal areas of mammals (96). Certain strains of *S. aureus* can, however, cause infections in poultry, such as tenosynovitis and omphalitis (111, 112). In humans, strains of this pathogen can produce an enterotoxin that induces GI illness upon consumption of foods containing the preformed toxin, and some of these strains have been detected in poultry meat (113, 114). Strains prevalent in poultry, however, have a low incidence of foodborne infections in humans (115). The link between *S. aureus* human infections and poultry appears to be the contamination of poultry carcasses during processing due to improper handling practices (116). Recently, concerns have been raised regarding the occurrence of multidrug-resistant *S. aureus* in poultry and meat production (117). Hence, implementation of and compliance with existing standard operating procedures and GMPs regarding sanitation during poultry processing are crucial.

Clostridium perfringens

Much of the attention that *C. perfringens* has received from the poultry industry is due to an increasing incidence of necrotic enteritis associated with antibiotic-free poultry production practices (118). However, *C. perfringens* is also an important cause of foodborne illness and can be transmitted to humans through consumption of contaminated poultry products (96). This pathogen is a Gram-positive, anaerobic, spore-forming bacterium. *C. perfringens* causes a GI toxicoinfection in humans when large numbers of the organism are consumed (>6 log CFU) (119). In the GI tract, spores of this pathogen can revert to their vegetative state and produce an enterotoxin that induces profuse, watery diarrhea (119). It is its spore-forming ability which makes this pathogen a concern for poultry processors. *C. perfringens* spores can survive thermal processing and persist in the final cooked product. In poultry processing, this scenario likely can

occur when large batches of product are insufficiently cooked and cooled. If the cooling rate during postprocessing is low and the product is temperature abused, spores can easily germinate, leading to potentially large numbers of vegetative cells in the final product that can produce the enterotoxin.

Listeria monocytogenes

L. monocytogenes is a widely distributed foodborne pathogen, and as such, it occurs commonly in poultry processing environments (96, 120). Characterized as a Gram-positive, facultative anaerobic, nonsporulating rod-shaped bacterium, *L. monocytogenes* is an opportunistic pathogen affecting mainly immunocompromised individuals. The disease caused by *L. monocytogenes*, i.e., listeriosis, is often manifested as a flu-type illness in healthy individuals. However, children, elderly persons, pregnant women, and other individuals with a weakened immune system can develop a systemic infection that may eventually lead to death (121). As a psychrotroph, *L. monocytogenes* can grow at a wide temperature range, including refrigeration temperatures (4°C). This pathogen is known to persist in cold and damp environments within poultry processing facilities and delis and has been commonly isolated from floor drains, refrigerators, and freezers (122, 123). Therefore, RTE poultry products that have the potential to be contaminated with the pathogen postprocessing are of great concern. To minimize the risk and incidence of disease associated with this pathogen, the USDA has implemented a "zero-tolerance" rule for *L. monocytogenes* in RTE meat and poultry products. The industry applies a zero tolerance, or <1 CFU/25 g of RTE product, for all *Listeria* species, to ensure control of *L. monocytogenes*.

Antimicrobial Interventions

Similar to antimicrobial interventions used for beef and pork processing, poultry-related food safety hazards such as *Salmonella* and *Campylobacter* are largely controlled by implementing HACCP plans and other food safety programs that include chemical interventions. The most widely used chemicals in the poultry industry include PAA,

cetylpyridinium chloride (CPC), chlorine, and to a lesser extent chlorine dioxide, citric and lactic acid, bromine, and TSP.

Chlorine has been used for more than 50 years in the poultry industry as an antimicrobial, and its application is still one of the most popular and effective methods used for pathogen reduction on poultry carcasses. Low cost and availability make chlorine an easy choice as an antimicrobial in immersion chillers and other large tanks. The FSIS acceptable levels of free residual chlorine are 50 ppm in bird washers and incoming potable water to the main chiller and 5 ppm in the reuse water or red water entering the prechiller (124). The efficacy of chlorine is dependent on several factors, including the pH of the water, the organic matter in the water, and the time in contact with the bacterial cell. The higher the amount of free residual chlorine in the water, the more effective the chlorine is as an antimicrobial; however, too high a level of free residual chlorine in the water can produce a hazardous amount of chlorine gas emanating from the immersion tanks. Northcutt and Jones (125) determined that a free available chlorine concentration of 50 ppm had no effect on *Campylobacter* and *Salmonella* levels when used in an inside-outside bird washer with a contact time of 5 seconds. Mead et al. (126) also observed that 10 to 20 ppm of chlorine had little to no effect on carcass contamination when used in a postevisceration spray.

PAA is one of the most widely used antimicrobials in the poultry industry. PAA is typically introduced into the water as a combination of peracetic acid and hydrogen peroxide, creating equilibrium in the water. The mixture works as both an oxidizer and an acid, disrupting the permeability of the cell membrane and altering protein synthesis. At 85 ppm in chiller water, PAA reduced *Salmonella* on carcasses by 92% and *Campylobacter* on carcasses by 43% (127). *Salmonella* on broiler carcasses was reduced by 2.1 log CFU/ml and *C. jejuni* on carcasses was reduced by 2.0 log CFU/ml after exposure to 1,000 ppm of PAA for 20 seconds in a postchilling immersion tank (128).

TSP is a mixture typically used as a spray in online reprocessing or bird rinse treatments. The FSIS has approved the use of a 12% solution of TSP on poultry carcasses; however, there are several negative

aspects of its use. When residual TSP on the poultry carcasses enters the immersion tanks, it raises the pH of the water to more than 11.0, thereby reducing the antimicrobial effectiveness of any other chemicals (such as chlorine) used in conjunction. Additionally, the phosphate concentration of the waste water of a processing facility increases, requiring further treatment to prevent pollution (129).

CPC is a quaternary ammonium compound (typically used in oral antiseptics) recently approved for use to treat the raw surface of poultry carcasses. The antimicrobial effectiveness of CPC has been determined for *Campylobacter* and *Salmonella*. Arritt et al. (130) obtained a 2.89-log CFU/ml reduction of *C. jejuni* on chicken skin when 0.5% CPC was applied. Beers et al. (131) determined that an application of 0.5% CPC to prechilling broiler carcasses reduced *Campylobacter* and *Salmonella* prevalence from 98% and 34% on untreated carcasses to 8% and 9% on CPC-treated carcasses, respectively.

PROCESSED MEAT PRODUCTS

Processing of meat and poultry products originated from the need to preserve the meat during prehistoric times and basically relied on drying to reduce a_w and on cooking to destroy the microorganisms and improve shelf life of the processed products. Other processes, such as fermentation and curing, developed over the centuries in Europe and other parts of the world and spread throughout the world.

The term “processed meat” refers to a variety of meat and poultry products that have diverse product characteristics, such as pH, a_w, and presence of secondary inhibitors; they can further be distinguished by the thermal treatments they receive—mild heat treatment (not fully pasteurized), pasteurization, and commercial sterilization.

The type of meat, ingredients, and processes used determine the types of microorganisms that survive processing and those that can grow and cause spoilage.

Thermally Processed Products

Types of Products

Advances in processing of meat and poultry have been made through the centuries by developing new techniques and technologies (e.g., fermentation or acidification, thermal processing, drying, and refrigeration) to prepare products with specific characteristics based on the raw materials (e.g., meat species and animal part used such as pork jowls, etc.) and ingredients (e.g., spices, smoke application, water addition, other functional ingredients such as phosphates, nitrite, erythorbate, etc.) used. Although major advances have been made in our understanding of the behavior of muscles and muscle proteins, ingredients used in processing, and processing technologies, meat processing, especially thermal processing of meat products, still remains an art form. A partial list of products and the processes used to prepare these products and the process category is provided in Table 6.4.

While most traditional products include thermal processing and repackaging of products subsequent to cooking, over the past 3 decades, the use of sous vide processing for the manufacture of pasteurized products has increased. While most of these products are prepared in restaurants and sold directly to consumers, some products are commercially manufactured and marketed through retail channels. These products present a different microbial challenge, because while sous vide processes can destroy vegetative cells, spores can survive and can cause spoilage and potentially foodborne illnesses.

Processing and Ingredient Effects

The source and type of meat, the ingredients used in preparation of the product, and the process determine the types of microbes that can survive in the product or contaminate it after processing and proliferate in the product under a variety of storage conditions (Table 6.5).

Typically, the ingredients used in these products can be salt, acidulants, spice and spice flavorings, flavor enhancers (monosodium glutamate and hydrolyzed animal or vegetable protein concentrates), antioxidants (synthetic or natural), water binders (phosphates,

starches, collagens, hydrocolloids, etc.), protein substitutes and enhancers (protein fractions from soy, corn, or milk and milk products), curing agents (nitrates and/or nitrites), cure accelerators (erythorbates or ascorbates), humectants and/or sweeteners (corn syrup solids, alcohols of sorbitol, and other sugars), dehydrated meat or poultry products (stocks), and antimicrobial agents (salts of organic acids). Use of these ingredients and the proportions used can vary, and when they are used, the characteristics of the resulting product (pH, a_w, antimicrobial ingredients, etc.) determine the type of microorganisms surviving the process, whereas the processing environment introduces microorganisms to the product by post-processing contamination. These are the two principal contributors to the types and populations of spoilage microorganisms that will be in the product subsequent to storage.

Foodborne Pathogens and Contamination

Thermally processed meat products are typically pasteurized, with the process being designed to destroy vegetative foodborne pathogens of public health concern, including *E. coli* O157:H7, STEC, *Salmonella*, *Campylobacter*, *S. aureus*, and *L. monocytogenes*, among others. The performance standards for lethality for such products are 6.5-and 7.0-log reductions in *Salmonella* spp. for beef and pork products and for poultry products, respectively (Table 6.6). Thus, the process should inactivate the foodborne pathogens and concurrently reduce or eliminate most of the vegetative spoilage Sausage casings Microbial populations in natural casings for sausages production *Vagococcus*, *Clostridium*, *Pediococcus*, *Lactobacillus*, *Acinetobacter*, *Staphylococcus* Contamination tracking

Table 6.4 Processed meat and poultry product categories, processes used for their production, and examples of products within each catgory

Product	**category Product**	**description Products**
Thermally processed, commercially sterile	Thermally processed, commercially sterile	Canned spaghetti with meat balls, canned corned beef hash, canned ham, canned chicken salad, canned soups with meat or poultry
Not heat treated, shelf stable	Not RTE, otherwise processed meat	Bacon, meals/dinners/entrees, pies/pot pies, rendered fats, oils, sandwiches/filled rolls/wraps, sauces, smoked parts, soups
	RTE acidified or fermented meat (without cooking)	Alessandri (dry sausage), apenino (dry sausage), Arles (or d'Arles) (dry sausage), bockwurst (semidry sausage), cacciatore (dry sausage), cervelat, soft cervelat, chorizo, Lebanon bologna, pepperoni, soft salami, salami (Genoa, Italian, German, summer sausage, Thuringer, soft Thuringer)
	RTE dried meat	Basturma, pastirma, basturmi, beef sticks, carne seca, dried beef, dry duck breast, meat/poultry jerky
	RTE salt-cured meat	Capicola, coppa, country ham, dry-cured duck, Parma ham, prosciutto

Product	category Product	description Products
Fully cooked, not shelf stable	RTE meat fully cooked without subsequent exposure to the environment	Meat: Berliner (cooked, smoked sausage), bologna, bratwurst, cooked, braunschweiger/liver sausage, breakfast link sausage or patties, brown-and-serve sausage, burritos, cheese smokies, cheesefurter, cheesewurst/cheddarwurst, chili, chorizo, cooked beef, cooked ham, cooked pork in barbeque sauce, salami cotto, fleischkaese (cured, cooked sausage), frankfurters, gyros, meatloaf, meat salads, frozen meat soups, nem chua (cooked, pickled ham with shredded pork skin), pasta with meat sauce, pastrami, pickled pigs' feet in vinegar, pickled sausages/meat in vinegar, piroshki, pork barbecue, pork sausage patties, ravioli, roast beef, roast pork, souse, stews, white hots, ieners Poultry (includes products containing any amount of poultry): chicken burritos, chicken barbeque, chicken bologna, chicken breast, chicken franks, cooked poultry, cooked poultry rolls, corn chowder with chicken, poultry loaf, poultry patties, poultry rolls, frozen poultry soups, turkey barbeque, turkey franks
Heat treated, not fully cooked, not shelf stable	Not RTE, otherwise processed meat	Bacon, pies/pot pies, sauces, sausage products, smoked parts, soups

Product	category Product	description Products
Product with secondary inhibitors, not shelf stable	Not RTE, otherwise processed meat	Bacon, pies/pot pies, sauces, sausage products, smoked parts, soups

Table 6.5 Microorganisms associated with processed meat and poultry products

Product	Study topic	Most abundant bacterial species involved in the process	Type of process
Pork	Microbiota and metabolome in spoiled, vacuum-packed pork	*Brochothrix*, *Photobacterium*, *Weissella*, *Lactobacillus*	Spoilage
Beef	Spoilage microbiota and metabolite production in beef stored under vacuum or in high-oxygen atmosphere	*Lactobacillus*, *Leuconostoc*, *Photobacterium*, *Lactococcus*	Spoilage
Salami	Microbiota during fermentation of traditional Italian salami produced in 6 local factories	*Staphylococcus saprophyticus*, *Staphylococcus xylosus*, *Staphylococcus equorum*, *Lactobacillus sakei*	Fermentation
White pudding	Bacterial populations involved in spoilage of Belgian white pudding (meat plus oatmeal)	*Carnobacterium maltaromati-cum*, *Lactococcus lactis*, *Lactobacillus fuchuensis*, *Lactobacillus graminis*, *Serratia*	Spoilage

Product	**Study topic**	**Most abundant bacterial species involved in the process**	**Type of process**
Minced meat	Bacterial populations involved in spoilage of minced meat stored under modified atmosphere with the addition of different preservatives	*Lactobacillus algidus*, *Leuconostoc*, *Pseudomonas*, *Propioni-bacterium acnes*, *Photobacterium*	Spoilage
Sausages, environment	Bacterial populations involved in spoilage of vacuum-packaged sausages and contamination in related processing environment	*Leuconostoc*, *Lactobacillus*, *Yersinia*, *Brochothrix*, *Strepto-coccus*	Contamination tracking and spoilage
Sausages	Effect of packaging (vacuum or modified atmosphere) and salt content on bacterial populations involved in pork sausage spoilage and related metabolites	*Lactobacillus sakei*, *Lactococcus piscium*, *Carnobacterium divergens*, *Carnobacterium maltaromaticum*, *Serratia proteamaculans*, *Brochothrix thermosphacta*	Spoilage

Product	**Study topic**	**Most abundant bacterial species involved in the process**	**Type of process**
Ham	Bacterial populations involved in spoilage of vacuum-packed, cooked ham and effect on sensorial properties	*Brochothrix thermosphacta*, *Lactobacillus*, *Micrococcus*, *Pseudomonas*, *Vagococcus*	Spoilage
Sausages	Bacterial populations during Italian salami fermentation and ripening	*Lactobacillus sakei*, *Leuconos-toc carnosum*, *Staphylococcus succinus*, *Lactobacillus curvatus*	Fermentation
Beef	Microbial populations involved in spoilage of beef burgers packaged under vacuum or in nisin-activated packaging	*Photobacterium phosphoreum*, *Lactococcus piscium*, *Lactobacillus sakei*, *Leuconostoc carnosum*	Spoilage

Product	**Study topic**	**Most abundant bacterial species involved in the process**	**Type of process**
Beef	Changes in spoilage-associated microbiota and metabolome according to storage conditions (air, vacuum, active packaging, MAP)	*Pseudomonas*, *Brochothrix*, *Carnobacterium divergens*, *Lactococcus*, *Streptococcus*, *Lactobacillus*, *Ralstonia*	Spoilage
Sausages	Effect of different concentrations of lactate and diacetate in fresh pork sausage spoilage	*Leuconostoc citreum*, *Pseudomonas lini*, *Carnobacterium divergens*, *Lactobacillus graminis*, *Lactobacillus gasseri*, *Serratia*	Spoilage

Beef, bacon, poultry sausages, shrimp, salmon, cod Identification of core and food-specific bacterial populations involved in spoilage of seafood and meta products and their ecological origin *Staphylococcus*, *Pseudomonas*, *Brochothrix*, *Leuconostoc*, *Flavobacterium*, *Chryseobacterium*, *Photobacterium*, *Corynebacterium*, *Propionibacterium*, *Lactobacillus*, *Entero-coccus*, *Clostridium* Contamination tracking and spoilage microorganisms during processing. Some microorganisms that have greater thermal resistance, such as *Micrococcus* and *Enterococcus*, may survive the process depending on the initial populations.

Pasteurization treatments are not adequate to destroy the spores of the spore-forming pathogens *C. perfringens*, *C. botulinum*, and *B.*

cereus. Since the spore populations in raw meats and ingredients such as spices used in the manufacture of such products are usually low, and the vegetative cells of these pathogens can be destroyed during thermal processing, it is adequate to control germination and growth of the spores of these microorganisms. The performance standards during cooling of thermally processed products are designed to minimize the potential germination and outgrowth of *C. perfringens* spores to less than 1-log growth during the cooling process. Control of this organism implies control of other spore-forming microorganisms as well. The compliance guidelines require rapid cooling of cooked meat and poultry products to minimize the germination and outgrowth of *C. perfringens* spores. Further, most of the antimicrobial agents (salts of organic acids and their combinations, from both traditional and natural sources) used in ingredient formulations to reduce the growth of *L. monocytogenes* in fully cooked RTE meat and poultry products can also reduce *C. perfringens* spore germination and outgrowth.

Most of these products are exposed to the processing environment during the slicing and packaging steps which occur subsequent to thermal processing. This environmental exposure can result in postprocessing contamination by microorganisms, specifically, *L. monocytogenes* and spoilage microbes. However, this postprocessing contamination can be minimized through proper sanitation and environmental control. A survey conducted by the World Health Organization (132) revealed that approximately 25% of foodborne outbreaks are attributed to recontamination of processed products. Additional factors include insufficient hygiene (1.6%), cross-contamination (3.6%), inadequate sanitation in processing or storage facilities (4.2%), contaminated equipment (5.7%), and contamination by personnel handling the products (9.2%). Significant sources of recontamination include the environment (processing equipment, air in the processing rooms, and other non-product contact surfaces harboring microorganisms) and personnel.

Thermal processes used for the manufacture of sous vide products are typically 70°C for 100 minutes or 90°C for 10 min. The main food safety concerns associated with these products are the spores of *C.*

botulinum, which can survive the pasteurization process and subsequently germinate, grow out, and produce toxins if the product is temperature abused. LAB are the main cause of microbial spoilage in sous vide-cooked meat products, with the heterofermentative LAB *Lactobacillus*, *Leuconostoc*, *Weissella*, and *Carnobacterium* (133) producing sour off flavors, slimy exudates, and carbon dioxide. However, spoilage resulting from growth of *Pseudomonas* has been reported in sous vide meat-based products.

In the United States, meat products that receive more severe thermal treatments than traditional sous videcooked meat and poultry products have gained popularity. Such products are distributed and stored refrigerated and allow consumers to reheat the product prior to consumption, thus providing convenience. These products are mostly meat and poultry products that contain gravy or sauce and are heated to 80 to 85°C for several hours in a vacuum pouch but do not achieve commercial sterility. However, literature on the adequacy of such a thermal treatment to destroy spores of *C. botulinum* as well as the potential for germination and outgrowth of such spore-forming pathogens is lacking.

Table 6.6 Performance standards for RTE and allpartially heat-treated meat and poultry products

Product category	**Pathogen or toxin**	**Requirement**
Non-thermally processed, commercially sterile products		
Lethality		
All meat products, other than poultry	*Salmonella* spp.	6.5-log reduction or 6.5D process
Poultry products or meat products containing any amount of poultry	*Salmonella* spp.	7D process
All fermented RTE meat and poultry products containing beef	*E. coli* O157:H7 (in addition to *Salmonella* spp. lethality)	5D process
Stabilization		
All meat and poultry products	*C. botulinum*	No multiplication of toxigenic microorganisms or *C. botulinum*
	C. perfringens	< 1.0 log10 multiplication of *C. perfringens*
General requirement		
All RTE meat and poultry products	Other pathogens, toxins, or toxic metabolites	Achieve performance standards for lethality and stabilization throughout product shelf life, under conditions of storage, distribution, and holding

Product category	Pathogen or toxin	Requirement
Postlethality contamination		
All RTE meat and poultry products	*L. monocytogenes*	Either incorporate one or more controls in HACCP plan or test food contact surfaces for *Listeria* spp.
Thermally processed, commercially sterile meat and poultry products		
All meat and poultry products	*C. botulinum* (depending on pH)	Eliminate (12D process) or control *C. botulinum*; product must be packaged in a hermetically sealed container and should be commercially sterile.

Antimicrobial Interventions

The risk of *L. monocytogenes* contamination of thermally processed meat and poultry products subsequent to cooking has prompted the industry to adopt risk mitigation strategies. The populations of *L. monocytogenes* that arise from postprocessing contamination are typically low (most samples of deli meats had a most probable number of ≤0.3/g) (134), and the contribution of products with low populations of *L. monocytogenes* to foodborne illness is low (135). Thus, mitigation strategies can include (i) control of the organism in the environment, (ii) eliminating listeriae in the product subsequent to contamination (in-package treatments), and/or (iii) preventing growth of listeriae using antimicrobial agents or processes. The FSIS has provided three alternatives for RTE meat and poultry processors based on those mitigation strategies.

Most processors of RTE meat and poultry products in the United States apply antimicrobial agents in their product formulations to mitigate growth of *L. monocytogenes* in the product during distribution and storage. Some processors have incorporated lethality treatments as well as antimicrobial agents into their product manufacturing processes. A brief description of each of those processes is provided below.

Physical methods

Methods to reduce *L. monocytogenes* in RTE meat and poultry products include heat treatments, delivered through either steam, hot water sprays, immersion, radiant heat, or high-pressure processing (HPP).

Thermal treatments (pasteurization). Since the *L. monocytogenes* cells from postprocessing contamination are assumed to be on the surface of the product, increasing the surface temperature of the product to achieve adequate lethality would enhance the safety of RTE meat and poultry products. The surface Temperature can be increased by exposing the packaged product to a heating medium, e.g., hot water or steam. In such cases, the product has been chilled, opened, or packaged in vacuum bags and subsequently exposed to the heating medium. The surface characteristics of the product play a significant role in influencing the temperature increase on the product's surface. Also, any purge (liquid expressed from the chilled product) collected at the bottom of the package or between the package (film) and the product surface requires longer heating times, as the temperature of the purge is the same as the product's internal temperature (chilled). Hence, formulating the product to minimize release of the expressible juice (purge) enhances the lethality achieved for a particular exposure time at a specific ambient temperature.

However, an adequate surface temperature treatment on the product will achieve *L. monocytogenes* lethality. In addition to the product surface characteristics, the product configuration can also be a factor. For example, the time required to heat frankfurters that are packaged as a single layer is significantly different from that required for a

double layer, because the cold spot varies with each product configuration, and so the doublelayered product needs to be heated for a longer time.

When thermal treatments are applied, proper microbial challenge studies for each product type or category and in some cases product formulation should be conducted to validate *L. monocytogenes* lethality.

HPP. The use of high pressure to achieve microbial safety and extend shelf life in a variety of food products has been in practice in the food industry for almost a decade. Commercially, pressures of 586 MPa have been used for treatment of RTE meat and poultry products with minimal changes in nutrient content and sensory properties, depending on the fat content. The order of effectiveness (high to low) of HPP is vegetative cells of Gram-negative bacteria, vegetative cells of Gram-positive bacteria, and fungi; viruses and bacterial spores are the most resistant. HPP inactivates microorganisms by cell membrane damage, solute loss, protein denaturation, and enzyme inactivation. Its ability to act on multiple cellular targets allows its use in combination with other treatments for better success through synergism. Heatassisted HPP for the destruction of bacterial spores in a variety of food products is being evaluated. The food is not heated and may not be deformed because HPP is isostatic (i.e., uniform and instant pressure transmission) and adiabatic (i.e., minimal temperature increases within the product; approximately 3°C per 100 MPa).

HPP has been applied to a variety of foods, including meat products such as cooked ham, fish, and precooked meals (136). Its use in RTE meat products, such as ham, for control of postprocessing *L. monocytogenes* contamination has gained industry acceptance as a lethality treatment. It is marketed as a natural alternative to chemical antimicrobials in order to meet regulatory requirements for antimicrobial alternatives applied to products allowing growth of the pathogen before consumption. HPP has also been considered for use as an alternative to mild heat for inactivation of *E. coli* O157:H7 and STEC in fermented sausages (137). Since the association of fermented

sausages with *E. coli* O157:H7 and STEC outbreaks, some countries have established regulations requiring 3-to 5-log-unit reductions of *E. coli* O157:H7 in such products. Alternative treatments to mild heating of dry-fermented sausages to eliminate STEC have been difficult to identify. HPP may have the potential to improve dry-fermented sausage safety without adversely affecting product quality (137).

As with any process, the product characteristics, such as pH, a_w, and processing temperature, influence the amount of microbial reduction achieved by HPP (Table 6.7). Increasing efficacy at lower pH values and higher a_w values in products can be achieved, thus allowing modification of product characteristics to achieve the desired reductions using HPP. Thus, there is a need to validate the microbial destruction achieved for various products, and any changes in product formulations may require evaluation and revalidation of the process to ensure microbiological safety.

While HPP has been accepted and used for ensuring microbiological safety and shelf life of some processed RTE meat and poultry products, it produces detrimental effects on product color and texture when used on fresh meat. HPP denatures myoglobin, thereby affecting its affinity for oxygen and preventing the formation of the cherry red color of freshly processed ground beef.

In the United States, feeding of raw-meat-based diets to pets has increased considerably. The base ingredients for these meat-based diets are either offal or residual meat from bones. Thus, the risk of foodborne pathogen contamination from such ingredients is high, and processors are required to meet the zero tolerance performance standard of RTE prepared products. Most raw pet food processors use HPP to eliminate the foodborne pathogens of principal concern, namely *Salmonella*, *Campylobacter*, *E. coli* O157:H7, and STEC. For such products, meat color is not a major concern as the meat is usually combined with vegetables and further ground and formed.

Chemical methods

Several antimicrobials have been used to mitigate *L. monocytogenes* contamination of RTE meat and poultry products. The efficacy of

these antimicrobials depends on their mechanism of action, their concentration, the amount applied, surface characteristics of the product, temperature, and other factors. Some of the more commonly used antimicrobials that have been evaluated include organic acids (lactic, acetic, or citric), lauric arginate, acidic calcium sulfate, and liquid smoke fractions. A constraint on using oxidizing antimicrobials such as PAA is their detrimental effect on surface color and fat oxidation of the product. Thus, antimicrobial chemicals having minimal effect on product quality characteristics such as color and flavor are used. Furthermore, these treatments, similar to other surface treatments, can reduce only a proportion of the population and do not eliminate listeriae. It is possible that listeriae, even though injured, can recover and grow during subsequent refrigerated storage. Hence, it is prudent to use such postlethality treatments in combination with antimicrobial ingredients that are included in the product formulation to reduce the potential for *L. monocytogenes* growth.

Table 6.7 Comparison of microbial inactivation after HPP processing[a] in spiked meat products with different water activities[b]

	Result in skin vacuum-packed product		
Measurement	Marinated beef	Cooked ham	Dry-cured ham
No. of *S. aureus* (log CFU/g)	>2.67	1.12	0.55
No. of LAB (log CFU/g)	>3.99	4.57	1.58
a_w	0.985	0.978	0.890

[a] Processing at 600 MPa and 31°C for 6 min.

[b] Adapted from reference 185.

Antimicrobials that are routinely used to control or reduce *L. monocytogenes* on RTE meat and poultry products include combinations of organic acid salts—sodium or potassium salts of lactic, acetic, or citric acid. The literature is replete with studies on the

efficacy of organic acid salts or their combinations in RTE meat and poultry product formulations. Although several potential antimicrobials have been evaluated, organic acid salts are extensively used compared to others and are effective. Mbandi and Shelef (138) determined that a combination of sodium lactate and sodium diacetate provides a synergistic effect in inhibiting *L. monocytogenes* growth on the surfaces of RTE meat and poultry products. Numerous subsequent studies have confirmed the synergism, and currently, the industry uses this combination of antimicrobials extensively in RTE meat and poultry products. Other antimicrobials evaluated include antimycotics such as sorbates, benzoates, and propionates (139, 140).

A recent meat industry trend is to produce "all-natural" meat products, which has resulted in processors searching for natural sources of antimicrobials. Ingredient providers have modified the production processes for several antimicrobials with cane sugar and other natural sources for fermentation and production of the lactic and acetic acids, followed by buffering with bases (hydroxides or carbonates) to produce the organic acid salts. In some instances, lemon and lime juice concentrates have been the sources of organic acids (primarily citric) and are buffered using bases to produce "all-natural" ingredients for use in RTE meat and poultry product formulations. Acetates and diacetates are manufactured from vinegar (natural) produced from cane sugar or similar natural sources of easily fermentable carbohydrates. With an increase in consumer health consciousness giving rise to the desire to reduce sodium intake, the industry is formulating products with reduced sodium content. While sodium chloride is a major contributor to the sodium content of RTE meat and poultry products, other ingredients, such as phosphate and organic acid salts, have also been targets for sodium reduction. Hence, these ingredients are being formulated as potassium salts or, to reduce the bitterness of potassiumbased organic acid salts in product formulations, combinations of sodium and potassium salts.

While these antimicrobials are being extensively formulated for inclusion in a variety of RTE meat and poultry products, the inhibition of *L. monocytogenes* observed is dependent on the other product characteristics, such as the pH, water activity, sodium chloride

concentration, and other ingredients in the product. Care should be exercised when the RTE meat and poultry products are being formulated with the antimicrobials through the use of validated computer simulation models, such as the Corbion *Listeria* control model, or through microbial challenge (validation) studies for individual products or products within similar categories with similar formulations and product characteristics.

The additional advantage of formulating organic acid salts for incorporation into RTE meat and poultry products is their ability to control or minimize *C. perfringens* spore germination and outgrowth. Thippareddi et al. (141) determined that adding buffered sodium citrate to roast beef and pork products inhibited *C. perfringens* spore germination and outgrowth during extended chilling times.

Commercially Sterile Products

Commercially sterile products include canned products containing meat or meat products. Such products are subjected to thermal processes to inactivate *C. botulinum* spores (F_0 [sterilization value] = 2.5 min), although more severe thermal treatments (F_0 = 4.0 to 5.0 min) are applied to address potential contaminating sporeformers with greater heat resistance.

Types of Products

Canned meat products include stews, soups, gravies, sauces, chili, pasta-containing products, sloppy joe products, roast beef, and gravy and similar products.

Foodborne Pathogens, Sources, and Contamination

The pathogen of concern in these products is *C. botulinum*. Since these products are usually stored under ambient conditions, and the spores of the proteolytic *C. botulinum* types are more heat resistant than nonproteolytic *C. botulinum* spores, foodborne intoxication is primarily due to survival of the spores of proteolytic types. Foodborne botulinum intoxications from commercially processed canned products have declined substantially since the FSIS implemented

process control measures based on containers and closures used for such products, which included specific thermal processing requirements such as process schedules for specific products and containers, application of critical factors in the process schedule, and specifications for equipment and procedures for heat processing systems.

Fermented and Dried, Salt-Cured, and Dried Meat Products

A variety of RTE meat products, such as acidulated or fermented and dried salami (dried or semidried), saltcured meat products, and dried meat products, make up this category. The a_w of these products is usually low based on the category of the product, and the pH may be low (≤ 5.0), depending on the product.

Types of Products

Meat products in this group are produced by a variety of manufacturing processes, including acidulation (summer sausages), fermentation and drying to varying degrees of pH and a_w (e.g., salami, pepperoni, Thuringer, and chorizo), salt curing (capicola, coppa, country ham, and prosciutto), and drying (basturma, beef sticks, and jerky). The microbiological profiles of these products vary depending on the product and the process or processes used.

Processing Effects

Several of the products in this category are prepared and consumed by methods developed in ancient times. These processes yield products that have extended shelf life and have reduced microbiological food safety risk. The fermentation processes once relied on back-slopping, a traditional method in which fermented meat from a previous batch was used as a starter culture to decrease the pH of the fermenting meat, and on drying processes that involved slow drying of products subsequent to fermentation (for fermented salami) or heat treatments (for dried products). Salt curing of meats has resulted in controlled

dehydration of the product to an a_w below 0.85 to achieve microbial stability under ambient storage conditions.

Foodborne Pathogens

These products historically have been microbiologically safe, with the exception of growth of *S. aureus* and production of toxin, which can occur when the fermentation rate does not progress steadily to achieve a pH of ≤ 5.0. Foodborne illnesses from *E. coli* O157:H7 in fermented dry salami in the United States have resulted in the industry and the FSIS recognizing the acid tolerance of this microorganism and the need for its control in fermented products that contain beef. Currently, the FSIS specifies a performance standard for achieving at least a 5.0-log reduction of *E. coli* O157:H7 in fermented dried products (e.g., salami), and a 6.5-log reduction of *Salmonella* spp. (142).

To address this, the degree-hour concept has been adopted in the United States using a combination of time and temperature to achieve a product pH of 5.3 during fermentation. The degree-hours of a process are calculated as the number of hours at the process (fermentation chamber) temperature multiplied by the degrees above 60°F.

A process is acceptable when it controls the growth of *E. coli* O157:H7 and staphylococci in the product and consistently reaches a pH of 5.3 or less using the following criteria.

1. Fewer than 1,200 degree-hours when the highest chamber temperature is less than 90°F.

2. Fewer than 1,000 degree-hours when the chamber temperature is between 90 and 100°F.

3. Fewer than 900 degree-hours when the chamber temperature is greater than 100°F.

Table 6.8 Time/temperature relationships for constant temperature processes

Degree-hours above 60°F	Chamber temp (°F)	Maximum hours to pH 5.3
1,200	75	80
1,200	80	60
1,200	85	48
1,000	90	33
1,000	95	28
1,000	100	25
900	105	20
900	110	18

For constant-temperature processes, Table 6.8 provides guidance on the maximum numbers of hours at specific chamber (fermentation) temperatures.

Subsequent to the *E. coli* O157:H7 outbreak associated with consumption of fermented salami, the National Cattlemens' Beef Association assembled a blue-ribbon task force and initiated research to develop validated control methods for this microbe in fermented, dried meat products containing beef (143). The report outlined the following five options.

1. Utilize a heat process as listed in federal document 9 CFR 318.17 (145°F for 4 min). The processor must provide documentation of the heat process.

2. Include a validated 5D inactivation treatment (i.e., treatment that reduces the population by 5 log cycles at a given temperature). A processor using a 5D inactivation treatment will have met requirements for validation.

3. Conduct a "hold and test" program for finished product. Testing finished product as the only means of ensuring safety is contrary to the philosophy of HACCP; this option involves finished product

testing, requires no knowledge of raw ingredients or the process, and is expensive.

4. Propose other approaches to assure there is at least a 5D inactivation. A processor could propose any combination that will demonstrate a collective 5D control but must provide precise documentation.

5. Initiate a HACCP system that includes raw-batter testing and a 2D inactivation. A combination of raw-material testing, processing through fermentation, thermal processing and drying, and finished-product testing can be used to demonstrate the adequacy of a given process to ensure the safety of dry and semidry fermented sausage products. The processor could include a HACCP plan combined with GMPs for fermented sausage; the option combines raw-batter testing and documen tation of at least a 2D lethality for *E. coli* O157:H7 between stuffing and shipping. This is a very practical means of ensuring the safety of certain dry fermented sausage products.

With regard to option 5, there are several key points that must be considered.

- The analytical method must be equivalent to the FSIS method in raw-batter testing.
- The sample size and compositing procedure must ensure a detection level of 1 CFU/g. It is recommended that 15 25-g samples be taken across each lot; these 15 samples can then be composited into five 75-g analytical samples.
- The definition of a "lot" must be scientifically statistically sound.
- GMPs must be applied.
- Processors must have data to document the 2D destruction between stuffing and shipping.
- As in the case of options 1 through 4, option 5 must address *Salmonella*, *Trichinella*, and *Staphylococcus*. The FSIS expanded the *S. aureus* monitoring program to include *E. coli* O157:H7.

- The lots of batter which test positive must be subjected to conditions that provide a total 5D process; procedures for dealing with positive lots must be defined in the HACCP plan.

Since fermented, dried, and semidried sausages containing any amount of beef in the United States are subjected to a mild thermal process to achieve lethality requirements for *E. coli* O157:H7, the flavor and aroma characteristics and the tangy taste are different from those of their traditional European counterparts. Research on alternate methods is needed.

Dried Meat Products

Numerous dry or dried foods with low aw have been implicated in foodborne-illness outbreaks, especially with *Salmonella* and, in some cases, STEC. Among the meat and poultry products, a good example of a dried product involved in such outbreaks is jerky, implicated in *Salmonella* Montevideo and *Salmonella* Kiambu outbreaks in New Mexico in 1995 and 2003, respectively (14, 144). The cause of survival of the microorganism was reported to be the drying process under low-humidity conditions (1% relative humidity; 82°C dry bulb, 30°C wet bulb) prior to achieving lethality at higher relative humidity (product surface moisture) conditions.

The traditional manufacturing process (commercial) of jerky consists of preparation of the meat strips, marination, application of antimicrobial interventions, surface preparation, lethality, drying, post drying heating, and handling. Of these, antimicrobial intervention and the lethality step are designed to reduce the microbial load and achieve adequate lethality to assure microbiological safety of these products. The antimicrobial intervention step includes immersion of sliced strips of meat in marinades (typically containing acids and pH-reducing agents and spices) or antimicrobial solutions (acidic calcium sulfate, acidified sodium chlorite, etc.) at appropriate temperatures and/or periods of time. The lethality step is designed to increase product temperature at high humidity for adequate time to achieve destruction of microorganisms of human health significance such as *Salmonella*, *E. coli* O157:H7, and others. The FSIS (142) specifies that

product time-temperature and relative humidity of the environment are critical operational parameters for the process to achieve at least a 5.0-log reduction of *Salmonella* spp. and STEC in products containing beef. In addition, the lethality treatment of meat and poultry jerky should achieve at least a 3.0-log reduction of *L. monocytogenes*.

While jerky is a traditional product and consumed worldwide, other ethnic foods (dried meats), such as biltong, charqui, pemmican, pastrami, tasajo, nikku, and sou gan, are gaining popularity (145). Many of these products have been prepared and consumed with minimal food safety issues over the years, although the microbiological safety of the processes has not been scientifically investigated and reported. Burfoot et al. (145) categorized the reported outbreaks attributed to these dried meat and poultry products as those caused by (i) *Salmonella* and *E. coli* O157:H7, (ii) *Trichinella*, (iii) *S. aureus*, and (iv) *C. botulinum*. While the foodborne illness outbreaks are a result of survival of the microorganisms due to inadequate lethality of the process, spoilage of these products is mostly from molds due to postlethality contamination.

Antimicrobial Interventions

As mentioned above, fermented dry or semidry products in the United States undergo a mild thermal treatment, resulting in an altered flavor profile, combined with a lower target pH for fermentation, which results in a tangy taste. Recent research using HPP has revealed that fermented products that are HPP treated either before or after drying can meet the criteria for reduction of *E. coli* O157:H7 populations if the HPP reduction is combined with the reduction that occurs during fermentation and drying. Porto-Fett et al. (146) reported that HPP treatment of Genoa salami (pH 4.58; a_w, 0.89 or 0.92) at 600 MPa or 483 MPa for 1 to 12 min reduced pathogen populations by an additional (in addition to those reductions achieved by fermentation and drying to target pH and a_w values) 1.6 to ≥ 5.0 (*L. monocytogenes*), 4.7 to ≥ 5.8 (*E. coli* O157:H7), and 1.9 to 2.4 (*Salmonella*) log CFU/g. After storage for 28 days at 4°C, *L. monocytogenes* levels decreased by up to an additional 3.0 log CFU/g,

whereas additional decreases of up to about 1.1 and 1.7 log CFU/g was observed for *E. coli* O157:H7 and *Salmonella*, respectively.

The HPP process can be used by manufacturers of fermented dry and semidry sausage in the United States to achieve microbiological safety of these products with minimal loss in product flavor and quality characteristics.

DETECTION AND ANALYSIS OF SPOILAGE, PATHOGENIC, AND RESIDENT MICROBES IN MEAT AND POULTRY

Meat and poultry products possess chemical and physical properties that allow the colonization and development of a variety of microbes, including bacteria and fungi (147, 148). Microbial growth can cause spoilage or even adulteration, making products no longer appealing and unsuitable for human consumption. While initial microbial loads significantly impact the products' microbial quality and safety, storage conditions as well as competition and interactions between resident microbes and spoilage and pathogenic microbes also contribute significantly to product quality and safety. Organization and reorganization of microbial communities during processing and storage directly determine the persistence of foodborne pathogens and spoilage microorganisms (149, 150). Therefore, it is necessary to quantitate and characterize the resident microbes in addition to the spoilage and pathogenic microbes present in meat and poultry products.

Techniques and technologies used for studying microbial populations have evolved tremendously over the past few decades. As a result, understanding of the composition of resident microbes present in live animals (fecal samples) and the processing environment, as well as in finished meat and poultry products, has improved dramatically. Cultivable bacteria often represent only a small fraction of the entire microbial community, resulting in frequent underestimation of the microbial diversity present in a given environment or sample when traditional plating methods are used (151, 152). It is also well accepted

that many foodborne pathogens, such as *E. coli* O157:H7 and *Salmonella* spp., may enter a viablebut-noncultivable state under certain treatment or storage conditions, making cell counts obtained based on plating methods questionable (153, 154). The ability of these microbes to remain undetectable and unculturable reveals the need for new technologies that can overcome the limitations associated with conventional plating. Next-generation sequencing, such as 16S rRNA sequencing and shotgun meta-genomics sequencing, allows analysis of microbial populations via culture-independent methods. Such culture-independent methods provide high-resolution identification of microorganisms without the limitations or biases associated with the use of selective and/or non-selective culture media.

Analyzing a microbial community using sequencing technologies provides taxonomic information about the microbial populations in the community. In addition, several indices can be used to evaluate and compare the microbial communities. Examples of these indices include Chao1 and abundance-based coverage estimators for the evaluation of species richness and Shannon's index and Simpson's index for the calculation of species diversity (5). Species richness refers to the number of different species in a given ecological system, whereas species diversity takes into consideration both species richness and species evenness (155, 156). In recent years, the terms "alpha diversity" and "beta diversity" also have been used to describe differences between microbial communities. Alpha diversity refers to the diversity within a sample; it reflects species diversity or the richness of the microbial community. Five main indices are used to describe alpha diversity. They are Chao1 (157), phylogenetic diversity, whole tree (158), observed operational taxonomic units (OTUs) (159), and Shannon (160). Beta diversity refers to the diversity between samples; it is the ratio or the difference of species diversity between samples. Beta diversity can be assessed by using distance matrices, including Bray-Curtis distance (161), Euclidean distance (162), unweighted UniFrac, and weighted UniFrac (163).

Here, the discussion about the detection and analysis of spoilage, pathogenic, and resident microbes in meat and poultry products starts

with a brief overview of the microbial populations present in the GI tracts of beef cattle and poultry. The composition of microbial populations and the prevalence and concentration of spoilage and pathogenic microbes present in meat and poultry products are largely determined by the microbial populations present in live animals, e.g., animals' GI tracts, hides, lymph nodes, and other organs (164). Next, the microbial populations present in the processing environment (e.g., air, floors, walls, processing equipment and containers, and hands of handlers), as well as the changes in micro-biomes during various storage conditions, are reviewed. Finally, methods used to detect spoilage and pathogenic microbes are discussed.

Microbiome of the GI Tracts of Beef Cattle and Poultry

Beef Cattle

Diverse factors, including diet, location, and age, determine the microbial populations present in live animals (165). The microbial communities present in the GI tracts of beef cattle can impact both the live animals' health and the quality and safety of products from the animals. Evaluating microbial populations present in beef cattle feces has been a direct method for determining the characteristics of the microbiome present in an animal's GI tract. These fecal samples contain complex bacterial communities. Shanks et al. (166) collected 30 rectal grab fecal samples from six cattle populations residing in four geographic locations (Oconee County, GA; Larimer County, CO; Hamilton County, OH; and Clay County, NE). These cattle were on three different types of diets, including a forage diet (more than 80% of feed consisted of plants such as alfalfa, corn silage, and/or fescue, wheat, and rye grasses), a processed-grain diet (at least 75% of the feed was steam-flaked, dry-rolled, and/or distiller's grain corn), and an unprocessed grain diet (containing more than 75% whole-kernel corn). The analyses of 633,877 high-quality bacterial V6 pyrotags revealed four main bacterial phyla from these fecal samples, including *Firmicutes* (55.2% relative abundance), *Bacteroidetes* (25.4%), *Tenericutes* (2.9%), and *Proteobacteria* (2.5%). These top phyla were followed by *Actinobacteria* (0.73%), *Spirochaetes* (0.54%),

Verrucomicrobia (0.19%), *Cyanobacteria* (0.15%), *Fibrobacteres* (0.02%), and *Lentisphaerae* (0.02%). The relative abundance of the different bacterial phyla correlated differently to the three types of diets. For example, while the abundances of *Bacteroidetes* exhibited a clear difference between the three diets, *Proteobacteria* abundances were not different. Similarly, different abundances were observed at the family and genus levels. For example, abundances of bacterial species belonging to the family *Ruminococcaceae* and the genus *Prevotella* were dramatically different from one diet to another (166).

The impact of diets on the GI tract microbiome was also evaluated by Rice et al. (167), who collected fecal grab samples from 20 steers. These steers were on five different diets, consisting of a traditional diet fed to finishing beef cattle in the southern high plains (steamflaked corn control with no distilled grain [DG]) and four other diets with different concentrations of cornbased DG or sorghum-based DG. The sequencing analysis generated a total of 127,530 operational OTUs, and 24 phyla were identified. The top six phyla were *Firmicutes* (61%), *Bacteroidetes* (28%), *Proteobacteria* (3%), *Tenericutes* (0.15%), *Nitrospirae* (0.11%), and *Fusobacteria* (0.086%) (167). Different phyla responded in different ways. It was found that steers fed diets containing 10% or more of a DG supplement had a higher relative abundance of *Firmicutes* than steers fed the no-DG diet. At the genus level, a total of 973 bacterial species distributed among 446 genera were identified. The DG diet significantly impacted the relative abundance of the top 60 most abundant genera (covering more than 97.5% of total genera observed; $P < 0.05$). Diets significantly ($P < 0.01$) influenced the average abundance of *Clostridium, Ruminococcus, Oscillibacter, Tannerella, Parabacteroides, Hydrogenoanaerobacterium, Pseudoflavonifractor, Acetivibrio, Ethanoligenens, Selenomonas, Desulfonispora,* and *Barnesiella* (167). Both of these reports, together with other reports (5, 168, 169), reveal that diet is a significant factor that impacts the relative abundance of different phyla, genera, and species identified from the GI tracts of cattle.

In addition to diet, the age of cattle is another important factor impacting the composition of microflora in cattle's GI tract. Zhao et al.

(170) collected fecal samples from 110 calves and 92 dams and determined that fecal bacterial diversity increased as cattle age increased. Such changes in the microflora also impact the shedding of pathogenic *E. coli*. It was found in the same study that the dams' STEC shedding levels were lower than the shedding levels of calves (170). Handling and management practices are two other factors that can impact the shedding prevalence of *E. coli* O157:H7 (171). In a survey study conducted in Washington State, *E. coli* O157:H7 was isolated from 10 of 1,412 fecal samples collected from pastured beef cattle, whereas the pathogen was isolated from only 2 of 600 fecal samples collected from feedlot beef cattle (171). The shedding of *E. coli* O157:H7 also has a seasonal pattern, with prevalence peaking during summer months and declining in winter months (172). Elevated temperatures in the summer provide favorable conditions for the bacteria to survive and even multiply to increase their abundance in animals as well as in the environment (173–175).

Weaning is a critical step in the preharvest continuum of beef cattle production (176). During the weaning process, the stresses on young calves caused by physical separation from dams as well as a change in diet can lead to depressed feed intake and immunity as well as loss of body weight (176, 177). As a result, the weaning step provides an increased opportunity for pathogen colonization and shedding (103, 169). In a study conducted by Zhao et al. (169), 60 calves (28 heifers and 32 steers) were weaned and randomly assigned to two groups for different weaning diets. One diet consisted of peanut and soy hull-based dry feed, and the other was a corn silage-based high-moisture diet. Fecal samples were collected from these calves before weaning, 14 days after weaning, and 56 days after weaning. The shedding prevalence of *E. coli* O157:H7 was evaluated by plating fecal samples onto CHROMagar O157 and confirmed by PCR. Significant loss of body weight was observed before and after weaning, regardless of diet, and the shedding prevalence of *E. coli* O157:H7 increased after weaning. Weaning significantly changed the microbial communities present in the fecal samples ($P < 0.05$), although no difference was observed between the two weaning diets (169).

Poultry

Although chickens have smaller intestines than mammals, which result in shorter digestion times, a chicken's digestive system does not appear any less complex (178, 179). Among the different GI tract sections, a chicken's cecum is the most heavily populated with microorganisms. These cecal microbes, together with the microbiome in other parts of the GI tract, are heavily involved in digestion and absorption of nutrients and in energy metabolism (180). Unfortunately, it is also known that this microbiota can be a source of human infections and a reservoir for antibiotic resistance determinants (181). The impact of the intestinal microbiota on the shedding of pathogens, such as *Salmonella* and *Campylobacter* spp., has been investigated by many studies. Since modern hatchery management prevents intimate contact between hatchlings and hens, inoculation of new hatchlings with appropriate microbial species is necessary for the development of a protective intestinal microbiome (182, 183). The formation of the competitive exclusion concept and the development of a series of competitive exclusion products are the result of more than 40 years of research related to the poultry intestinal microbiota and its impact on animal health and pathogen shedding (184). The competitive exclusion concept was originally designed for reducing the prevalence and shedding levels of *Salmonella* in growing chickens; it has now been expanded to the control of other enteropathogens, such as *C. jejuni* and *C. perfringens* (186), as well as to improving feed digestibility and chicken performance (187, 188).

Next-generation DNA sequencing has provided new opportunities to reinvestigate the GI tract microbiome and reexamine some long-standing observations about performance differences associated with animal husbandry practices and environmental factors. It was reported that up to 11 log CFU/g of microbes comprising hundreds of species can be identified from chickens' intestinal content (189, 190). Recent sequencing results revealed that the top phyla present in the cecal microbiome are *Bacteroidetes* (29.7 to 63.5% of the total bacterial population) and *Firmicutes* (30.2 to 59.8% of the total

bacterial population) (191). This observation matches well with previous reports obtained via culture-based methods (192, 193).

Several factors, such as weather, diet, breed and genetics, age, and location, can influence the composition of the GI tract microbiome of poultry. In a recent study, 87 commercial broiler chickens were sampled for the evaluation of the cecal microbiome and its impact on *Campylobacter* shedding (194). DNA was extracted from the cecal contents, and the microbiome was analyzed using 16S rRNA sequencing. The analyses revealed that the taxonomic composition of the microbiome did not have a significant relationship to the *Campylobacter* shedding status (positive or negative) but did correspond significantly to the season ($P = 0.000$). The relative abundance of several genera changed significantly among different seasons. For example, the OTUs that were classified as *Lachnospiraceae* were less abundant in the fall than in other seasons (194). This seasonal variation in the GI tract microbiome might be caused by temperature changes, as the different taxa have different optimal growth temperatures. In addition, host stresses and immune responses may change as the seasonal environment changes, which in turn impacts the microbial community composition.

The impact of the age of chickens on the GI tract microbiome was studied by Awad et al. (195). In this study, 45 1-day-old broiler chickens were obtained from a commercial hatchery. Five were sacrificed immediately to collect the microbiota for sequencing, while the rest were sampled on days 7 and 14. On day 14, 15 birds were infected with *C. jejuni*, and both the infected and uninfected chickens were analyzed at 7 and 14 days postinfection. Of the 8,285 OTUs identified, *Firmicutes, Proteobacteria, Bacteroidetes, Actinobacteria*, and *Tenericutes* were the main phyla identified, with *Proteobacteria* and *Firmicutes* being the most abundant phyla. The factor of age had a significant impact on the composition of the microbiome. Compared to the older birds (which were >14 days old), the young birds had more *Proteobacteria* and *Firmicutes*. In contrast, the older birds had a higher abundance of *Tenericutes*. The 28-dayold birds had more diverse bacterial communities than younger birds. Infection by *C.*

jejuni altered the GI tract microbiome, with the infected birds having significantly less *E. coli* (195).

Cecal microorganisms are involved in detoxifying harmful substances, recycling nitrogen, digesting resistant carbohydrates, and absorbing additional nutrients (196). Thus, the composition of the cecal microbiome can also be altered by diet and dietary supplementation (197–200). Corrigan et al. (198) used 16S rRNA sequencing to evaluate the impact of mannan oligosaccharide (MOS) on both culturable and unculturable bacteria.

Firmicutes, *Bacteroidetes*, *Proteobacteria*, *Actinobacteria*, and *Tenericutes* were the top five phyla in the groups treated with MOS, representing more than 99% of allsequences identified. Similar dominant phyla, including *Firmicutes*, *Bacteroidetes*, and *Proteobacteria*, were reported in the control group (regular corn-soy diet). MOS supplementation altered the bacterial community 7 days after the treatment, and *Bacteroidetes* replaced *Firmicutes* to become the dominant phylum as a result of supplementation (198).

As discussed above, a complex population of microbes is present in the ecosystem of an animal's GI tract (in both cattle and poultry). These microbes not only play significant roles in animal nutrition, animal welfare, and performance but also impact animal products' safety by altering the harboring and shedding of human pathogens. Traditional culturing methods have limitations in analyzing these microbes, because only 1% of all bacteria are culturable (201). New sequencing technologies provide researchers with opportunities to better evaluate the microbial populations present in the GI tracts of animals. These methods, such as comparative metagenomics, enable the comparison of microbial populations obtained from different ecosystems and help with the identification of factors that impact the diversity and abundance of GI tract microbiome and the shedding of pathogens. Another advanced tool for studying microbiomes is functional metagenomics, which brings the study of GI tract microbes into a new era. Information about the functions of identified genes in microbes aids in the identification of new prebiotics, probiotics, and metabolism

for protecting animal health, controlling human pathogens, and improving animal products' quality and safety.

Background Microbes Present in Meat and Poultry Products

Meat

After processing, more than 80% of the total microbial population of fresh ground beef, or 75 to 85% of the microbial population present on chicken parts, consists of chromogenic bacteria, molds, yeasts, and spore-forming microorganisms (202). However, at the time of spoilage (when food has an off odor and/or sliminess), the primary microorganisms are bacteria. Thus, bacterial counts have traditionally been used to evaluate meat spoilage. A microbial load of >7 log CFU/cm^2 is usually associated with the occurrence of off odors. When bacterial counts are as high as 9 log CFU/cm^2, a "fruity" off odor and sliminess may develop due to the metabolism of free amino acids (202). Unfortunately, plating methods are not adequate to provide an understanding of the actual shifts in the microbial populations of raw meat in response to different storage conditions.

To better understand the changes in beef's background microbiome, Olofsson et al. (151) used two different methods to evaluate the composition of the microbiome of beef stored at 4°C for 8 days. One method used sequencing of DNA samples extracted directly from the meat juice to analyze the microbial population, whereas the other method relied on plating to obtain initial bacterial isolates, which were then used for DNA extraction and sequencing. At the end of storage, viable plate counts for the beef samples increased from ~2 log CFU/cm^2 to 7 log CFU/cm^2. Significant differences in microbial composition were observed between the two analysis methods. While direct 16S rRNA sequencing analysis revealed dominant *Bacillus*-like sequences in fresh meat, no such sequences were found in isolates obtained from the plates. Instead, *Chryseobacterium* was the dominant bacterial genus identified by the plating method. The two methods were in agreement when used to analyze the 8-day-old beef

samples. Both methods revealed that *Pseudomonas* was the dominant spoilage microbe present in the beef samples (151). The results revealed that the plating and sequencing methods matched each other better when a dominant bacterial species is present in the samples. As indicated by Nychas and Skandamis (203), spoilage is usually caused by a fraction of microbial species out of the initial entire microbial population; for the 8-day-old beef samples analyzed by Olofsson et al. (151), *Pseudomonas* was the dominant species.

The composition of microbial populations present in meat samples is determined by several factors, including the type of meat or animal, the physiological status of the animal at slaughter, harvesting procedures, the harvesting and handling equipment and harvesting environment, packaging and storage conditions, and storage time. Based on the literature, members of *Enterobacteriaceae*, LAB, *Pseudomonas*, and *Brochothrix* are principal players in meat decay, although their dominance and prevalence can change depending on packaging or storage conditions (28, 147).

The use of molecular methods enabled the discovery of new microbes that are of significant importance to meat safety and quality. Audenaert et al. (204) evaluated the LAB populations present in cooked ham, turkey, and chicken products that were in MAP. These products were sampled and analyzed on their sell-by dates, and DNA samples were extracted for PCR-denaturing gradient gel electrophoresis analysis. The results of this analysis revealed that the same core microbiome was present in the cooked ham, turkey, and chicken products, with *Leuconostoc carnosum* being the most abundant psychrotrophic species. Ercolini et al. (205) evaluated the microbiome present on beefsteaks when the steaks were stored using three types of packaging systems. The packaging systems were air, high-O_2 MAP, and lower-O_2MAP. *Rahnella aquatilis*, *Rahnella* spp., *Pseudomonas* spp., and *C. divergens* were more abundant in samples stored in air, whereas *Pseudomonas* spp. and *L. sakei* were in greater abundance when samples were stored in the high-O_2 MAP, i.e., with 60% $O_2$and 40% CO_2. When the oxygen concentration was reduced to 20%, *Rahnella* spp. and *L. sakei* were more abundant. All of these samples were refrigerated at 5°C throughout the study.

The use of culture-independent high-throughput sequencing also enables researchers to explore potential sources of contamination by spoilage bacteria. De Filippis et al. (206) collected swab samples and meat samples from different locations on beef carcasses (brisket, chuck, and thick flank) 12 hours before slaughtering and after washing but before chilling. Swab samples were also obtained from the meat processing environment and from the hands of operators, slicing knives, bench surfaces, and walls of the cold storage room. DNA was extracted and used for sequencing analyses. Results revealed that the carcass swabs had a very high degree of microbial diversity, and different microbial compositions were observed from the three sampling locations on the beef carcasses. *Bacteroidetes*, *Firmicutes*, *Proteobacteria*, and *Actinobacteria* were the most abundant phyla present on both fresh beefsteaks and carcass swabs. *Moraxellaceae*, *Aerococcaceae*, *Staphylococcaceae*, *Flavobacteriaceae*, *Rhodobacteraceae*, and *Corynebacteriaceae* were the most abundant bacterial families identified from the carcass swabs. Analysis of the environmental swabs and the beefsteaks revealed that although both had highly complex microbial diversity before cold storage, only a few organisms, including *Pseudomonas* sp., *Psychrobacter* sp., and *B. thermosphacta*, dominated after 1 week of aerobic storage at 4°C. Microbes present in the environmental swabs included allof the species found in spoiled beef, indicating that there was microbial adaptation to the processing and storage environments. Skin-associated bacteria identified from the handlers, such as *Propionibacterium acnes*, *Staphylococcus equorum*, and *Staphylococcus* sp., were detected in the beefsteaks only at time zero; they were outcompeted by the dominant spoilage microbiota after storage. By combining observations of the results from beefsteaks and samples collected from the environment and the handlers, the authors concluded that spoilage-associated bacteria originated from the carcasses and were carried to the butchering environment, where they became part of the resident microbiota. These microbes could then be spread to meat products. Microbes that could tolerate cold storage temperatures and effectively metabolize available nutrients were the ones that caused beef spoilage by the end of storage (206).

Stellato et al. (207) conducted a similar study, sampling and analyzing results from 20 butcheries, including 10 small-scale retail distribution facilities and 10 large-scale retail distribution facilities. Results revealed that although the microbial populations present in the environment were complex, there were no significant differences between different butchery types (small scale versus large scale). These results matched those of two previous studies (208, 209). The complexity of the meat microbiome decreased sharply after storage because of the impact of storage temperatures and the type of packaging. Chopping boards had greater microbial diversity and overall microbial counts than knives, suggesting that meat surface contamination is strongly influenced by the surface materials used for chopping boards. The comparison between the meat microbiome and the environmental microbiome indicated a strong correlation between these two microbiomes. *Pseudomonas* spp., *Brochothrix* spp., *Psychrobacter* spp., *Streptococcus* spp., and *Acinetobacter* spp. were identified from both the meat samples and the environmental samples, suggesting that these species were part of the resident microbiome present in the processing facility. These species were identified in previous reports as well and are recognized as undesirable bacteria in the food processing environment (147, 210, 211).

Different processing practices used for different production lots are another factor that can change microbial populations. For example, some meat may be processed directly from fresh cuts (stored for less than 2 days in cold rooms), whereas some lots may be processed from carcasses that have been stored for 3 to 4 days in the cold room. A study conducted by Säde et al. (212) evaluated the potential impact of different lot practices on the microbial populations present in boneless beef shoulder steaks. They collected steak samples from six product lots during a 3-week period and analyzed these samples 2 days after packaging, on the processor-defined use-by date (8 to 10 days of 6°C storage), and 2 days after the use-by date (10 to 12 days of 6°C storage). All samples were packaged in a high-O_2 MAP system. Results revealed that, although early samples had distinct bacterial communities between different lots, after 8 to 12 days of storage at

6°C, the communities were similar and composed of common meat spoilage bacteria, such as *Carnobacterium* spp., *Brochothrix* spp., *Leuconostoc* spp., and *Lactococcus* spp. (212).

Carcass treatment is another processing practice that can differ from one facility to another. In a study conducted by Botta et al. (213), beefsteaks were treated with aqueous ozone (AO) or electrolyzed water (EW) before they were vacuum packaged and stored at 4°C for 15 days. Results from sequencing analysis revealed that *Pseudomonas fragi* was the most frequently isolated species before and after treatment with AO and EW, as well as in the untreated control. As storage time increased, *L. sakei*, *Leuconostoc gasicomitatum*, and *Lactococcus piscium* became dominant in meat samples. The different carcass treatments (EW versus AO) used in this study did not modify the microbial populations present in beef samples.

As discussed above, storage (both storage conditions and storage duration) has a significant influence on the final microbial populations present in meat. Although initial microbial populations present in freshly processed meat can be significantly different, the microbial composition stabilizes towards the end of the storage. Depending on storage conditions and time, one bacterial species becomes dominant at the end. Culture-independent sequencing methods can provide new insight about the microbiome present in meat, abattoirs, and slaughtering facilities, and the microbiome changes during storage. This information is important for the development of new intervention methods to control microbial populations present in meat products.

Poultry

The microbiome present on poultry carcasses is a reflection of the poultry species (turkey versus chicken), the cut (pieces or whole carcasses), the slaughtering and processing environment, and storage and packaging conditions. Total APCs of bacteria sampled from different parts of poultry carcasses vary significantly. Dawson et al. (214) determined that the total APC of skin-on chicken breast meat was approximately 2.5 log CFU/ml (meat rinse), whereas APCs of

skinless products were ca. ~3.5 log CFU/ml. Handley et al. (215) determined that whole chicken carcasses had total APCs of ca. 4.63, 3.21, and 0.89 log CFU/ml when sampled at the rehanging, prechilling, and postchilling stages, respectively. Their *Enterobacteriaceae* counts were approximately 2.99. 1.95, and 0.35 log CFU/ml at the three sampling points. James et al. (216) determined that postchilling carcasses had *Enterobacteriaceae* counts and APCs of ca. 2.51 log CFU/ml and 1.75 log CFU/ml, respectively. The different designs of the processing lines and the use of different antimicrobials and hurdle techniques are reasons for the different APCs and *Enterobacteriaceae* counts reported in these studies.

Dominant microbial species isolated from poultry products are similar to those identified in beef products, including *Acinetobacter*, *Corynebacterium*, *Micrococcus*, *Pseudomonas*, and *Psychrobacter*. The application of next-generation sequencing has provided new opportunities to analyze the microbiome present in different poultry products and enables detailed comparison between different chicken carcass treatments. In a study by Kim et al. (217), 80 chickens were randomly chosen and processed to carcass following the steps of stunner, bleeding tunnel, scalder, depilation, hock cutter, evisceration, and chiller. Two antimicrobial treatments, i.e., PAA and Amplon (a blend of sulfuric acid and sodium sulfate), were applied to the carcasses. Chicken carcass rinsates were collected for microbial and sequencing analyses. Based on the sequencing analysis, the top five phyla identified from the chicken carcasses were *Firmicutes*, *Proteobacteria*, *Bacteroidetes*, *Actinobacteria*, and *Cyanobacteria*. In addition, the abundance of proteobacteria decreased as processing progressed. *Bacillales*, *Lactobacillus*, *Ruminococcaceae*, *Clostridiales*, *Lentibacillus*, *Rikenellaceae*, *Pseudomonas*, *Gallibacterium*, *Veillonella*, and *Clostridiaceae* were the top 10 groups identified at the different stages of poultry processing (217). In addition to the general microbiome analysis, all chicken rinsates were plated to determine the presence of *Campylobacter* and *Salmonella*. The level of *Campylobacter* present in the chicken carcass rinsate was ca. 3.75 log CFU/chicken (n = 80). In contrast, *Salmonella* was detected only by qualitative analysis, which included an enrichment step. When the

microbiome present in the *Campylobacter*-or *Salmonella*-positive samples was compared to that in the negative samples, no significant differences in bacterial abundance at the phylum level were observed between *Salmonella*-positive and *Salmonella*-negative samples, although there was a greater abundance of *Actinobacteria* (3.74%) in the *Campylobacter*-positive rinsates than in the *Campylobacter*-negative samples (1.70%). At the genus level, *Salmonella*-positive samples had a lower abundance of *Clostridium* than *Salmonella*-negative samples, whereas a greater abundance of *Clostridium* (8.41%) was observed in *Campylobacter*-negative samples than in positive samples (4.49%) (217).

Mapping out the indigenous microbial communities and their dynamic changes during poultry processing and product storage is the foundation for identifying new indicator bacteria to evaluate product quality and safety and to provide a basis for designing new antimicrobial carcass treatments. Handley et al. (215) evaluated the microbial profiles present on commercial broilers after evisceration and immersion chilling. Upon analysis of the microbial changes, *Pseudomonas*, *Enterobacteriaceae*, and *Chryseobacterium* were identified as potential indicator microorganisms for evaluating the efficacy of different processing steps. Previous studies have revealed that different antimicrobial treatments, such as dips, rinses, sprays, and chill tanks, have different optimal modes of application, and different antimicrobials have their own target microorganisms. For example, it was found that citric acid was more effective against Grampositive bacteria than Gram-negative bacteria (218–220). As discussed above, next-generation sequencing and the information obtained about the background microbes associated with different antimicrobial treatments will ultimately help optimize microbial food quality and safety control.

Fungi Associated with Meat and Poultry Products

Fungi are ubiquitous in their distribution. Air, water, walls, and floors of abattoirs are considered the main sources of fungi that contaminate meat and poultry products (148, 221, 222). A culture-based study revealed that airborne fungi in various animal confinement buildings

ranged from 3 to 6 log CFU/m^3 (223–226). *Penicillium*, *Cladosporium*, and *Aspergillus* were most frequently isolated from the air as well as from the floors of slaughtering facilities (221, 222, 225). In a study conducted by Ismail et al., a total of 34 fungal genera, representing 62 species and one variety, were identified from beef carcasses and the surrounding environment. *Aspergillus*, *Cladosporium*, and *Penicillium* were the top three genera identified from water and air (80 to 90% prevalence in air and 65 to 100% prevalence in water), whereas *Nectria haematococca* was the top species identified from floor and wall samples, and *Aspergillus niger* was the top species identified from beef carcasses (148). Jay et al. (164) provided a comprehensive list of fungi identified from fresh and refrigerated meats and poultry. According to Jay et al. (164), *Cladosporium*, *Geotrichum*, *Mucor*, *Rhizopus*, *Sporotrichum*, and *Thamnidium* are the top genera of mold identified from fresh and refrigerated meats, with *Candida* and *Torulopsis* being the top yeast genera identified. For poultry products, the mold genera *Alternaria*, *Aspergillus*, *Cladosporium*, *Geotrichum*, *Mucor*, *Penicillium*, and *Rhizopus* and the yeast genera *Candida*, *Cryptococcus*, *Debaryomyces*, *Pichia*, *Rhodotorula*, *Saccharomyces*, *Torulopsis*, *Trichosporon*, and *Yarrowia* are the top fungi associated with poultry.

In addition to fresh meats and poultry, the contribution of fungal species to processed meats has also been investigated. Some of them contribute significantly to the ripening process and flavor development of dry-cured meats because of their proteolytic and lipolytic activities. Taking dry-cured Iberian ham as an example, 95% of the yeast population is *Debaryomyces hansenii* (227). However, yeast species such as *Yarrowia lipolytica*, *Rhodotorula* sp., and *Cryptococcus* sp. have been associated with the spoilage of meat, leading to discoloration, sliminess, and off flavors (228, 229). Because of the importance of these yeast species, rapid detection and identification techniques such as PCR, randomly amplified polymorphic DNA PCR, and inter simple sequence repeat PCR, which target the internal transcribed spacer (ITS) regions of these species (e.g., ITS1–5.8S rRNA–ITS2), have been developed (229–231).

For processed meats, fungal species that are involved in product spoilage are determined by product formula, product types, fermentation and processing steps, and storage conditions (232). Different fungal or even bacterial species can be identified as the cause of spoilage, even for the same type of products. As an example, *Carnimonas nigrificans* was identified as the cause of blackspot spoilage of dry-cured ham, while *Pseudomonas fluorescens* was identified as the cause of black spots in spoiled dry-cured Iberian ham (233, 234). In chilled meat, black-spot spoilage can be caused by *Cladosporium cladosporioides*, *Cladosporium herbarum*, *Penicillium hirsutum*, and *Aureobasidium pullulans* (235). Lozano-Ojalvo et al. (232) investigated the molds that were responsible for black-spot spoilage of dry-cured, fermented sausages. Results revealed that *Penicillium* spp. and *Cladosporium oxysporum* were the two main spoilage molds. *Penicillium* spp. have been reported previously as the most commonly found molds in dry-cured meat products and fermented sausages because they can tolerate large concentrations of salt (236, 237). *Cladosporium* species are widely distributed in indoor environments, the air and foods (232, 238). Both genera, *Penicillium* and *Cladosporium*, are also responsible for black-spot spoilage in dry-cured ham (239).

Next-generation sequencing of the ITS region has provided new opportunities to analyze fungal communities present in animal production and processing environments and animal products. Kumari et al. (225) collected aerosol samples in both winter and summer from seven commercial swine farms in South Korea. The composition, abundance, and diversity of airborne fungi were analyzed using culture-independent methods. The ITS1 region of each DNA sample extracted was targeted and amplified using the universal fungal primers ITS1FI2 and ITS2 (240, 241). Among allfungal phyla, *Ascomycota* (representing 75.4% of allsequences), *Basidiomycota* (15.3%), *Zygomycota* (4.2%), and *Glomeromycota* (1.5%) were the top four phyla identified from the aerosol samples. The dominant fungal classes were *Dothideomycetes* and *Sordariomycetes*, which belong to the phylum *Ascomycota*. Statistical analyses revealed that the fungal OTU compositions were largely determined by the swine house units,

the seasons, and the interactions between these. Microclimate variables, relative humidity, particulate matters, ammonia, and stocking density within the swine house unit were also significantly correlated with OTU composition (225).

Fungal populations, as important background microorganisms present in animal production and processing environments, play important roles in product quality. Their involvement in flavor development as well as product spoilage needs further elucidation through research. Traditional fungal analysis methods have several limitations. For example, some fungal species might not grow on regular plates, and taxonomy analysis based on culturing is time-consuming. In addition, taxonomic analysis of macrofungal fruiting bodies requires years of training and expertise in order to accurately identify and classify morphological characteristics (242). Thus, next-generation sequencing methods are new and efficient tools for fungal analysis in meat and poultry as well as in the animal production and processing environment.

ANTIBIOTIC RESISTANCE

Antibiotic-Resistant Pathogens

The discovery of antibiotics, which are substances that kill or inhibit the growth of microorganisms, is considered one of the greatest discoveries of the 20th century (243). Antibiotic resistance is defined as the ability of bacteria to survive exposure to a definite concentration of an antimicrobial agent, and the emergence of antimicrobial-resistant pathogens has become a serious concern worldwide (244, 245). According to the Centers for Disease Control and Prevention, more than 2 million people are sickened every year from infections caused by antimicrobialresistant agents, and 23,000 people may die from these infections (246). From 1973 to 2011, 55 foodborne outbreaks were associated with bacteria that were resistant to at least one antibiotic (247). It is estimated that the cost of antimicrobial-resistant infections exceeds $20 billion every year in the United States (248). In food animals, antimicrobials have been used

for both disease treatment and growth promotion. According to FDA reports, the sale and distribution (domestic and export) of antimicrobials approved for use in food-producing animals increased by 22% from 2009 to 2015. In 2015, 15,576,975 kg of antimicrobials were sold and distributed in the United States, including 9,701,978 kg of drugs important for human medical therapy (249). The formation of antimicrobial-resistant zoonotic pathogens, which can be transferred to humans through contaminated food or direct contact with the animals, emerged and spread as an undesired consequence of antimicrobial use. Antimicrobial-resistant phenotypes have been identified from multiple zoonotic pathogens, such as *Salmonella* Typhimurium DT104, STEC, *C. jejuni*, *L. monocytogenes*, and *Y. enterocolitica* (245). An increasing number of foodborne pathogens are drug resistant (246).

Shiga Toxin-Producing *Escherichia coli*

Among STEC types, *E. coli* O157:H7 is the classic serotype, causing a substantial number of foodborne outbreaks in North America, Europe, and Japan. In addition, it is estimated that at least 70% of non-O157 STEC cases are caused by the other top six serogroups, which are O26, O45, O103, O111, O121, and O145 (250). These six non-O157 STEC serotypes, which are collectively referred to as the “big six,” have been classified as adulterants of raw beef products in the United States since 2011 (251).

Antimicrobial resistance was not commonly identified in early clinical isolates of *E. coli* O157:H7. In a report by Ratnam et al. (252), 97% of the 174 strains tested were susceptible to commonly used antimicrobial agents, including ampicillin, cephalothin, carbenicillin, tetracycline, kanamycin, gentamicin, tobramycin, amikacin, trimethoprim-sulfamethoxazole, sulfisoxazole, nalidixic acid, and nitrofurantoin (252). However, the percentage of O157:H7 isolates that are resistant to antimicrobials has increased in the last few decades. Meng et al. determined the antimicrobial resistance of *E. coli* O157:H7 and O157:NM strains isolated from animals, food, and humans and found that 30 (24%) of the 125 strains of *E. coli* O157:H7 and O157:NM were resistant to at least one antibiotic and 24 (19%)

strains were resistant to three or more antibiotics (253). Two *E. coli* O157:NM strains isolated from cattle were resistant to up to six antibiotics, including ampicillin, kanamycin, sulfisoxazole, streptomycin, tetracycline, and ticarcillin (253). Vali et al. (254) tested 297 O26, 152 O103, and 13 O145 strains isolated from two cohorts of beef cattle from two farms and found that some of the 297 *E. coli* O26 isolates were resistant to ampicillin (0.3%), amoxicillinclavulanic acid (0.3%), neomycin (0.3%), streptomycin (2%), sulfamethoxazole (2.4%), tetracycline (2%), and trimethoprim (1.7%). *E. coli* O103 isolates (n = 152) were resistant to the same antibiotics, but at higher percentages. For example, 37.5% of the O103 isolates were resistant to sulfamethoxazole, compared to the 2.4% found for O26 isolates. In addition, O103 was resistant to cephalexin. Of the 13 O145 isolates, more than half (53.8%) were resistant to sulfamethoxazole. Singh et al. (255) determined the antimicrobial resistance profiles of 274 STEC strains isolated from poultry, cattle, swine, and humans. Thirty-four percent of the strains were resistant to streptomycin, 32% to sulfamethoxazole, 30% to tetracycline, 18% to ampicillin, 11% to cephalothin, 8% to trimethoprim-sulfamethoxazole, 7% to gentamicin, 5% to chloramphenicol, and 4% to cefoxitin. By analyzing both the resistance and the presence of class 1 integrons, the authors concluded that antimicrobial resistance is common in STEC. Class 1 integrons, which are located on mobile plasmids, can facilitate the formation and dissemination of antimicrobial resistance among different STEC strains isolated from humans and food animals.

Nontyphoidal *Salmonella* spp.

The genus *Salmonella* includes more than 2,500 different serotypes. Nontyphoidal *Salmonella* causes approximately 1.2 million illnesses every year in the United States, resulting in $365 million in medical costs annually (256). *Salmonella* is spread from animals to people mostly through food, and according to reports from the CDC, 100,000 cases of *Salmonella* infections are caused by antibiotic-resistant strains (96). Among the nontyphoidal *Salmonella* strains tested, 3% were resistant to ceftriaxone and about 5% were resistant to five or more antibiotics (246). Resistance to tetracycline in *Salmonella*

species increased from 9% (in 1980) to 24% (in 1990), and resistance to ampicillin increased from 10% to 14% during the same 10-year period (257). Over the past decades, the incidence of human infections with multidrug-resistant *S.* Typhimurium DT104 also has increased dramatically (245). In 2018, several outbreaks associated with animal products and attributed to antibioticresistant *Salmonella* serovars were reported. A total of 92 illnesses had been reported from 29 states by 17 October 2018, due to *Salmonella* Infantis-contaminated raw chicken products, with 21 people being hospitalized. This *Salmonella* Infantis isolate was found to be multidrug resistant (258). In the summer of 2018, multidrug-resistant *Salmonella* Reading was identified in a raw-turkey-associated outbreak in which 90 people from 26 states were sickened and 40 people were hospitalized (259).

The use of antibiotics in food animals plays a key role in the formation of antibiotic-resistant *Salmonella*. Multiple resistance to antimicrobials is commonly observed in isolates from food animals (260–262). In the recent National Antimicrobial Resistance Monitoring System report, multidrug-resistant nontyphoidal *Salmonella* was found more frequently in turkey (34%) and ground beef (20%) than in chicken (10%). The prevalence of multidrug-resistant isolates ranged from 26 to 40% among retail foods (263). The increasing prevalence of antimicrobial resistance in foodborne pathogens globally is indeed challenging, and it is important that more be done in veterinary and human medicine to limit its negative effects.

Most antimicrobial agents exert their effects on bacteria by one or more of four basic mechanisms. These mechanisms are interference with cell wall synthesis, inhibition of protein synthesis, interference with nucleic acid synthesis, and inhibition of metabolic pathways (264). Bacterial cells can be intrinsically resistant to certain drugs or become antibiotic resistant by gene mutation or by acquiring resistance from other microorganisms by acquiring the corresponding genes from plasmids, transposons, integrons, bacteriophages, or a combination of the above (265–268). The main defense mechanisms used by bacteria to resist the effects of antibiotics include antibiotic inactivation or modification (e.g., production of β-lactamase), use of efflux pumps to export antibiotics from inside cells, and alteration of

the drug target in bacterial cells. Food animals, companion animals, wild animals and insects, and environments are reservoirs of antibiotic-resistant microbes and antibiotic resistance genes. In order to mitigate antibiotic resistance in foodborne pathogens and reduce the occurrence of antibiotic-resistant pathogens in animal products, it is crucial to better control the use of antibiotics in animal agriculture and in human medication. New strategies that can effectively detect, prevent, and control the formation and spread of antibiotic resistance genes and bacteria are still needed.

PACKAGING SYSTEMS

More and more meat and poultry products are processed in a centralized location and then transported over increasingly long distances. As a result, the industry has utilized different packaging technologies to increase shelf life of meat and poultry products in order to consistently deliver high-quality product to consumers. Packaging plays a critical role in preserving meat throughoutits distribution cycle. Its primary role is as a physical barrier, and it assists in handling of the product, dissemination of nutritional information, and promotion of sales. Fresh and processed meat is packaged to avoid contamination, to delay spoilage, to control enzymatic activity and improve tenderness, to prevent lipid oxidation, discoloration, and dehydration, to reduce weight loss and loss of aroma, and, where applicable, to improve appearance during retail display. Different packaging systems have different attributes and applications, ranging from simple overwrap packaging for shortterm chilled storage for retail display to a diversity of MAP systems for longer-term chilled storage and distribution. Beef and pork produced in North America are predominantly vacuum packaged and stored and distributed under strictly controlled temperatures. At retail, these vacuum-packaged meats are refabricated and repackaged using simple overwrap packaging for display. Thus, meat packaging systems are designed to enhance consumer acceptance by enhancing the bright red color of the meat and prevention of off odors by controlling the exposure of meat to the high O_2concentration in air. Technological

advances in packaging equipment and material have optimized the challenge that oxygen exposure of meat poses, resulting in the development of MAP systems. These MAP systems include low-oxygen permeable shrinkfilm vacuum packaging; MAP with different concentrations of N_2, CO_2, and O_2; and no-O_2 MAP with low CO, CO_2, and N_2.

Aerobic Packaging

Fresh meat and poultry are packaged and stored aerobically by simply overwrapping the meat placed on Styrofoam trays using high-oxygen permeable films made of polyvinyl chloride. These films do very little to contain microbial growth or extend shelf life but instead enhance the attractive red color due to the reaction of myoglobin and hemoglobin in the presence of oxygen to form oxymyoglobin and oxyhemoglobin, respectively. However, prolonged storage under these aerobic conditions results in the formation of metmyoglobin when the iron has oxidized, resulting in browning, which consumers associate with spoilage. This simple overwrap packaging of meat stored under aerobic refrigerated conditions is widespread in retail stores and results in a shelf life of approximately 5 to 7 days at refrigeration temperatures.

Vacuum Packaging

Vacuum packaging is commonly used for fresh, raw meat and poultry and is simply the process of removing air around the product and then sealing it in oxygenimpermeable barrier bags. Once moist air around the meat product is removed and the oxygen-impermeable barrier bag is sealed, O_2levels continue to decrease while CO_2 levels increase due to muscle and microbial metabolism, which utilizes the residual $O_2$to produce CO_2. These low $O_2$and high CO_2 levels significantly inhibit the growth of bacteria, yeasts, and molds that require $O_2$for their growth, thereby enabling a longer shelf life of the vacuum-packaged product. However, the low O_2levels in the vacuum-packaged products preferentially support the growth of psychrophilic and psychotropic anaerobic and facultatively anaerobic bacteria, such as *Brochothrix*

spp., *Lactobacillus* spp., *Leuconostoc* spp., and *Carnobacterium* spp. and other species of LAB. In addition, the low O_2levels also lead to the unattractive but reversible purple color of vacuum-packaged meat due to accumulation of deoxymyoglobin. In spite of this, a predominant amount of meat produced in North America is stored and shipped to retail under vacuumpackaged conditions at temperatures between 0 and −1.5°C to maintain quality and achieve maximum shelf life. At temperatures between 0 and 4°C, the product is expected to have a shelf life of 40 days (269), whereas when held at subzero temperatures (up to −1.5°C), vacuumpackaged beef has a shelf life of 140 days (270).

Modified-Atmosphere Packaging

MAP is a type of packaging in which the atmosphere surrounding the product is different from air and is one that inhibits the growth of spoilage and pathogenic bacteria. It involves enclosing the product in some kind of barrier and then modifying the atmosphere around the product by either drawing a vacuum or flushing and then filling with a gas mix. Vacuum packaging of fresh meats is essentially a form of MAP, because muscle and microbial metabolism utilizes the residual O_2around the product to produce CO_2, whereas MAP introduces large volumes of gases into the headspace of the package and also eliminates the physical pressure on the product created by the barrier bags during vacuum packaging. Thus, during MAP, fresh meat or poultry is placed in special trays or rigid containers, and the air in the headspace is replaced with a gas mixture and sealed using gas-impermeable films. A variety of gases and gas blends in different ratios have been used to meet different product needs. The three most commonly used gases for MAP are CO_2, N_2, and O_2. Although these gases are present in the air removed from the product atmosphere prior to MAP, the ratio of the gases used in MAP applications is considerably different from that in air. MAP systems can be broadly categorized into two groups depending on the gas blend used: high-oxygen MAP and low-oxygen MAP.

High-oxygen MAP systems utilize gas blends that have high levels of O_2 (70 to 80%) combined with 20 to 30% CO_2 as the atmosphere in the headspace of the meat product. They were developed as an alternative to the simple overwrap aerobic packaging to produce packages of fresh meat that is bright red and case ready for retail display. Fresh meats packaged using high-oxygen MAP may last for 10 to 14 days, compared to 3 to 7 days for fresh meat packaged using simple overwrap aerobic packaging. This allows retailers to offer fresh meat products at lower prices, as they can avoid expenses related to in-store packaging. Exposure to high levels of oxygen results in the saturation of meat pigments with O_2 and slows the formation of surface metmyoglobin. However, exposure to such high concentrations of CO_2 results in the accelerated oxidation of lipids and generation of off flavors. In any case, high-oxygen MAP results in fresh meat products that have a shelf life greater than that achieved with aerobic packaging but substantially less than that achieved with vacuum packaging. Unlike fresh red meat, poultry meat has very low myoglobin concentrations and is generally considered white meat. The color of poultry meat is not as significant a consideration as that of beef, and therefore, maintenance of the bright red color is not a priority for poultry products. Storage of poultry meat in a high-oxygen MAP containing 70% O_2 and 30% CO_2 has no additional beneficial effect on its quality and shelf life (271).

Low-oxygen MAP uses a gas blend in which $O_2$is reduced to the minimum level or completely replaced with another gas to inhibit bacterial growth. For example, MAP of fresh meat primals with a gas blend in which 20 to 25% is CO_2 and the remainder is N_2successfully inhibits bacterial growth and extends shelf life (272, 273). Carbon dioxide is most effective against Gram-negative bacteria and increases the lag phase and generation time of affected microorganisms. It has been suggested that the antimicrobial effect of CO_2 is due to its ability to penetrate bacterial membranes and alter cellular pH and metabolic processes (274, 275). Carbon dioxide is highly soluble in meat to form carbonic acid, which reduces the pH and is thought to contribute to its antimicrobial activity. However, when large volumes and high

concentra tions of CO_2 are used in the MAP headspace, the gas concentration in the headspace declines significantly until a product saturation or equilibrium is reached, which could risk package collapse when the amount of CO_2 absorbed by the meat is large enough. Package atmospheres with less than 30% CO_2 are seldom reported to result in package collapse (276). Hence, N_2 is typically used as a filler gas to exclude $O_2$and create the modified atmosphere in the package headspace. Nitrogen has low solubility in fat and water and does not affect microbial growth, but when used to exclude O_2, it prevents growth of aerobic bacteria and indirectly helps to extend the shelf life of fresh meat.

An issue with excluding O_2 during packaging of meat is discoloration of the product. The principal role of O_2 in packaging of meat is the development of the cherryred color that is considered essential to display fresh meat. Carbon monoxide has a very high affinity for hemoglobin in the blood and myoglobin in the muscle that results in a stable, bright red meat color. Very low concentrations (0.3 to 0.5%) of CO are sufficient to produce the stable, bright red meat color, and these concentrations do not pose a human hazard. The FDA has approved the use of 0.4% CO for meat packaging and has categorized CO at these concentrations as generally recognized as safe when it is used as described for MAP (277). Use of CO in low-oxygen MAP at very low levels of 0.4% combined with 20 to 30% CO_2 and the remainder N_2can result in a shelf-ready product that is bright red with low microbial counts and superior quality attributes, such as flavor acceptability and tenderness, compared to aerobic or high-oxygen packaging. Despite these benefits, consumer concern that the use of CO can mask the appearance of spoiled meat and a perceived potential health hazard due to CO toxicity have been hurdles in widespread application of CO in MAP. The color of poultry products such as ground chicken and turkey meat remains more stable in an oxygen-free environment (278), and the best color stability and lowest microbial counts were observed in a 100% CO_2 atmosphere compared to 100% O_2, 100% N_2, or a mixture of 25% CO_2, 66% O_2, and 9% N_2(279, 280). Hence, for poultry products where the appearance of

bright red color is not a requirement, low-O_2 and high-CO_2 atmospheres are preferred to enhance shelf life.

Smart Packaging Systems

Packaging systems that apply technologies that assist in the maintenance or enhancement of the quality and safety of packaged foods without any physical modification to the food are generally referred to as smart packaging systems. Technologies that are in use or being developed are broadly grouped into two categories: active packaging and intelligent packaging systems.

Active packaging refers to the incorporation of additives or changing the environment around the food in a package to extend shelf life and/or to improve safety and sensorial properties, while maintaining the quality of packaged foods. This can involve physical, chemical, or biological actions that alter the interaction between the package or package headspace and the product to reach a desired outcome. Some of these interactions include oxygen scavengers in low-O_2 MAP, CO_2 emitters and scavengers in low-O_2 MAP and fermented foods containing meat, and moisture control to lower aw. Oxygen scavengers are used to absorb the residual oxygen in fresh meat and poultry products packaged using low-O_2 MAP systems or vacuum packaging, thereby enhancing the shelf life of these products by controlling growth of aerobic bacteria and also reducing lipid oxidation, product discoloration, and drip loss. Existing O2-scavenging systems use one or more of these reactions: iron powder oxidation, ascorbic acid oxidation, photosensitive dye oxidation, enzymatic oxidation, unsaturated fatty acid rice extract, or immobilized yeast on a solid substrate. These O2-scavenging reactions can be packaged in a sachet, label film (reactive agents incorporated into the packaging film), card, closure liner, or concentrate. Similarly, CO_2-generating systems are complementary to O_2scavengers. When fresh meat is packaged using vacuum packaging or MAP, CO_2, which is highly soluble in the muscle, is absorbed, resulting in a partial vacuum and pack collapse. In these situations, the simultaneous release of CO_2 from CO_2-generating systems could eliminate the partial vacuum and maintain CO_2 levels

in the packages. A list of commercially available O_2 scavengers, CO_2 emitters and scavengers, and moisture control systems has been published by Wyrwa and Barksa (281).

Microbial contamination and the subsequent growth of microbes on fresh meat and poultry products reduce shelf life and increase the risk of foodborne illness. On fresh meats, because microbial contamination is primarily restricted to the surface, antimicrobial sprays and dips have been used in an attempt to improve safety and shelf life. However, neutralization of the antimicrobials on the surface of the meat limits their antimicrobial efficacy when they are applied as sprays or dips. Similarly, by including the antimicrobial agents in the meat formulation, the meat constituents can partially inactivate the active ingredient or make the antimicrobial inaccessible to the surface-contaminating microflora. Hence, antimicrobial packaging is a promising form of active packaging, especially for meat products. To confer antimicrobial activity, antimicrobial agents are used to coat, incorporated into, immobilized onto, or surface modified onto the packaging material, which, when the packaging comes into contact with the food, results in migration of the antimicrobial agents to the food surface. Although antimicrobial packages have had relatively limited commercial success outside Japan, where Ag-substituted zeolite is the most common antimicrobial agent incorporated into plastic, a large volume of available scientific information has been published on the antimicrobial properties of different classes of antimicrobials in various film structures, synthetic polymers, and edible films. These classes of antimicrobials include bacteriocins, bacteriophages, enzymes, essential oils, organic acids, plant extracts, and polysaccharides. Most of the research on antimicrobial active packaging has been on RTE meats, whereas their application in fresh meat and poultry has been limited.

Antioxidant active packaging is another type of active packaging. Oxidation is a major mechanism of food deterioration. Lipid oxidation in meats results in the development of rancidity and off odors, especially in meats with high fat levels. Many studies have addressed the direct application of antioxidants to meats to control lipid oxidations; however, the use of antioxidants in packaging materials is

rare, but it is of interest. Oregano oil has been evaluated for its ability to inhibit lipid oxidation and extend the shelf life of beefsteaks. Similarly, rosemary extract, tocopherol, ascorbic acid, and many plant extracts have been successfully used in biobased films, and their antioxidant potential to decrease lipid oxidation in meat products has been tested. Publications by Appendini and Hotchkiss (282), Camo et al. (283), Irkin and Esmer (284), and Suppakul et al. (285) provide a comprehensive list of antimicrobial and antioxidant food packaging materials.

Intelligent packaging systems use sensors and indicators to monitor the quality of packaged foods during transport and storage. These sensors and indicators determine whether a product has been subjected to temperature abuse or has been tampered with, thereby resulting in the loss of package integrity. An example of such sensors are gas sensors which measure $O_2$and CO_2 levels in MAP systems. These gas sensors visually indicate O_2 and CO_2 levels by using the principle of luminescence quenching, or absorbance changes caused by direct contact with the analyte. OxySense was the first commercially available fluorescence quenching sensor system for measurement of headspace or dissolved oxygen in transparent or semitransparent sealed packages. Toxin-Guard is a biosensor developed by Toxin Alert (Ontario, Canada) that incorporates antibodies in a polyethylenebased plastic system capable of detecting *Salmonella* spp., *Campylobacter* spp., *E. coli* O157, and *Listeria* spp. (286, 287). Another biosensor system, the Food Sentinel System (SIRA Technologies, Pasadena, CA), is capable of continuous detection of contamination through an immunological reaction wherein a barcode is rendered unreadable in the presence of contaminating bacteria.

Indicators indicate the presence or absence of a substance or the degree of reaction between two or more substances which are visualized by a change in color. Specific types of indicators include gas leak indicators that monitor pack integrity in MAP systems, freshness indicators, and time-temperature indicators. Examples of commercialized $O_2$and CO_2 indicators that are used in different foods include the Ageless Eye, Vitalon, and Samso-Checker. Freshness

indicators react with metabolites associated with food spoilage. These include indicators sensitive to organic acids, ethanol, and biogenic amines, which are metabolites produced by spoilage microbes during the degradation of meat (288–291). Time temperature indicators are used to show a measurable, time-temperature-dependent change that reflects the full or partial temperature history of a food product to which it is attached (292, 293). These indicators are dependent on microbiological, chemical, biochemical, mechanical, and electrochemical changes that result in a visible response, such as a mechanical deformation or color change. Essentially, time-temperature indicators monitor the time-temperature relationships of a product throughout its movement through production, processing, storage, transportation, distribution, and retail display. Finally, radio frequency identification tags are semiconductor tags that are placed on packaged products to assist in traceability, inventory management, labor cost savings, security, and promotion of quality and safety. Although such tags have been available for almost 40 years, their application in the food packaging and distribution arenas is relatively recent.

Many active and intelligent packaging systems are being developed, and their commercialization has been enhanced by the rapid pace of sensor and indicator development.

MEAT TRACEABILITY

Traceability of meat and poultry products is essential to provide transparency and security to consumers. It guarantees the quality and safety of products entering commerce and prevents fraud and unfair competition. In general, traceability is the ability to know where food comes from and where food goes at any given stage of the food production chain. It enables locating products implicated in foodborne illness outbreaks and facilitates their recall when a safety or quality standard is breached (294). A key concept relating to product traceability is that of the “traceable unit.” GS1, an international notfor-profit association that designs and implements global standards and solutions to improve supply chain management, divides traceable

units into batches, trade units, and logistic units (295). While trade units and logistic units are defined as externally traceable units, batch is considered an internally traceable unit (296, 297).

The meat and livestock sector has been at the forefront of traceability policy because of the number of outbreaks and food safety crises (298). Different beef supply chain traceability models can be used based on production methods. The GS1 guideline (299) lists the key traceability elements for various trade items. For example, when livestock is the trade item, the key elements for traceability include individual or mob animal identifiers, cattle production information (e.g., age, region, fattening, and finishing), feed and quality identification through supply documentation for feed supplements, livestock mob movement declarations, and animal treatment. When beef carcasses are considered the trade item, important elements to link the carcasses to individual animals are the application identifier, the global trade item number, the application identifier batch, lot, and/or serial numbers, and the registration number of the slaughterhouse facility issued by the government or authority. Also important are the date, time, batch, and properties that supply the livestock (299). For poultry products, one document for industry to follow is “GS1 global meat and poultry traceability guideline, part 5. Poultry supply chain” (300). As described in this document, key traceability elements for live poultry are similar to those for beef products. These elements include batch and/or lot identification, information about flock production (e.g., age, region, fattening, and finishing), feed and feed supplements, animal treatment, and the poultry batch or lot movement declaration (300).

Technologies and devices used for traceability have continuously improved to ensure implementation. Efficient methods for tracking agro-products include radio frequency identification, near-field communication, isotope analysis and DNA barcoding, and the combination of the use of isotopes with other techniques, such as chromatography, isotope ratio mass spectrometry, inductively coupled plasma mass spectrometry, and near-infrared spectroscopy (301, 302). Overall, traceability systems are important tools to ensure the safety and quality of meat and poultry products. The constant improvement

of technologies for wireless sensing, real-time tracking, and remote monitoring will lead to a more rapid and reliable traceability system for animal products.

CONCLUDING REMARKS

The contamination of raw meat and poultry is natural; however, efforts should be focused on minimizing contamination throughout the farm-to-fork continuum. Control measures should begin on the farm and should continue through the harvest stages until the products are consumed by consumers. Contamination is minimized through the production and processing continuum by regulatory inspection programs and other food safety programs used by the meat and poultry industry, i.e., HACCP systems, to prevent any foodborne illnesses related to meat and poultry products.

7
Microbiological Issues Associated with Fruits, Vegetables, Nuts, and Grains

This chapter addresses several plant-based food groups, each of which has been extensively investigated. While each of these food groups is easily distinguished from the other, processing operations may produce another set of unique products from each food group that have their own characteristics and associated microbiological issues. Hence, a vast variety of foods are covered in this chapter. The first major section provides a short description of each food group. The second section addresses the major microbial groups associated with these food groups and their products. The remaining sections discuss common themes associated with all these food products, including quality and safety repercussions associated with microbial contamination of these food groups, sources of contamination, detection of contamination, interventions available to reduce microbial contamination, and risk assessment.

PRODUCT TYPES ASSOCIATED WITH EACH FOOD GROUP

Fruits, vegetables, nuts, and grains are classified according to the part of the plant from which they originate. In broad terms, fruits are foods that develop from the flower of a plant and contain seeds, whereas the other parts of the plant (i.e., roots, stems, and leaves) are categorized as vegetables. There are a number of subcategories within the fruit classification scheme that are based on the fruit's morphology (Table 7.1). Similarly, subcategories of vegetables are dependent on the part of the plant that is eaten, but differentiation of vegetables is also often based on where they originate (Table 7.2). Of note in Table 7.1 is that tomatoes, nuts, and grains are categorized as fruits. Mushrooms, on the other hand, are included in Table 7.2 as vegetables but are actually fungi. The lists of crops provided in Tables 7.1 and 7.2 are not comprehensive, as they constitute only about 50% of the produce items listed in USDA Agricultural Handbook 66 (1).

Many fruits and vegetables are consumed in their raw state, as their preparation steps (i.e., peeling, stoning, cutting, shell cracking) are minimal. Other processing steps, such as drying, scalding, blanching, pressing, and

freezing, are more involved and may be conducted in the home or by the food industry. The resulting product may in some cases be consumed shortly thereafter, but it may also be stored. When the product is stored, both the processing and storage will likely influence the microbiological profile associated with the final product.

Although this chapter addresses many crops and plant-based products, these foods may be divided into two categories: high-moisture foods and low-moisture foods. Moisture availability is a critical factor in determining the dominant microflora that will be resident initially and subsequently during storage. The high-moisture category is addressed first, followed by crops in the low-moisture category.

TYPES OF MICROBIAL CONTAMINATION ASSOCIATED WITH EACH FOOD GROUP

Bacteria, molds, yeasts, and viruses are ubiquitous in the environment, but within each crop, there are major types of microbes that dominate shortly after harvest. In many cases, the dominant microbial groups that are initially present do not persist, as the environmental conditions favor other microbes that may be present in small numbers at the outset. This is the situation for undamaged fresh fruits and vegetables. In some cases, microorganisms may also be introduced after the crop is harvested, which is a reflection of the hygiene conditions to which the food item is exposed. Hence, there is a wide diversity of microorganisms that may be present on various crops during their journey to the table (2). Some examples of the microbial contaminants that could be associated with fruits, vegetables, nuts, and grains are provided in Tables 7.3 and 7.4. Most of our knowledge in this area has been obtained from culture-dependent methods; however, results from culture-independent methods (i.e., metagenomics studies) may reveal differences in the diversity and structure of the microbial communities in those food groups as we know them today.

Table 7.1 Fruit classification

Fruit type	Fruit category	Description	Examples
Fleshy (pericarp is soft or fleshy at maturity)	Drupe or stone/pit	A one-seeded simple fruit in which the innermost portion of the ovary wall (endocarp) becomes hard and stony and the outermost part (exocarp) becomes either fleshy or fibrous	Almond, apricot, cherry, mango, olive, peach, plum
	Berry	A simple fruit in which the inner portion of the ovary wall becomes enlarged and juicy but it has no rind	Grape, pepper, tomato
	Hesperidium	A berry in which a leathery rind forms and the interior part of the fruit is divided by septa	Grapefruit, lemon, lime, orange
	Pepo	A berry in which a relatively hard rind is formed but no septa divide the fruit	Banana, cantaloupe, cucumber, papaya, pumpkin, squash, watermelon
	Pome or seed fruit	An accessory fruit formed by a group of carpels more or less firmly united with each other and surrounded by and united to the floral tube or receptacle	Apple, pear
	Aggregate fruit	A fruit formed by the development of multiple pistils from the same flower	Blackberry, raspberry, strawberry
	Multiple fruit	A fruit formed by the coalescence of many flowers crowded together in the same inflorescence, typically surrounding a fleshy stem axis	Fig, pineapple

Fruit type	Fruit category	Description	Examples
Dry (pericarp is dry at maturity)	Legume	A dry fruit developed from one carpel that at maturity splits along both the dorsal and ventral sutures	Bean, chickpea, lima bean, mung bean, peanut, pea, soybean
	Nuts	A dry fruit where the seed is attached to the fruit wall, which is greatly thickened and hardened	Chestnut, hazelnut, hickory
	Grain	A dry fruit where the fruit wall and the seed coat are fused	Barley, corn, oats, rice, rye, wheat

Table 7.2 Vegetable classification

Location	Category	Description	Examples
Underground	Bulbs	Usually consist of layers or clustered segments just below the surface of the ground with a fleshy, leafy shoot above ground	Fennel, garlic, leek, onion, shallot, spring onion
	Roots	Usually a long or round-shaped taproot	Beet, carrot, parsnip, radish, turnip
	Tubers	Grows underground on the root of a plant	Artichoke, potato, yam
Above ground	Flowers	Immature flowers	Artichoke, broccoli, cauliflower
	Fungi	Possesses a stem, cap, and gills	Mushroom
	Leaves	Edible leaves of plants	Brussels sprouts, cabbage, lettuce, spinach
	Stems	Edible stalks of plants	Asparagus, celery, kohlrabi

QUALITY AND SAFETY OF FOOD CROPS ASSOCIATED WITH MICROBIAL CONTAMINATION

Most food crops that are harvested are of optimal or near-optimal quality and ready for consumption or further processing. However, some food crops are harvested in an immature state and then, during storage and transport, continue to metabolically change to their mature state. Since crops are living tissues, it is inevitable that chemical and biochemical changes will continue past maturity and will contribute to quality losses, a state that is termed spoilage. However, in addition to this chemical activity, microbiological contamination and its associated activities will also be a major factor contributing to spoilage. Such spoilage is often caused by a complex mixture of bacteria rather than one microbial species (3), and those activities ultimately lead to changes in the appearance, texture, and flavor of the product. Examples of these types of spoilage for both high-moisture and low-moisture food crops are given in "Spoilage" below.

Another serious consequence of microbiological contamination of crops is that some contaminants cause human illness. These microbial pathogens can be categorized as two types, pathogens of which a low dose (<100 cells) can cause illness (e.g., *Escherichia coli* O157:H7, *Salmonella*, and norovirus) and pathogens requiring growth in the food to large cell populations to cause illness. In the latter case, food becomes unsafe either from consumption of toxins produced during the pathogen's growth (e.g., mycotoxins) or from consumption of the amplified pathogen populations (e.g., $>10^6$ cells) present in the food (e.g., *Listeria monocytogenes*). Examples of the pathogens that may be present in both low-and high-moisture crops are described in "Outbreaks and Prevalence of Pathogens and Toxins" below.

Spoilage

High-Moisture Food Group (Fruits and Vegetables)

Appearance is the main factor influencing consumers' purchase of produce, which includes color, gloss, shape, size, and absence of defects. One of the first noticeable changes in quality is often browning, which arises from the interaction of polyphenol oxidase and phenols that are released during minimal processing. Hence, microorganisms are not directly responsible for this defect, but they may contribute indirectly through their release of enzymes that break down plant constituents to accelerate the interaction of the browning enzyme and its substrate (4). Interestingly, browning is often mistaken for mold growth, such as that which occurs with the brown or black spots on cauliflower.

Another noticeable change in produce quality is the loss of firmness. Contributing to this quality defect are both bacteria (e.g., *Erwinia* and *Pseudomonas*) and yeasts that produce and release pectinases (pectin methylesterase, polygalacturonase, and pectin lyase) and cellulases that are in turn responsible for breaking down pectins and cellulose, respectively. The latter compounds are key components in the middle lamella and plant cell walls, whose breakdown results in tissue maceration, loss of rigidity of plant tissue, and nonreversible cell damage (3). However, prior to this textural breakdown, the pectinolytic activity often results in "soft-rot" spots or other unacceptable visual defects. Bacterial and yeast counts that are associated with these spoilage defects often exceed 8 log and 5 log CFU/g, respectively (3). However, a high microbial count is not always indicative of spoilage, nor does a low microbial count necessarily indicate that spoilage is absent. In the latter case, densities of spoilage bacteria or yeasts may be high near damaged surfaces but could be diluted by less-contaminated Undamaged surfaces when plant tissue is homogenized for determining microbial counts (3).

Table 7.3 Examples of bacterial genera contaminating crops at harvest and processed foods from those crops

Fruits	**Vegetables**	**Nuts**	**Grains, flour, bakery products**
Acidovorax	*Acinetobacter*	*Achromobacter*	*Bacillus*
Alicyclobacillus	*Bacillus*	*Acinetobacter*	*Clostridium*
Bacillus	*Chromobacterium*	*Bacillus*	*Enterobacter*
Buchnera	*Clostridium*	*Brevi bacterium*	*Escherichia*
Erwinia	*Enterobacter*	*Clostridium*	*Klebsiella*
Gluconacetobacter	*Escherichia*	*Corynebacterium*	*Pantoea*
Microbacterium	*Erwinia*	*Enterobacter*	*Salmonella*
Pantoea	*Flavobacterium*	*Escherichia*	*Serratia*
Pectobacterium	*Janthina bacterium*	*Flavobacterium*	*Staphylococcus*
Photobacterium	*Klebsiella*	*Lactobacillus*	
Pseudomonas	*Lactobacillus*	*Leuconostoc*	
Xanthomonas	*Leuconostoc*	*Microbacterium*	
	Listeria	*Micrococcus*	
	Pantoea	*Proteus*	
	Pectobacterium	*Pseudomonas*	
	Pedobacter	*Salmonella*	
	Pseudomonas	*Staphylococcus*	
	Salmonella	*Streptococcus*	
	Xanthomonas	*Xanthomonas*	

Table 7.4 Examples of fungal (yeast and mold) genera contaminating crops at harvest and processed foods from those crops

Fruits	Vegetables	Nuts	Grains, flour, bakery products
Alternaria	*Alternaria*	*Acremonium*	*Alternaria*

			Zygosaccharomyces

It is common practice to package many perishable produce items in atmospheres that minimize oxygen exposure to reduce browning and extend shelf life. In addition, modifying the atmosphere shifts the dominant microbial species of produce, such as fresh-cut iceberg lettuce, from *Pseudomonas* spp. to

lactic acid bacteria such as *Leuconostoc* spp. and *Lactococcus* spp., which thereafter proliferate (5, 6). Off odors described as sour (6) or pungent or fermented (5) then become the principal characteristics for rejecting the lettuce as spoiled.

Off odors are also responsible for the rejection of fruit products. For example, immature apples are stored postharvest to accommodate exportation and extension of shelf life; however, if the apples are infected with fungi such as *Penicillium expansum*, the growth of these microorganisms leads to the production of primary and secondary volatile metabolites that adversely affect their odor and acceptability (7). Similarly, in commercial pasteurized fruit juices, the presence of the heat-resistant, acid-tolerant spore-forming bacteria *Alicyclobacillus* spp. leads to the production of medical, phenolic, or antiseptic off odors and off flavors (8).

Low-Moisture Food Group (Nuts and Grains)

Maintaining water activity (a_w, a measure of the water available to microbes) values of less than 0.70 largely mitigates bacterial and most fungal growth in nuts. Under such conditions, spoilage of nuts is primarily due to oxidative rancidity of their fats. When nuts are not kept dry, mold may grow on them and can change the product's appearance, making it unacceptable to the consumer. However, the more serious concern regarding the presence and growth of molds is that the production of mycotoxins makes the product unsafe. Additional discussion on mycotoxins is found in "Low-Moisture Food Groups (Nuts, Grains, and Dried Fruits)" below.

As in nuts, molds are a common contaminant of cereal grains both pre-and postharvest. Damage of the entire crop may occur when grains, particularly wheat and barley, are infected with field fungi and subjected to below-normal temperatures and above-normal precipitation (9). When grain has been separated from the chaff and dried to moisture levels of 12 to 14%, it may be stored for 1 year or longer before being processed (10).

Once grain is processed into flour and subsequently baked products, the mold spores and vegetative microbial cells originating from the grain are eliminated. However, during the relatively long period of product cooling before packaging, the surfaces of baked products are subject to recontamination with airborne mold spores. Hence, mold growth is the predominant cause of baked-product spoilage. In addition, for bakery products with a moist interior, a spoilage condition known as "ropy" formation can develop. In this case, rope formation is the result of extracellular capsular material produced by germinated endospores of *Bacillus subtilis*. These spoiled products are characterized by a

mucilaginous appearance when pulled apart and by the presence of a melon-like odor (10).

Outbreaks and Prevalence of Pathogens and Toxins

High-Moisture Food Group (Fruits and Vegetables)

Although fruits and vegetables are considered part of a healthy diet, foodborne illness associated with the consumption of produce has become a major food safety concern in the past 2 decades. Li et al. (11) compiled and summarized data on produce-related outbreaks and sporadic illnesses that occurred in five industrialized regions or countries (Australia, European Union, Japan, New Zealand, and the United States) from 2010 to 2015. Overall, there were 988 produce-related outbreaks and 45,723 cases of produce-related illness in those regions and countries. As to the magnitude of the food safety risk of this commodity group compared to other groups, Gould et al. (12) reported that produce was responsible for about one-third of the outbreaks and more than 80% of outbreak cases associated with imported foods in the United States during the period of 1996 to 2014.

One of the challenges in assessing the food safety risk of fresh produce is the difficulty of finding enteric pathogens in the products during routine surveys (13, 14). Based on such results, the European Commission estimated that the overall prevalence of foodborne pathogens on fresh vegetables is <1% (15). This low prevalence is influenced by many factors, including the methods used for detection, the sources contributing to contamination, the environmental stresses encountered by the contaminated produce item, and the management strategies and interventions applied both pre-and postharvest to reduce pathogen contamination.

Low-Moisture Food Group (Nuts, Grains, and Dried Fruits)

Until recently, the primary food safety risk associated with low-moisture plant-based foods was the presence of toxigenic and pathogenic fungal species and their exposure to environmental conditions that would allow their growth and production of mycotoxins and other toxic metabolites (e.g., aflatoxins, ochratoxin, fumonisins, zearalenone, patulin, and trichothecanes, including deoxynivalenol). Consumption of mycotoxin-contaminated foods can cause acute or chronic toxicity in humans and animals. In addition to these adverse effects from direct consumption of mycotoxin-contaminated foods, there is also concern regarding the use of these contaminated crops as animal feeds and subsequently the ingestion of animal-derived food products that could contain residues or metabolites of mycotoxin residues or metabolites. Contamination

of plant-based foods by mycotoxins remains a problem despite extensive efforts to minimize their presence (16). A recent estimate reveals that about 25% of the world's harvested crops are contaminated by mycotoxins annually (17). Mycotoxin contamination of low-moisture plant-based foods is particularly pervasive in developing countries where there are high temperatures and humidity levels, which are conducive to mold growth and mycotoxin production. As a result, hundreds of hepatocellular carcinoma cases occur each year due to ingestion of mold-contaminated products (18). Not discounting these acute cases, many more carcinoma cases may be identified as our understanding of the complementary toxicity mechanisms of action that occur when multiple types of mycotoxins are present in a food system increases (19).

Following are examples of studies conducted within the past decade addressing the pervasiveness of molds and their metabolites in nuts. Investigators determined that 100% of walnuts (n = 20), 91% of pine nuts (n = 11), 76% of almonds (n = 17), 6% of pecans (n = 16), 25% of dried apricots (n = 8), 20% of dried cranberries (n = 10), 8% of dried pineapple (n = 12), 60% of dried raisins (n = 10), and 0% of dried papaya (n = 10) sampled in the Washington, DC, area were contaminated with viable fungi (20). *Aspergillus* was identified as the most common mold, being present in 66% of the nut samples and 50% of dried raisins. Analysis of dried fruits (n = 75) and nuts (n = 90) purchased from retail shops in Pakistan revealed that 22.7% and 35.6% of these items, respectively, were contaminated with aflatoxin (21). The presence of low levels of aflatoxins is tolerated; however, this study revealed that 6.7% and 11.1% of the dried fruit and nut samples, respectively, were contaminated at levels that exceeded the limit (4 μ g/kg) set by European Union regulations (22).

Generally, all cereal crops improperly stored for a prolonged time can be subject to mold growth and mycotoxin contamination; however, maize is considered the crop most susceptible to mycotoxin contamination, and rice is the least susceptible (23). The molds most likely to contaminate grain and produce mycotoxins include *Fusarium* species, which infect and grow on crops (e.g., wheat, barley, and corn) in the field, and *Aspergillus* and *Penicillium* species, which grow on these crops during storage (16). Neme and Mohammed (24) recently reviewed studies of the prevalence and levels of mycotoxins that have been found in grains such as maize, peanut/groundnut, sorghum, millet, wheat, and rice. A literature review by Ferrigo et al. (25) addresses *Fusarium* mycotoxins, providing a perspective on the range of the levels of different *Fusarium* mycotoxins in different cereals originating from different geographical areas. These authors suggest several factors that potentially contribute to the variability in type and level of mycotoxins between regions, including the species and strain of *Fusarium*, the environmental conditions

surrounding the crop in the field and during storage, and other endogenous and exogenous factors that can affect mycotoxin production (25).

Another food safety issue of major concern is the contamination of low-moisture food products with enteric pathogens. Outbreaks of foodborne illness associated with the consumption of tree nuts, peanuts, and sesame seeds have occurred frequently within the past decade, and a list of these is available online (26). Most have been attributed to *Salmonella*, a pathogen noted for its resistance to desiccation (27). Hence, the long-term storage of nuts does not preclude them from being contaminated, albeit generally at low cell populations (28). A recent outbreak of salmonellosis associated with Kellogg's Honey Smacks cereal, which has a 1-year "best if used by" date, highlights the concern that this wheat-based product continued to cause illness when consumers failed to heed warnings to discard the product (29). Many other outbreaks have been associated with grains, dried fruits and vegetables, and nuts (30, 31), and such outbreaks are likely to continue, as their low levels of contaminants are typically heterogeneously distributed (28, 30), thereby precluding the testing of final product for *Salmonella* as a realistic safety measure.

ENUMERATION AND DETECTION OF MICROBIAL CONTAMINANTS AND INHERENT LIMITATIONS

For many decades, enumeration of microbial contaminants in produce, nuts, and grains primarily relied on dislodging the microorganism from the food item into a liquid medium using some mechanism of physical force (shaking, stomaching, vortexing, sonicating, or grinding). In the case of bacterial, yeast, and mold counts, this extract was then collected and applied to a culture-based assay for enumeration of the microbes using some form of solid agar medium. The composition of the medium varied and was dependent on the metabolic requirements of the organism being enumerated. Once the agar plate had been held for a specified period of time at a specified temperature, often optimal for the target organism, the colonies were counted. Although it is still widely used, a limitation of this approach is that the plant-based food to which the microbes are attached and the strength of attachment by different microorganisms to the food vary (32). This variability in attachment can affect the number of cells dislodged into the extract, which can represent a large portion of the total number of cells from the food when populations are low, such as often occurs when enteric pathogens are present. A similar limitation may occur when viruses or parasites are extracted from plant-based foods; however, in this

instance, either microscopy or molecular detection would primarily be used for the detection and/or quantification of those microbes.

Although enumeration of the microbial content yields more information on the degree of spoilage of a food, often only the presence or absence of a specific type of microorganism is necessary. Molecular detection methods have become a preferred approach by many laboratories for detecting foodborne pathogens in foods. For molecular detection, either the food item may be homogenized directly with an enrichment medium or an extract from the food item can be mixed with the enrichment medium. An enrichment is needed to enable the growth of the pathogen of interest to sufficient levels for detection (typically 5 to 6 log). After incubation of these enrichment mixtures, portions are removed for DNA or RNA extraction and subjected to a molecular assay, such as PCR (the polymerase chain reaction assay), whereby a gene specific for the target organism is amplified and detected. The shorter time to results is the primary advantage to using molecular assay-based detection rather than culture-based detection. However, two limitations of molecular-based detection have become apparent. One is that when an enrichment medium is used, the medium itself predisposes some strains of a targeted microbe such as *Salmonella* to outcompete others (33). This limitation is especially relevant for epidemiologic investigations, as certain strains may appear to be less significant than they would be under natural conditions. However, such concerns may not have to be considered in the future if metagenomic sequencing is able to overcome this limitation (see chapter 36 of this volume).

A second limitation of molecular assay-based approaches for detecting microbial contaminants in plant-based foods is the inability to distinguish between viable and dead cells of the microbe of interest when quantitative PCR (qPCR) is used. Two approaches (propidium monoazide qPCR [34] and reverse transcriptase qPCR [35]) have been applied with the assumption that they would amplify only RNA associated with viable organisms and not amplify DNA from dead organisms. However, Ju et al. (36) observed that in lettuce, when dead *E. coli* O157:H7 cells were present at 100-fold-higher numbers than viable cells, false-positive enumerated results occurred with propidium monoazide qPCR. These investigators also determined that highly degraded RNA was amplified by reverse transcriptase qPCR, thereby discounting the presumption that mRNA quickly degrades after death of the cell. Given these findings, investigators should be cautious in using these approaches.

As noted previously, enteric pathogens contaminating produce, nuts, and grains are often present at very low levels and heterogeneously distributed. Although mixing and/or pooling of samples or testing more samples or greater quantities can increase the likelihood of detection, there is often an increased analytical

cost that can be disproportionate to the benefit. For those reasons, a common practice used by the industry, environmental agencies, and public health organizations is to screen for indicator organisms instead of microbial pathogens (37). Such indicator organisms (e.g., generic *E. coli*) may serve as markers of potential fecal contamination; however, their validity as predictors of pathogen presence is often not reliable. Generally, the relationships between the presence or levels of an enteric pathogen and an indicator microbe are random, site-specific, or time-specific events. Therefore, the suitability of predicting the presence or cell populations of pathogens through indicator organisms has been challenging to determine and strongly depends on the circumstances (38).

SOURCES OF MICROBIAL CONTAMINATION

Preharvest Sources

During the cultivation of fruits, vegetables, nuts, and grains, the open nature of fields and orchards in which they are grown can expose the crop to multiple sources of contamination. However, for any of these sources, it is often difficult to determine their impact on a crop's microbiological community, as there are competing factors (i.e., biological, chemical, and physical) that could potentially modify that input fairly rapidly. For example, soil could contribute substantially to both the rhizosphere (i.e., below-ground) and phyllosphere (aboveground) microbial communities. However, when the bacterial communities on leaf surfaces and their surrounding soil were compared through pyrosequencing, only a very small fraction (0.5%) of microbial Taxonomic units were found to be shared between the two environments (39). In contrast, Truchado et al. (40) determined that the phyllosphere bacterial community of baby spinach was influenced more by the soil bacterial community than that of the irrigation water.

In addition to field soil contributing to the microbial community of crops grown in that matrix, other sources, both intentional and unintentional, may contribute both beneficial and pathogenic microorganisms to the crops. Two of the intentional sources introduced into crops in the field are manure and soil amendments. Added primarily for their nutrient content, these materials themselves have complex microbiotas and thus could contribute a new array of microbial groups into the soil that would then compete with the existing microflora for space and nutrients. Despite this dynamic interplay of nonpathogenic microbial communities, food safety specialists are more concerned with untreated manure, as domesticated animals' fecal waste is often contaminated with enteric pathogens, but not always predictably. For

example, the prevalence of *E. coli* O157:H7 in cattle feces has ranged from 0% to 57% (41). Due to this contamination risk, good agricultural practices (GAPs) and regulatory guidelines advise that one of the following measures be taken: (i) the manure be treated with some approved intervention to inactivate the enteric pathogens residing within the matrix or (ii) before application to fields, the manure be stored for some predefined interval that is appropriate for the specific region and field conditions in order to allow die-off of the pathogen (42).

Another major potential source for introducing microorganisms to fields and orchards is irrigation water (42, 43). The amount and type of irrigation water will vary with the crop and the aridity of the region. Types of irrigation water include municipal water, groundwater, collected rainwater, surface water (i.e., rivers, lakes, ponds, and reservoirs), and wastewater (43). In terms of microbiological quality, municipal water is considered one of the safest sources, although protozoan parasites may be present, as they are resistant to water treatment systems that use chlorine for disinfection (44). However, the chief disadvantages of using municipal water are its expense and unavailability in many developed countries. Groundwater is the next safest water source, and while it is used quite extensively in some areas, the quality and sustainability of natural groundwater reservoirs are threatened in some regions by excessive removal. In other production areas, surface waters may be used, but the quality of these waters is unpredictable, as discharges of wastewater, storm water runoff, and livestock or wildlife feces may occur in them. The degree to which irrigation water impacts microbial contamination of food crops depends on the method by which it is applied to fields and orchards, with methods that result in direct contact of the water with the phyllosphere tissue (i.e., spray and furrow irrigation) having a greater risk of contamination than those in which the water is applied directly to the soil (i.e., drip or subsurface drip irrigation) (45).

Soil amendments and irrigation water are two sources of contamination that can result in the entire crop being contaminated; hence, they are examples of sources of broadcast contamination (46). Other types of contamination that may occur during preharvest include directional contamination, whereby microorganisms in aerosols or in storm runoff reach the field either from adjacent urban areas or from adjacent land used for domesticated animal production or for manure composting operations (47–49). Under these conditions, there may be a gradient in pathogen populations, with the greatest concentrations at the site(s) of introduction. Another mode of preharvest contamination is pinpoint contamination, which occurs when fecal matter from wildlife is deposited at discrete locations or when pathogens are deposited on

plants from contaminated insects traversing a section of the field (46). This mode of contamination could also be used to describe the contamination of nuts that drop into fecal wastes left by domesticated animals grazing in the orchards. An additional mode of preharvest contamination is designated as cross-contamination, which occurs when biotic (i.e., humans) or abiotic (i.e., harvest machinery) vehicles are contaminated from an isolated contamination site and subsequently spread the pathogens to other plants within the field (46).

Considering all four modes of contamination, it is evident that there is a major difference among them in the extent of contamination that occurs within the crop. Hence, it is reasonable to assume that sampling plans designed to determine whether a field is safe for harvesting in each of these instances would likely have different probabilities for detecting the contamination.

Postharvest Sources

After crops are harvested, they are subjected to a range of operations that varies with the crop type and the desired end product. However, an element common to all of these operations is the introduction of spoilage and pathogenic microorganisms when facilities used to store or process the crop have not been properly sanitized (50).

Another contamination event that can occur during postharvest storage and processing is contact between one batch of product or its residues with another, which transfers portions of one batch's microbial load to the other batch. For example, Holvoet et al. (51) reported that in the absence of sanitizers, *E. coli* was transferred from lettuce to washing water and then from the water to lettuce that had not been contaminated with this organism. Poorly cleaned and maintained equipment may also harbor microorganisms and act as a reservoir for contamination, as it did when contaminated shredding equipment led to an outbreak of salmonellosis in Queensland, Australia (52). Equipment surfaces can have "hot spots" where buildup of food residues and microbial contaminants in fresh ready-to-eat vegetable processing occurs, especially at the conveyor belt and shredder (53). Postharvest operations identified by Castro-Ibáñez et al. (54) where cross-contamination may occur include produce selection, cleaning, washing, trimming, peeling, cutting, sanitizing, and packing. Regarding the packing operation, both spoilage and pathogenic microorganisms have been determined to survive on cardboard and plastic packaging materials (55). Hence, if these packaging materials become contaminated and are not sanitized before use, they may serve as a source of contamination.

FACTORS THAT CONTRIBUTE TO THE FATE OF MICROBIAL CONTAMINANTS

Inherent Properties of Individual Food Groups and Variability between Cultivars

Structural Properties

Agricultural crop plants are composed of many different plant cells, some of which provide protection from microbiological contamination and others of which permit access by microorganisms to inner tissues. When microorganisms are restricted to the crops' surfaces, water and nutrients are often limiting. These conditions, in turn, restrict their growth and direct microbes to shift their metabolism to a survival mode. Restricting entry of microorganisms from the surface to internalized tissues is one of the first lines of defense for food crops. For example, in nuts, seed coats or pellicles develop from tissues originally surrounding the ovule. These seed coats may be as thin as paper (e.g., peanuts) or thick and hard (e.g., coconuts). Another barrier that nuts possess is a relatively rigid outer casing or shell. In addition, some nuts (e.g., almonds, coconuts, pecans, pistachios, and walnuts) possess a hull whose pulpy tissue serves as a protective outer covering for the shell.

In most food crops, one or more layers of epidermal cells form the core outer structural covering and serve as the first line of defense to minimize microbial intrusion. In some crops, such as potatoes, several layers of epidermal cells form a corky layer protecting the underlying cells, whereas in other crops, such as citrus and melons, the epidermal cells form rinds whose thick structures offer a greater resistance to crack formation and thus penetration by spoilage microorganisms. Another common feature of epidermal cells in many crops is synthesis of a cuticle layer that forms on top of the epidermal cells. Composed of a lipid polymer impregnated with waxes, the cuticle can vary in thickness in different crops and hence has varying capacities to prevent contamination of underlying tissues by invading microorganisms. However, the main function of the cuticle is to serve as a barrier to prevent evaporation of water from the epidermal surface. Hence, vegetables from above the ground are more likely to have waxy cuticle skins than root and tuber vegetables.

Interrupting the outer layer of parenchyma cells or cuticle are natural openings known as stomata and lenticels. Stomata are openings that allow gas exchange between the inside and outside of the plant tissues, but the degree of opening is actively controlled by guard cells responding to water pressure within the cell. Lenticels, in contrast, are sunken openings in the outer covering that cannot be

closed. They also tend to be found on storage organs such as sweet potatoes, cucumbers, and other fruits and vegetables. Both types of openings have been suggested as entry points for both pathogenic and nonpathogenic microorganisms that occur at internalized tissue sites (56–59). Flowers are also entry points of pathogens for tomatoes, cucumbers, and wheat heads (60–62). However, these modes of entry are different from those seen in roots, where microorganisms infiltrate and translocate to the edible tissues. Infiltration of microorganisms through roots can occur in hydroponic systems (63) but is less likely in natural soil matrices given that in order for it to occur, either the microbial exposure levels must be extremely high (64, 65) or the roots have to be wounded (63).

Attachment of microbes to nonwounded aerial plant surfaces is not uniform, and one of the major contributing factors is presumed to be differences in localized physical topography. In general, preferential residence of microorganisms on leaves occurs at the base of trichomes, on the outer rims of stomata, and in cell grooves along veins (66), whereas in certain fruits, *E. coli* O157:H7 cells were found entrapped in the grooves or cavities (67). Another study that revealed localization at selected niches determined that *Salmonella* had a higher affinity for older than younger romaine lettuce leaves, as the former was characterized as having greater topographic complexity (68). Once present in these niches, the microorganisms have substantial protection against dehydration (69). Hence, leaf blade roughness correlated positively with the persistence of *E. coli* O157:H7 on different spinach cultivars (70). Similarly, minimization of dehydration explained the preferential location of *Salmonella* on romaine lettuce leaf regions close to the petiole compared to surfaces at the far end of the leaf blade (68).

The observed results of microbial attachment and fate studies on plant tissues are dependent on the method used to introduce the microbes to the plant tissue. For example, many studies submerged the tissue in a suspension of the microorganisms under study. This method is representative of postharvest washing in the absence of a disinfectant but is not typical of a route of preharvest contamination such as spray irrigation. Ultimately, these two modes of contamination (i.e., dipping and spraying) result in different patterns of microbial deposition. For example, bacteria remained at the site of initial contact when administered in small aerosol droplets (average volume of 750 μm^3), but when bacterial cells were applied in large droplets (>5 μl), the microorganisms collected through the forces of gravity at sites of indentation (71). The collection of water and microbes at grooves and indentations also occurs in response to the repellency of the hydrophobic epicuticular waxes

present on plant surfaces, which are constituents that do not favor plant-bacterium interactions (72).

Under the premise of developing more effective practices for preventing microbial contamination of plant surfaces, studies involving microfabrication of plant surface structures and simulation exercises involving a Lagrangian particle tracking model have been conducted with the purpose of systematically varying parameters of interest and avoiding the confounding influences of natural variation (69, 73, 74). As an example, silicon surfaces were microfabricated to study attachment of *E. coli* to trichome-and stoma-like structures and grooves between epidermal cells (73). Results from the study revealed that more bacteria attached at the base of the trichome and at a location 2.5 to 5.0 μm from the stoma opening. However, no localization was observed for *E. coli* at grooves. The investigators provided a completely different perspective by concluding that surface protrusions (i.e., trichomes) decreased attachment, whereas openings (i.e., stomata and grooves) created shear gradients that increased attachment (74). More specifically, the simulation results revealed that trichomes decreased attachment by reducing shear stress, whereas stomata and grooves enhanced attachment by creating small regions of increased shear stress.

Chemical Properties

In addition to surface topography, the fate of attached microorganisms is dependent on the accessibility of the microbe to the crop's water and nutrient content. Fruits and vegetables are characterized as generally having a high water content (>95%). Therefore, when the microorganism is able to gain access to internal tissues where the water is stored, inactivation due to desiccation stress is no longer an issue. Instead, there is the potential for microbial growth, as fruits and vegetables also contain significant amounts of nutrients essential for that activity. However, the type of nutrients available depends on the type of fruit or vegetable and the rate at which it starts to metabolically break down from its optimal state.

For metabolic breakdown, fruits and vegetables are classified according to their respiration rate (75). For example, commodities with a high respiration rate that equates to >20 ml of CO_2/kg/h at 5°C (e.g., strawberries, raspberries, Brussels sprouts, spinach, broccoli, asparagus, and mushrooms) have a shorter shelf life than those with a low respiration rate, i.e., one that equates to <10 ml of CO_2/kg/h at 5°C (e.g., apples, citrus fruit, potatoes, onions, garlic, carrots, cantaloupes, and watermelons). Metabolic breakdown of the fruit or vegetable is important in that many of the structural barriers that had prevented access of microbial contaminants to internal tissues are eroded. Hence, microbial

degradation of the product becomes an issue of concern. However, in the case of fruit, initiation of this metabolic breakdown is also influenced by the maturity status at which it is harvested. For example, nonclimacteric fruit (e.g., strawberries, grapes, and cherries) are picked at their horticultural maturity, when consumers may immediately consume them. In contrast, climacteric fruits (e.g., apples, tomatoes, avocados, and bananas) are harvested at an immature state. Then, during storage, ethylene is produced through respiration, and that, in turn, leads to horticultural maturity (76). However, once horticultural maturity is achieved for either fruit type, deterioration of the product (i.e., senescence) ensues, making the fruit more susceptible to microbial invasion.

Although agricultural crops are susceptible to microbial invasion and deterioration, plants have at their disposal variable levels of plant defenses that help prevent a microbe's residence and proliferation. These plant defenses can be divided into those that are constitutive (i.e., components that are present in the plant prior to its being exposed to the microorganism) and those that are activated (i.e., components that are generated when the plant senses that a microbe is in its vicinity). Constitutive defenses include the structural barriers discussed in "Structural Properties" above as well as the presence of antimicrobials (e.g., phenols, tannins, glucosinolates, etc.). An example in which such antimicrobials were suggested to have contributed to reduced survival of *Salmonella* was a study in pine nuts, hazelnuts, and pecans (77). In this study, it was noted that *Salmonella* was in contact with the polyphenolic-containing skin of hazelnuts and pecans, thereby increasing the rate of *Salmonella* inactivation, whereas pine nut kernels do not have this skin, and *Salmonella* survived in them for a longer period of time. However, demonstrating the effects of antimicrobials in plant resistance has been difficult because of the heterogeneous distribution of these compounds in plant tissues and therefore the difficulties in correlating their levels to the degree of inhibitory activity for invading microorganisms (78).

In contrast, activated plant defenses are expressed through a process known as microbe-or pathogen-associated molecular pattern (MAMP/PAMP)-triggered immunity and effector-triggered immunity. MAMP/PAMPs are common proteins found on invading microorganisms that are recognized by receptors in the plants. Once recognized, a cascade of reactions is initiated to limit the invasion (e.g., stomatal closure) and kill the microorganisms (e.g., generation of reactive oxygen species). For more information about the nature of these plant defensive reactions, see the study by Peng et al. (79). However, the level at which the plant's immune system routinely participates in thwarting microbial invasions in field environments has not been fully elucidated. Still,

these defensive reactions are likely constantly being stimulated to minimize microbial threats but are effective only against threats involving small numbers of invading microorganisms. Hence, when plants are exposed to large numbers of microbes (>3 log), as often occurs in an experimental study, the results are often not an accurate representation of what is likely occurring in the field.

Processing and Mechanical Damage

Once crops are harvested, they are often subjected to one or more operations that will provide a product that is distributed for institutional and consumer preparation and consumption. These operations, as described below, directly affect the fate of microbes contaminating the product. However, physiological processes are also often accelerated by these operations, and their activities indirectly affect microbial activities and the fate of those microbes. Hence, physiological and microbial activities are often intertwined, and their respective roles are difficult to separate. Given the widely differing set of operations and physiological activities associated with each of the crop types addressed in this chapter, the fruits and vegetables, the nuts, and the grains are discussed separately below.

Fruits and Vegetables

Processing of fruits and vegetables involves a series of operations. For products that are considered minimally processed and will be consumed in the raw state, operations are primarily restricted to washing and cutting or removal of outer barriers (i.e., destruction or removal of surface cells). At this stage, many types of fruits and vegetables undergo additional processing operations, some of which involve subjecting the product to heat or extreme cold (e.g., blanching, canning, steaming, freezing, etc.) either in the processing plant, in an institutional setting, or in the home. Such operations generally delay or halt any microbial activity that may be present at the time the operation is performed. The product, if properly stored under recommended conditions, then has a defined quality state and is safe to consume. Hence, microbial contamination is of greater concern in minimally processed fruits and vegetables that do not receive a treatment to kill pathogens and many spoilage microbes and are to be consumed raw.

Washing fruits and vegetables in chlorinated water is one of the more common operations applied to harvested items in the field and in minimal processing plants. Its primary function is to remove soil and other debris from the product; however, it also removes some, but not all, of the microbial load on the surface (80). In particular, substantial numbers of microorganisms remain in hollows at the junctions of epidermal cells and in folds in the epidermis.

Although any reduction in microbial loads may be beneficial from the standpoint of extending shelf life or reducing risk associated with consumption of pathogen-contaminated stored product, these advantages are manifested only when the wash water contains a disinfectant that is capable of destroying the microorganism before cross-contamination of previously noncontaminated product occurs. Further discussion as to the types of disinfectants used in wash water to kill dislodged microorganisms is addressed in “Oxidizing treatments” below.

Additionally, microbial dislodgement from produce surfaces may be improved by applying a suitable mechanical washing process in combination with a selected surfactant that enhances the wettability of the surfaces. This concept is supported by research using a benchtopscale washing device that revealed detachment of *E. coli* O157:H7 from inoculated leaf samples increased with increasing shear stress and the addition of a surfactant to the washing solution (81).

Another concern associated with fruits and vegetables is the potential for internalization of microorganisms during washing or cooling of the product with nondisinfected water (i.e., hydrocooling or vacuum cooling). For example, enhanced internalization can occur through the stem scar of numerous fruits (e.g., apples, avocadoes, mangoes, oranges, and tomatoes) when the product is washed with water colder than the product temperature (64, 82, 83). Under these conditions, a negative pressure differential is produced as air spaces within the product are contracted, allowing water to seep in. In the case of vacuum cooling applied to crops (e.g., lettuce, spinach, and celery), cooling occurs when the applied vacuum evaporates water at the surface; however, water is sprayed on the product to replace this moisture loss. A study by Li et al. (84) revealed that this method of cooling is risky, as there was greater infiltration of pathogens from contaminated water sprayed on vacuum-cooled lettuce than when the product was not cooled by vacuum. Similarly, increased internalization occurred when produce having exposed internal tissue was washed in contaminated water (85). These results from internalization studies highlight the importance of maintaining effective levels of sanitizing agents in produce wash or cooling waters.

Even under processing conditions in which disinfectants are used in wash and cooling waters, operations that adversely affect the integrity of the fruit or vegetable also change the dynamics of the food system and the extent to which microbial contaminants can infiltrate tissue and proliferate. More specifically, unit operations of cutting, peeling, slicing, shredding, and removing outer skins and rinds inflict damage to the product. In turn, this damage can accelerate the respiration rate of the product and associated deterioration, promote the

release of nutrients or antimicrobials from plant cells, and increase the surface area on which microbes may reside and proliferate (86). A study has revealed that increased microbial growth occurred on carrots cut with blunt machine blades as opposed to sharp machine blades or razor blades, presumably through an increased release of exudates from the carrots (87). Similarly, mechanical abrasion peeling of carrots resulted in greater microbial contamination and more rapid microbial growth than hand peeling.

Nuts

Both labor-intensive and highly mechanized processing operations are available worldwide to harvest and process nuts; however, the methods that are applied vary significantly among the various types of nuts. This section focuses on different types of nuts for which at least one harvest or processing operation is distinctly different from the others.

Two distinct methods of harvesting nuts are available. For pistachios, the nuts are harvested directly from the trees by mechanically shaking the trees and collecting the nuts on a V-shaped catch frame. From there, the harvested nuts are collected on a conveyor belt and transferred to a plastic bin directly into a gondola trailer. The second method may also involve shaking the trees, but in this case, the nuts fall to the ground. After this operation, pecans are swept into windrows, where they are picked up by a mechanical harvester and subsequently transferred to a hulling facility. Almonds are also swept up from the orchard floor but they may first be left on the ground for a short period to partially dry by solar radiation. The orchard floors have the potential to be contaminated with an array of both spoilage and pathogenic microbes that are deposited there by domestic-or wild-animal wastes or by runoff from adjacent contaminated land. Hence, nuts can be contaminated when they land on these contaminated sites, or contaminated soils picked up during collection of the nuts may contribute to contamination in the hulling facility.

Once at the hulling facility, both the pecans and almonds are separated from debris using forced air and sifting operations, but aerosols generated during these cleaning operations may contaminate other equipment in the facility. Pecans that are to be stored and sold in the shell are mechanically dried, whereas wetting of the pecans to soften the shell before cracking is used to minimize breakage and facilitate removal of the intact kernel halves. A wet process is also used to assist in removing the hulls of pistachios with an abrasive peeler. Good-quality pistachio nuts sink to the bottom of a float tank, where they are then moved to a heated drier. However, concerns with water-assisted hull removal are the same as those for washing of fruits and vegetables. Specifically, the lack of sufficient sanitizer in the water may

facilitate cross-contamination between contaminated and noncontaminated materials. In addition, salmonellae can subsequently infiltrate in-shell nuts and reach the kernel, where they survive after drying (88). However, mechanical separation of hulls from the kernel under dry conditions, as is done for almonds, is not without its own safety issues. In particular, large amounts of fine particulate matter are produced, and this matter is extremely difficult to eliminate from the processing environment and thus could potentially contribute to the microbial contamination of kernels.

Grains

Many different types of grains are grown throughout the world (e.g., barley, maize, millet, oats, quinoa, rice, rye, sorghum, soybeans, teff, and wheat), and each may be subjected to processing operations that vary from being very labor-intensive to highly mechanized. Hence, there are many permutations in the processing of grains that could be discussed. However, the focus of this section is on the processing of wheat and how those operations affect the fate of microbes and their toxins.

Three general operations are applied to wheat: cleaning, tempering, and milling. In the cleaning process, a sequence of operations, involving aspiration and screening, is applied to wheat to remove unwanted materials (e.g., sticks, stems, stones, unsound wheat kernels, attached soil, and insects) based on their shape, density, size, and magnetism. Depending on the level of contamination of these impurities with spoilage microbes, mycotoxins, and pathogens, the degree of their reduction is variable (89). For example, no differences in *Aspergillus* contamination were observed between unclean and cleaned Algerian wheat, with fungal counts ranging from 2.7 to 2.9 log CFU/g (90). In contrast, there was a 53 to 62% reduction in two mycotoxins after cleaning of durum wheat in a study by Pascale et al. (91).

The second stage of processing of wheat, tempering, involves spraying the grain with precise amounts of water to reach a desired moisture level and then holding the wetted material in tempering bins for specific holding periods (6 to 18 h) to soften the surface of the grain, toughen the bran, and soften the endosperm. Tempering is a critical conditioning step in processing of grain, because improper implementation of this step can encourage microbial growth either in the wheat or on the milling equipment.

Once the grain is conditioned, milling occurs, which involves a series of reduction, grinding, and sifting operations designed to separate the germ and the bran fractions from the endosperm. Overall, milling does not reduce microbial or mycotoxin contaminants in the grain; rather, it redistributes contaminants, with the milled fractions more commonly used for human

consumption (flour and semolina) having lower levels than the germ and bran, which have higher levels (92). In general, the extent of the redistribution depends on the variety of wheat, the degree of penetration of mycotoxin-producing molds, transfer of mycotoxins to the inner parts of the kernel, and flour extraction rate (93). Historically, higher microbial and mycotoxin levels in the germ and bran fractions were not of concern, as these fractions were less likely than flour to be used in food production. This practice has been changing as the consumer desire for more whole-grain products increases, owing to their known health benefits (94).

Once flour is produced, the products made from this ingredient generally involve the application of heat, including baking, frying, cooking, steaming, or extrusion. Such thermal treatments are sufficient to kill vegetative microbial cells and thus reduce the number of spoilage and pathogenic microorganisms that may be present. However, both mycotoxins and bacterial spores of the genus *Bacillus* are highly resistant to thermal treatment (95–97). Survival of *Bacillus* spores in baked goods is of concern from both a spoilage and safety perspective. In the former case, germination of heat-resistant *B. subtilis* spores may occur under conditions of prolonged cooling or improper storage that ultimately results in a ropy baked good. In the latter case, *Bacillus cereus* spores may germinate under similar improper storage conditions, with the vegetative cells producing toxins (96).

Over the past decade, a new problem that has come to the forefront of the food industry is the potential for enteric bacterial pathogens to contaminate flours. Although incapable of multiplying in this low-water-activity product, they are capable of surviving in a dormant state for long periods of time (30). Furthermore, they retain the ability to multiply when flour is incorporated into higher-moisture environments, such as batters and mixes. Pathogen contamination of flour would not be an issue if consumers were to abide by educational and label statements that indicate there is a health risk if flour-based products are eaten in the raw rather than cooked state (89).

Environmental Conditions

Environmental conditions (temperature, atmosphere, and relative humidity) have been used for decades to control the physiological activity of fruits and vegetables, with the intent of delaying ripening and senescence and prolonging shelf life (3). These conditions are now well established and have been extensively reviewed (1). For example, holding temperatures near 0°C are recommended for most commodities. The exceptions to this guideline are products of tropical origin and produce items that suffer from physiological disorders (chilling injuries) when stored at refrigeration temperatures. For

those products, the optimal storage temperature is close to 10°C. Fortunately, storage at these low temperatures is beneficial for reducing the growth of many spoilage and pathogenic microorganisms. However, maintaining a consistently low temperature throughout the distribution chain is challenging. For example, a study of the holding temperatures of fresh-cut leafy greens transported from California and Arizona to distribution centers across the United States revealed that all16 shipments would have been rejected based on the Food and Drug Administration (FDA) standard of maintaining leafy greens at 5°C during shipment (98). Furthermore, applying time-temperature profiles obtained during commercial transport, retail storage, and display to commercial bags of romaine lettuce mix contaminated with *E. coli* O157:H7 and *L. monocytogenes* led to an increase in pathogen population of nearly 2 log CFU/g (99).

Environmental storage temperatures have also been influential in affecting microbial survival and growth in the low-moisture food groups of nuts and grains, respectively (100, 101). For example, increased survival of *Salmonella* was observed as temperatures of pecans, hazelnuts, and pine nuts decreased from 25°C to 4°C (101). However, fungal growth exhibited varying minimum and optimal temperatures dependent on the species but ranged from 0 to 12°C and 20 to 35°C, respectively (100). Minimal temperatures for mycotoxin production by each of the mycotoxin-producing fungal species were in almost all cases higher than their minimal growth temperatures. In contrast, the optimal temperatures for mycotoxin production were either similar to or lower than those documented for optimal growth.

Another environmental condition that affects the quality of produce is relative humidity. For most produce, garlic and onions being examples of exceptions, the relative humidity should be 90 to 100% (3). Otherwise, water loss will occur and many produce items will lose their turgor and be limp. The disadvantage is that high humidity also favors the survival of microbes and potentially leads to growth if favorable temperature conditions and nutrients are also present. Hence, when nuts and grains are stored, the relative humidity should be maintained such that the water activity is below the minimum needed for growth of microorganisms. In line with this recommendation, the minimal and optimal aw for fungal growth/mycotoxin production range from 0.70 to 0.94 and 0.90 to 1.00, respectively (100). However, decreasing the a_w to extremely low values is not necessarily beneficial, as *Salmonella* survives longer in tree nuts at an a_w of 0.4 than at 0.6 (101).

Modified atmospheres are also used in combination with chilled temperatures to reduce the physiological activity of fresh produce. To achieve this state, CO_2 concentrations recommended for produce storage rarely exceed 10%, and 1 to 5% oxygen is tolerated (1). Higher CO_2 or lower O_2 concentrations often lead to

physiological disorders that, in turn, lead to loss in quality, but the level at which this occurs varies with the horticultural crop, as different products have different tolerances to these gases (1). Similarly, the response of microorganisms to these gases is not consistent (3). As a result, adjustments made to the atmosphere during storage of produce must consider their effects on both the plant tissue physiology and the microorganisms' metabolic systems.

Variation in Resident Microbes

Microbiological spoilage of foods involves the breakdown of the food through the action of hydrolytic enzymes released by microorganisms into the food. Although many microorganisms may be present in the food and contribute to the hydrolytic activity, each microbial strain could potentially express a different profile of hydrolytic enzymes. For example, in a study conducted by Al-Najada and Gherbawy (102), 33 fungal isolates were obtained from 40 fruit and vegetable samples and were subsequently assigned to 21 fungal genera through sequencing of their internal transcribed spacer regions. These isolates were then screened, and 85%, 79%, and 73% of the isolates produced xylanase, amylase, and cellulase, respectively. Although only a qualitative assessment for these enzymes was performed, it is likely that the enzymes produced by these isolates also had varying degrees of activity. Hence, it would be difficult to assess the potential damage that a population of fungi would exert if present in a food. Similarly, discovering that bread is contaminated with *Bacillus* does not provide sufficient proof that ropy spoilage could occur, as five of 15 strains of *B. subtilis* and two of six strains of *B. licheniformis* were unable to cause ropy spoilage of laboratory-based bread (103).

Even when only one microbial species may be responsible for a spoilage defect, wide ranges between isolates' metabolic capacities to create a spoiled state can occur. Notably, *Lactobacillus buchneri* is detrimental to preserving cucumbers by fermentation, as this bacterium metabolizes the lactic acid produced during fermentation into acetic acid and 1,2-propanediol (104). However, when eight *L. buchneri* isolates were compared, all were capable of degrading lactic acid, but they differed in their rate and extent of lactate degradation (105). Biodiversity in bacterial growth rates was also observed when three *Bacillus amyloliquefaciens* strains were inoculated into various pan bread recipes (106). Therefore, on the premise that biological diversity is an inherent characteristic of microorganisms in general, one should be cautious in comparing inactivation or spoilage rates from separate challenge studies when different isolates of a microbial species are used in those studies.

INTERVENTIONS

Since horticultural crops are usually grown in environments where there is constant exposure to external sources of microbial contamination, it is inevitable that the microorganisms will be transferred to those crops. Considerable research has been conducted on how to minimize crop losses due to plant pathogen activity, to delay loss of food quality due to spoilage microbe activity, and to minimize the distribution of unsafe product due to human enteric pathogen contamination. These intervention efforts are addressed below in two categories: prevention of contamination and reduction of postharvest contamination.

Prevention of Contamination

To address contamination challenges posed at the preharvest and postharvest stages during the production and processing of fruits, vegetables, nuts, and grains, the principles of GAPs, good manufacturing practices (GMPs), and hazard analysis and critical control points (HACCP) remain the prerequisite cornerstones of food safety management strategies to establish safe practices. Each of these programs has played a unique role toward achieving a safe food supply.

GAPs are considered guidance documents (i.e., not required by the government) and are written either by the industry or with input from the industry on recommended practices that growers should apply in the production of fresh produce. These documents focus on areas of production that potentially contribute to contamination of the product. In some cases, specific guidance (metrics) may be provided, but in general the guidelines have not been scientifically validated. Despite these limitations, growers have been encouraged to adopt GAPs to help assure buyers that the produce was safely produced and could offer some protection against liability claims.

In contrast to GAPs, which are strictly voluntary, GMPs are regulated by the U.S. FDA and apply to processed fruits and vegetables but not to fresh fruits and vegetables. GMPs include many operational conditions and procedures that are common among all food manufacturing facilities, including (i) the construction and layout of the site, (ii) condition of the external environment, (iii) adequate maintenance of equipment and utensils used with the facility; (iv) avoidance of foreign matter within the finished product; (v) waste disposal sites that are clearly identified; and (vi) a routine schedule for pest control and hygiene practices to ensure the cleanliness of the facility. GMPs have their greatest impact when the procedures are clearly described in written documents and records of their implementation are kept routinely. For

additional information on this topic, an extensive description of GMP-related control measures that may be used in low-aw-food production environments has been provided in a review by Beuchat et al. (30).

Although GMPs constitute the operational requirements necessary to enable a food business to produce food safely, they also are a requisite component of HACCP programs. However, for the commodities being considered in this chapter, HACCP is required by law only for producers of fruit juices. HACCP is considered a tool to identify within a food manufacturing facility specific hazards and the critical control points (CCPs) for controlling those hazards. Subsequent steps in applying HACCP are to monitor the CCPs, take corrective action on deficiencies in the CCPs, if needed, verify that the processing procedures are working appropriately, and maintain accurate records. However, HACCP programs are not feasible to apply to primary produce production because of the lack of applicable CCPs.

In lieu of HACCP, the U.S. FDA developed the produce safety rule, which is part of the Food Safety Modernization Act (FMSA) and has enforceable standards for growing, harvesting, packing, and holding produce for human consumption. This rule was enacted in 2011, but not all fresh-produce-growing operations will be subjected to the rule, as farms having less than $25,000 in sales are excluded.

Additional information on the produce safety rule is found in chapter 42 of this volume. Additional approaches that have been used to prevent microbial contamination of crops in the field are to alter the plant's susceptibility by applying treatments to the plants or by breeding plants to be resistant to the microorganisms causing the damage. An example of a treatment to protect plants from plant pathogen invasion is the application of calcium or a calcium solution directly to a fruit or vegetable such that absorption of the calcium by the plant's tissues reinforces their pectin bonds, thereby making their cell walls more resistant to the pectic enzymes of plant pathogens (107). Hence, soft rot caused by *Erwinia carotovora* subsp. *atroseptica* on potatoes and growth of *P. expansum* on apples are controlled. An example of applying plant breeding to prevent damage by plant pathogens is the breeding of peanuts to have increased tannin content, amino composition, waxy surfaces, and cell structure arrangement, thereby enabling the peanuts to resist fungal invasion (108). More recently, several acquisitions of germplasm resistant to the pathogens that cause blue mold and bitter rot of stored apples have been obtained and are envisioned to serve as a foundation for a conventional breeding program to develop apples resistant to blue mold rot (109).

Reduction of Contamination on Produce

One of the most prolific areas of research over the past decade has been the development and evaluation of interventions that would either reduce the extent of microbial contamination or prevent the growth of existing microbial contaminants in fruits, vegetables, nuts, and grains. These interventions can be grouped into three categories: physical, chemical, and biological. A fourth group of interventions consists of applications, in combination or in sequence, of two or more interventions from the three intervention categories, which provides a synergistic response by employing different mechanisms of inactivation of the microorganisms.

A brief overview of the mechanisms of action of each of the types of interventions and their advantages and limitations is provided below. Considering the large number of studies that have been conducted on interventions over the past decade, only selected studies are discussed to provide examples for each of the commodity groups. Additional information on these interventions is provided in a number of recent review articles that are listed in Table 7.5.

The efficacy of postcontamination interventions is assessed primarily by observing the initial microbiological reduction achieved as well as the continuation of this reduction during storage. However, the success of an intervention should not be judged solely by its efficacy. The occurrence of undesirable quality effects following application of the intervention would eliminate it as a useful treatment. Similarly, if the cost of the intervention increases the cost of the product to adversely affect sales, the treatment would not likely be applied for routine use. Hence, the interplay of these three criteria (i.e., microbiological efficacy, quality losses, and treatment costs) should be considered when the likely success of an intervention is being evaluated. Very few research papers address the costs of new interventions, ignoring the expense of equipment needed to perform an intervention treatment or the costs that recur per treatment. Under these circumstances, a risk assessment (described in more detail in “Risk Assessment” below) should be conducted to determine whether the public health benefits would warrant the implementation of an expensive intervention. If not, then continued research with that intervention would best address opportunities to reduce its cost.

Physical Treatments

Thermal treatments

Refrigeration has long been used as the most convenient and effective means to reduce physiological activities of plant tissues, to reduce the growth of spoilage and pathogenic microorganisms, and thus to extend shelf life without

compromising the safety of the product (24, 86). Alternatively, these benefits may be accomplished by heat treatments, but their applicability will depend on their effect on the targeted product. For example, one of the qualifying descriptors of fresh-cut fruits and vegetables is that heat not be applied, as it would alter their quality. Canned, blanched, and frozen vegetables and juices, on the other hand, are commonly subjected to heating operations that will reduce if not eliminate resident microbial populations. However, short-term exposure to heat (e.g., a few seconds at 60 to 62°C; 120 min at 45°C) has also been used with some success to reduce postharvest spoilage of a wide range of fresh produce, including green pepper, apple, and citrus (110, 111). Application of superheated steam (85°C for 240 s) to cantaloupe rind also decreased surface-inoculated *Listeria innocua* by nearly 4 log CFU/cm^2 (112). However, a limitation of that type of treatment is that heating also decreases the competitive indigenous microflora (e.g., yeasts, molds, and coliforms) to levels that would allow the proliferation of harmful microbes such as listeriae that may be introduced to the rinds postheating.

In crops such as nuts and grains, the application of heat has been routinely used as a treatment in their processing. There is renewed interest in applying these thermal treatments to low-a_w foods such as nuts and grains in which *Salmonella* and mycotoxins are known to have a high degree of heat resistance. For example, Beuchat and Mann (113) determined that hot-air treatments could not be relied upon to reduce *Salmonella* by 5 log CFU/g on raw pecan nutmeats without adversely affecting their sensory qualities, whereas temperatures and times typically used to oil-roast nutmeats were sufficient to reduce the pathogen by 5 log CFU/g. Similarly, hot-air drying of pistachios has been viewed as being insufficient to ensure their microbial safety, whereas sequential infrared drying, tempering, and hot-air drying could shorten the drying time while reducing the levels of a surrogate of *Salmonella* by ca. 6 log CFU/g kernel (114).

For grains, the application of dry heat postharvest generally can decrease the microbial load of spoilage organisms without compromising the grain's quality (115). However, such treatments require considerable amounts of energy and may last for several days. Furthermore, the conditions must be adjusted carefully to achieve sufficient microbial decontamination while maintaining grain quality. Other disadvantages to the use of dry heat for grain processing are its inefficiency in killing spores of heat-resistant bacteria and its inability to destroy mycotoxins produced in the field (115). In contrast, superheated steam is a more efficient treatment for microbial decontamination and mycotoxin degradation. For example, when naked oats were subjected to superheated steam (160°C for 2 min), the numbers of surface bacteria and mold were

reduced from 4.26 to 2.44 log CFU/g and from 4.02 to 2.34 log CFU/g, respectively, which were both below the acceptable safe storage numbers for this grain (116). Similarly, exposure of wheat grain for 30 s to superheated steam at 110°C or higher reduced mold populations to undetectable levels in the product, and higher temperatures (170 or 200°C) killed *Bacillus* spp. (117). For mycotoxin degradation, deoxynivalenol was reduced by up to 52% by treatment at 185°C for 6 min (118). However, optimal parameters for superheated steam treatments in different matrices still need to be determined. Additionally, the safety of the degradation products of mycotoxins thermally degraded by superheated steam is unclear, as the potential remains that they are as toxic as the original mycotoxin (115).

Table 7.5 Selected review articles (2017 to 2018) that address the efficacy of postharvest interventions applied to fruits, vegetables, nuts, and grains

Type of interventions addressed	Title (reference)
General	Application and kinetics of ozone in food preservation (161)
	Essential oils: sources of antimicrobials and food preservatives (163)
	The hurdle approach-a holistic concept for controlling food safety risks associated with pathogenic bacterial contamination of leafy green vegetables. A review (180)
Fruits and vegetables	Challenges in the microbiological food safety of fresh produce: limitations of post-harvest washing and the need for alternative interventions (124)
	Ready-to-eat vegetables: current problems and potential solutions to reduce microbial risk in the production chain (54)
	Recent developments in novel shelf life extension technologies of fresh-cut fruits and vegetables (4)
	Nonthermal physical technologies to decontaminate and extend the shelf-life of fruits and vegetables: trends aiming at quality and safety (131)
	A review on microbiological decontamination of fresh produce with nonthermal plasma (136)
	Postharvest ozone application for the preservation of fruits and vegetables (181)
	Plant-based edible coatings for managing postharvest quality of fresh horticultural produce: a review (165)
	Bacteriocins from lactic acid bacteria and their potential in the preservation of fruit products (182)
Grains	Current and future technologies for microbiological decontamination of cereal grains (132)
	Critical factors responsible for fungi growth in stored food grains and non-chemical approaches for their control (129)
	Recent advances in physical post-harvest treatments for shelf-life extension of cereal crops (115)

Type of interventions addressed	Title (reference)
	Mold spoilage of bread and its biopreservation: a review of current strategies for bread shelf life extension (183)
	Biocontrol of mycotoxins: dynamics and mechanisms of action (184)
	Mycotoxin occurrence in grains and the role of postharvest management as a mitigation strategies. A review (24)
	Deoxynivalenol and its masked forms: characteristics, incidence, control and fate during wheat and wheat based products processing-a review (185)

Modified atmosphere packaging

Modified atmosphere packaging (MAP) is packaging with modification of the gas composition surrounding the product inside, with the intent of extending the shelf life of the product. Used for over 90 years (4), the atmospheres that have been typically applied are discussed in "Environmental Conditions" above. Both active and passive MAP can be used to create the desired atmosphere, which is a function of the product type, the packaging materials, and the storage temperature. In active MAP, the target atmosphere is created by either displacing or replacing the gases in the package with those that are desired, or scavengers or absorbers are added within the package to remove a specific gas. In passive MAP, the desired atmosphere develops naturally as a result of the product's respiration and the diffusion of gases through the permeable packaging film (119).

Oxygen, CO_2, and nitrogen are the gases most commonly used in MAP. Nitrogen is considered an inert gas, with its primary function being to prevent the package from collapsing. Other gases that have been used as gas mixtures for MAP include carbon monoxide, argon, helium, and nitrous oxide (4). Due to the higher density of noble gases, increased diffusivity of O_2 and CO_2 from plant tissues is likely to occur and, through this mechanism, would affect plant tissue metabolism. For example, packaging fresh-cut watercress in noble gas-enriched MAP modified its respiration rates, whereas there was no effect on the growth of psychrotrophic microbes and *Enterobacteriaceae* (120). Another variation on the traditional gas atmospheres of MAP is the application of high-O_2 MAP in lieu of low O_2 concentrations, which can stimulate the growth of anaerobic psychrotrophic microorganisms. However, the success of this approach is dependent on the spoilage microbe of interest. For example, growth

of the yeast *Candida sake* on fresh-cut honeydew melon cubes was greatly suppressed by the presence of 50% or 70% O_2 in the atmosphere, whereas growth of the lactic acid bacteria *Leuconostoc mesenteroides* and *Leuconostoc gelidum* was affected to only a minor extent (121).

Irradiation

Gamma rays, X rays, and electron beams are all considered different forms of ionizing radiation because they are electronically charged atoms or molecules. They differ from each other in the manner in which they are produced. In the case of gamma irradiation, the rays are produced from the degradation of the radioisotopes of cobalt-60 or cesium-137. In contrast, X rays are produced by accelerating electrons through a potential difference onto a target material (e.g., tungsten) where, upon slowing, X rays are released. Electron beams are generated from machines capable of accelerating electrons very close to the speed of light at high energy levels (0.15 to 10 MeV) in a vacuum environment. Once formed, the mechanisms by which they interact with foods and microorganisms are similar. More specifically, the principal target of the ionizing radiation is water that breaks down to produce free radicals that, in turn, react with organic matter. Inactivation of microorganisms occurs when the free radicals disrupt the organisms' DNA structure and denature their enzymes and membrane proteins, resulting in the loss of their reproductive capabilities and other functions of the cell.

The main advantages of electron beam irradiation are faster operation, lower irradiation dosages, and the use of electricity rather than radioactive materials to generate the ionizing radiation. Hence, electron beam irradiation is considered more flexible and easier to use. Its chief disadvantage is that its penetration power is less than that of gamma irradiation, rendering the former a tool restricted primarily to surface disinfection. Despite this limitation, electron beam irradiation is allowed for the treatment of vegetables, fruits, and grains in many parts of the world, with the exception of Europe. However, there are restrictions on the levels of irradiation that may be applied. For example, the FDA caps the irradiation dose on most fresh fruits and vegetables at 1.0 kGy but allows fresh lettuce and spinach to be irradiated at 4.0 kGy. Doses of 0.1 to 0.5 kGy are permitted by the FDA for the treatment of insect infestations of wheat and wheat flour.

Many studies have during the past 2 decades addressed the irradiation of fruits and vegetables; examples are provided in the review articles listed in Table 7.5. The irradiation dose is positively correlated to the degree of killing of microorganisms; however, different microorganisms have different tolerances to this treatment. For example, among vegetative bacteria, Gram-positive

bacteria are more resistant to irradiation than Gram-negative bacteria (122). As another example, populations of *Salmonella enterica* serovar Poona were significantly reduced in fresh-cut cantaloupe by electron beam irradiation; however, at the same dosage, yeasts were not reduced significantly (123). Viruses, endospores, and enteric protozoa are also very resistant to irradiation (124). For example, an irradiation dose of 1 kGy reduced *E. coli* O157:H7 populations by 5 log CFU in bagged spinach (125), whereas spinach treated with a dose of 2.5 kGy resulted in <1 log reduction of rotavirus (126). The sensitivities of fungal species in grains, nuts, and fruits to irradiation also differ substantially (115, 127), although the form of fungal contamination (mycelium or spores) as well as the moisture content of the commodity may contribute to the reported differences (115). Uneven dose distribution may also be a contributing factor in disparities among irradiated nuts. Karagöz et al. (128) determined that the D_{10} values (dose required to achieve 1-log reduction in population) of *Salmonella* and *E. coli* inoculated on the flat surfaces of pecans were 13 to 44% greater than bacteria inoculated within the dorsal grooves of the pecan, which absorbed higher doses of irradiation. However, irradiation is generally regarded as being effective in controlling fungi (129). In contrast, many mycotoxins are not affected substantially by irradiation (130), with aflatoxin and ochratoxin being more insensitive to irradiation than *Fusarium* toxins (115).

Despite irradiation being recognized as an effective intervention step for microbial decontamination, its use commercially has been minimal. A major concern has been lack of consumer acceptance. Most irradiated foods must be labeled as having been irradiated, which deters consumers from consuming them. Hence, food processors are reluctant to irradiate foods, justifying their decision on the basis that consumers would not be willing to pay the additional costs for irradiating the food.

Cold plasma

Cold plasma is a new intervention for decontaminating foods under nonthermal conditions. Cold plasma is generated by applying an energy source (heat, electricity, laser light, radiation, etc.) to gases (air, O_2, N_2, or a mixture containing some proportion of noble gases). The resulting quasineutral ionized gases consist of UV photons, neutral or excited atoms and molecules, negative and positive ions, free radicals, and free electrons, that in combination have the capacity to inactivate microorganisms on the surfaces of fruits, vegetables, nuts, and grains (131–133). Additional potential applications include applying gas plasmas within MAP containing fresh produce (134) and detoxification of aflatoxins in hazelnuts (135).

Currently, cold plasma is still considered a new technology that is in an early stage of development (4). Attributes that are attractive for this technology include a relatively low operating temperature, low water consumption, low cost, timely production of the reacting agents, and a lack of residues during production compared to thermal and chemical treatments (136). Some of the limitations that need to be addressed are the long treatment times (300 s to 20 min) that are required (136) and the need for the food to be in close proximity to the plasma source (124). Additionally, more research is needed to address the physicochemical and functional changes that can occur in the treated food products.

UV light

Nonionizing radiation with wavelengths ranging from 100 nm to 400 nm is classified as UV light. UV light, in turn, is further subdivided into three categories: near-UV radiation, or UV-A (315 to 400 nm); midrange UV, or UV-B (280 to 315 nm); and far UV, or UV-C (100 to 280 nm). UV-C that encompasses the maximum germicidal wavelength of 254 nm is the most common type of UV light applied to fresh fruits and vegetables and serves as an antimicrobial agent, either by causing direct DNA damage to microorganisms or by inducing resistance mechanisms in the plant tissues against pathogens (137). However, microbial inactivation is limited to the food's surface due to UV-C's extremely low penetration in solid foods. Hence, with comparable UV doses, surfaces that are uneven (e.g., cantaloupes and berries) have pathogen reductions of only ca.1 log CFU, compared to reductions on the smooth surfaces of apples of 2 to 3 log CFU (138, 139). The application of UV-C is also limited by its adverse effects on the sensory and nutritional characteristics (e.g., browning and decreases in vitamin C content in fresh-cut pineapples [140]) of produce. UV light can completely degrade aflatoxin B_1; however, the degradation products remain cytotoxic (115).

Pulsed light

Pulsed-light interventions are an emerging technology for inactivating microorganisms which uses pulses of an intense broad spectrum (200 to 1,000 nm) rich in UV-C light. By storing the energy in a high-power capacitor over fractions of a second, the power is released within millionths or thousandths of a second, producing several high-energy pulses per second. The energy intensity is heightened through this process and contributes to the inactivation of both spoilage and pathogenic microorganisms (141). The major advantages of this intervention approach are substantial microbial reductions in very short treatment times, lower energy costs, flexibility, and the lack of residual chemicals (4). However, there are two main drawbacks to applying pulsed light

to grains and nuts: (i) their uneven surfaces, which protect microorganisms in shaded areas; and (ii) their abundance of proteins and fats, which absorb the effective wavelengths (142). Two approaches have been taken to address the former limitation. In one approach, strawberries and raspberries were exposed to the pulsed light while being immersed in agitated water (143). In the second approach, it was envisioned that light-emitting diodes (LEDs) that deliver UV at multiple angles could be constructed (144). In addition, LEDs could apply a range of different UV wavelengths, thereby providing a synergistic antimicrobial action (145).

High-pressure processing

High-pressure processing (HPP) is a process in which elevated pressures, typically in the range of 100 to 700 MPa, are applied to either an aqueous food product or a product that is suspended in a liquid medium, normally water. The pressure is transmitted isocratically throughout the food sample, thereby shortening the time necessary for the treatment independent of food shape or size (124). In general, yeasts and fungi are more sensitive to pressure than vegetative bacteria, and Gram-negative bacteria are more sensitive to pressure than Gram-positive bacteria (146). Pressure resistance also varies greatly between and within taxonomic groups and strains of viruses (146).

Investigations into potential HPP applications for plant-based foods have primarily focused on purees and juices (131). This process does not lend itself to treating cereals and nuts, as it would require an additional drying step after suspension of the product in a liquid medium for treatment (115). In contrast, HPP treatment of fresh produce is theoretically possible; however, there are barriers to commercial application that relate to cost, limited capacity, batch system, and incompatibility with produce packed using MAP (124). In addition, issues of texture loss through plant cell disruption and browning caused by chlorophyll degradation have been observed for leafy greens treated with HPP (124).

Chemical Treatments

Oxidizing treatments

A variety of antimicrobial chemical treatments have been used as postharvest interventions for the purpose of either product decontamination or the avoidance of cross-contamination. Chlorine is the most frequently used disinfectant, which is easily applied to water in controlled amounts, either as chlorine gas, which readily dissolves in water at room temperature to generate hypochlorous acid, or as a salt of hypochlorite. Concentrations used in produce

operations vary from 50 to 200 ppm, with contact times of less than 5 minutes. Under those conditions, typical reductions of vegetative bacteria on produce are 1 to 2 log CFU/g, whereas reductions on pecan nutmeats are even less. Hence, decontamination of these products with chlorine is only marginally better than washing the items in water (147). The ineffectiveness of chlorine for decontamination of tissue surfaces has been attributed to microbial cells being strongly attached to the tissue or embedded in biofilms or in cracks and crevices that are inaccessible to the chemical agent (86, 147). In contrast, chlorine is considered to be very effective against suspended vegetative bacteria, making it an excellent sanitizing agent for preventing cross-contamination during produce wash operations (54). However, it is imperative that chlorine levels in the water be monitored constantly, as chlorine not only oxidizes microorganisms but also is capable of reacting with other inorganic and organic molecules in the system to form disinfection by-products (DBPs) such as trihalomethanes. Many of these DBPs have been associated with adverse health effects (148) and have led several countries (e.g., Germany, Netherlands, Denmark, Belgium, and Switzerland) to prohibit the use of chlorine-based disinfectants in washing of fresh-cut produce (54). However, one conciliatory outcome of washing fresh-cut lettuce with chlorine has been that despite high levels of total trihalomethanes being observed in the wash water, no measurable amounts of the DBPs were detected on the fresh-cut lettuce (149).

Due to the limited effectiveness of chlorine in decontaminating tissue surfaces, alternative oxidizing agents have been evaluated. Chlorine dioxide is an example and is considered to have greater biocidal efficacy than free chlorine. Chlorine dioxide is an undissociated gas when dissolved in water and is relatively stable, as it is less likely than chlorine to react with oxidant demand substances. However, its aqueous concentration decreases if left in an open tank due to its volatility (150). Furthermore, chlorine dioxide is photoreactive in sunlight, producing the by-products of chlorate, chlorite, and chloride (151). Since adverse effects in humans have been associated with chronic exposure to chlorates, the European Food Safety Authority (152) has imposed maximum limits for this chemical of 0.7 mg/kg in foodstuffs and 0.7 mg/liter in drinking water. However, a recent pilot-scale study using chlorine dioxide at 5 and 3 mg/liter in the wash water revealed that the upper limits for both chlorate and chlorite were exceeded in the process water but not in the lettuce (153). These results, along with the requirement in the United States that chlorine dioxide treatment of fruits and vegetables be followed by either a potable rinse or another preservative method (154), may preclude extensive use of this disinfectant in washing fresh produce. A review of studies utilizing chlorine dioxide as a decontamination agent on a range of produce items revealed that

applying the agent as a gas is a more effective antimicrobial measure than applying it as a liquid because it has greater penetration ability as a gas (155).

Ozone is another oxidizing disinfectant that has been of increased interest to the produce industry in the past 2 decades. In 1997, ozone received GRAS (generally recognized as safe) status and was later approved in 2001 by the FDA as a secondary direct food additive and antimicrobial agent for all food types (156). Comparatively, aqueous chlorine and ozone have similar levels of effectiveness as a decontaminant of produce, as log reductions with ozone have been reported to range between 0.8 and 1.8 log CFU (155). However, the advantage to using ozone is that it decomposes into molecular oxygen and hence does not leave hazardous residues on the food product (157). Similar to chlorine dioxide, however, gaseous ozone is more efficacious than the antimicrobial applied in the liquid state. To support this assertion, Shynkaryk et al. (158) determined that the depth of penetration of aqueous ozone into lettuce was limited to several millimeters due to slow diffusion of the antimicrobial and self-decomposition, whereas gaseous ozone reached a depth of 100 mm.

An interesting application of ozone is its proposed use as a disinfectant/fumigant for produce and grains. In these cases, the product is often stored in large contained areas for lengthy periods of time. A study with spinach revealed that low concentrations of ozone diffused into 300-liter containers reduced *E. coli* O157:H7 populations by 1.4 log CFU/g (159). Replenishment of ozone into storage structures, on the other hand, has been advocated as the solution to ozone decay in the treatment of grains (129). Benefits to treatment of grains with ozone include inactivation of molds (160, 161) as well as degradation of mycotoxins (162).

Novel natural sources and applications

The consumers' desire for natural food ingredients has prompted the food industry to find alternatives to artificial additives. In response, natural antimicrobials found in edible plants have been identified as possible alternatives. Many plant-based compounds (e.g., albumins, lectins, protein hydrolysates, flavonoids, isoflavonoids, terpenoids, etc.) have potent antibacterial and antifungal activities. However, cost constraints as well as government regulations pose limits to their commercial application and restrict their application to foods as crude plant extracts. Other additional limitations associated with their use are discussed in chapter 42. However, these limitations have not hampered research in this area, as exemplified by the publication of several recent reviews addressing this topic (163–165). Future applications of this approach will likely be limited to very specific uses where

the costs associated with the incorporation of natural antimicrobials into products would be offset by increased sales or added shelf life or safety to the product. An example is the use of an extract of a legume (pea, lentil, and fava bean flours) hydrolysate as an ingredient in bread making. Not only did the bread have a longer shelf life than the control (based on the absence of mold growth), but the chemical, structural, and sensory characteristics of the bread were not affected by the addition of the extract (166).

Another approach to applying chemical interventions to produce is to improve the efficacy of the antimicrobials by modifying the method for delivery of the chemical to the agricultural crop. Examples include application of the antimicrobial in a nanoemulsion to lettuce (167), application of nisin-incorporated films onto minimally processed mangoes (168), application of antimicrobial sachets in the packaging of lettuce (169), and utilization of antimicrobial films to packaged apple slices (170).

Biological Treatments

Biological interventions are based on the application of either naturally occurring microorganisms that are inhibitory to spoilage organisms or pathogens or the antimicrobials that are produced by these microbial antagonists (e.g., bacteriocins) directly to agricultural crops. Recent examples include the application of antimicrobial peptides derived from *Lactobacillus plantarum* LR/14 for the prevention of grain spoilage (171), the application of *L. plantarum* and *Lactobacillus fermentum* to freshcut cantaloupe to reduce *L. monocytogenes* contamination (172), and the application of the bacteriophage Listex P100 to reduce *L. monocytogenes* contamination on fresh-cut melon slices (173). Many more examples are provided in the review articles listed in Table 7.5. However, it is important to recognize that although inhibiting microbial degradation is the purpose of the treatment, the application of these biological agents may cause adverse changes to the food quality. Therefore, it is important that the treated foods' quality characteristics be evaluated to determine if the treatment will yield a product that is acceptable to consumers. In addition, the safety of the product in which any new microbes such as lactic acid bacteria are to be used should be considered, as there has been an association of some lactobacilli with sepsis, endocarditis, and bacteremia (174).

Hurdle Treatments

Hurdle technology consists of using a sequence or combination of mild interventions to inhibit or inactivate food spoilage microorganisms or pathogens. A basis for using this approach is that it would control the microbes of interest but would have a lesser effect on the organoleptic quality of the

product than a single intervention. One of the more common recent applications of the hurdle approach involves using a physical intervention (e.g., ultrasound or UV light) in combination with chemical interventions (e.g., chlorine or organic acids). Another novel hurdle approach is to generate chlorine dioxide within the tissue of fresh produce instead of relying on it to migrate to those sites (175). This is accomplished by applying a sequential treatment that includes first submerging the produce item (cantaloupe rinds, cucumber peels, tomato stem scars, or spinach leaves) in a sodium chlorite solution for 10 or 30 min, drying for 20 min, and then soaking in a hydrogen chloride solution for 10 or 30 min. When the hydrogen chloride interacts with the sodium chlorite, chlorine dioxide is generated. Greater reductions of *Salmonella* and *L. monocytogenes* (4.8 log and 2.7 log CFU/g, respectively) occurred with the sequential treatment than with a control treatment in which the produce item was treated only with either sodium chlorite or hydrogen chloride.

RISK ASSESSMENT

Due to the complexity of the systems used to grow and process agricultural crops as well as the many factors that affect the microbiological profiles of the crops and subsequent products at any one point, there is a need to understand the impact of each individual factor within the system on the overall response (e.g., the risk of becoming ill from eating a contaminated product or the risk of the product's becoming spoiled and not suitable for consumption). To estimate these risks, quantitative microbial risk assessment (QMRA) is applied using mathematical models that are based on data sets for the statistical distributions of microbial concentrations as foods are subjected to certain conditions and interventions. Recent QMRA studies have addressed leafy greens (176, 177), raw produce (178), pistachios (179), and pecans (77). QMRA outcomes are not absolute values, as there is often variability or uncertainty associated with data sets used within the models. Hence, risk assessors may have to use surrogate data or make assumptions in order to generate an outcome, and therefore, the results should be used only as an indication of the level or degree of risk.

CONCLUDING REMARKS

Microbiological contamination of agricultural crops such as fruits, vegetables, nuts, and grains will continue to contribute to preharvest crop losses, postharvest spoilage losses, and contamination of food with enteric pathogens. Understanding the sources and the factors that contribute to survival of resident microorganisms provides the basis for implementation of

management programs that will keep plants healthy and in a state that will provide near-optimal quality during storage and distribution. The analytical tools for detection of microorganisms continue to improve. With these advancements, our knowledge of plants' microbial ecosystems will increase and will help to provide a road map on how to cost-effectively utilize postharvest interventions for controlling or eliminating the microbes that cause spoilage or illness.

Epidemiology of Foodborne Illnesses

Foodborne illnesses result from the dynamic interaction of agents (i.e., bacteria, viruses, and parasites), hosts (humans and animal reservoirs), and the environments in which these interactions occur (Fig. 8.1). The depiction of these relationships is known as the epidemiological triad. It serves to illustrate the need to integrate information from multiple disciplines to understand the occurrence of foodborne illnesses. It also suggests why the epidemiology of foodborne illnesses is constantly changing. As new foods and new sources of foods become available, new opportunities for foodborne illness transmission often follow. As the population ages, more people are at risk for serious illness from common foodborne pathogens. The use of antimicrobial agents in production environments or clinical settings may select for the development or promotion of antimicrobial resistance. These are some examples of changes in one area that will change the pattern of illnesses which are observed. The dynamic nature of our food systems results in a constantly changing epidemiology of foodborne illnesses.

The ability to monitor changes in the patterns of foodborne illnesses in the population is the subject of epidemiology, and such monitoring is one of the primary functions of public health agencies. Public health surveillance for foodborne illnesses has been rapidly evolving with the development of new laboratory methods to identify agents in clinical specimens, food, and the environment. In particular, whole-genome sequencing (WGS) is increasing the sensitivity of outbreak detection and simultaneously increasing the specificity of outbreak investigation, much as pulsed-field gel electrophoresis (PFGE) did 20 years ago. However, the ability of WGS to link isolates from human, food, and

environmental sources presents new opportunities and challenges to foodborne illness surveillance. Laboratory evidence alone is not sufficient to establish a causal relationship. Detailed exposure assessments and epidemiologic evaluation of the exposures are critical. Developing and maintaining a framework to effectively incorporate WGS into public health surveillance and food regulatory activities is a priority that requires the ongoing engagement of public health and food regulatory officials and food safety specialists in industry and academia.

This chapter provides an introduction to epidemiology and epidemiologic methods as they are applied to problems of the surveillance and control of foodborne illnesses. It also discusses major advances in the world of foodborne illness outbreak detection and the role of surveillance in source attribution of foodborne illnesses. An understanding of epidemiology is important, because despite our best efforts to prevent foodborne illnesses, humans remain the ultimate bioassay for low-level or sporadic contamination of agents of foodborne illness in our food supply. Epidemiologic methods of foodborne illness surveillance are needed to detect outbreaks, identify their causes, and assess the effectiveness of control measures. Epidemiologic data are also important in establishing food safety priorities, allocating food safety resources, stimulating public interest in food safety issues, establishing risk reduction strategies and public education campaigns, and evaluating the effectiveness of food safety programs. The examples provided in this chapter are drawn from recent literature, outbreak reports, and multi-stakeholder collaborations. They were chosen to illustrate key concepts and emerging approaches. Epidemiologic data relevant to individual foodborne illnesses are presented in their respective chapters.

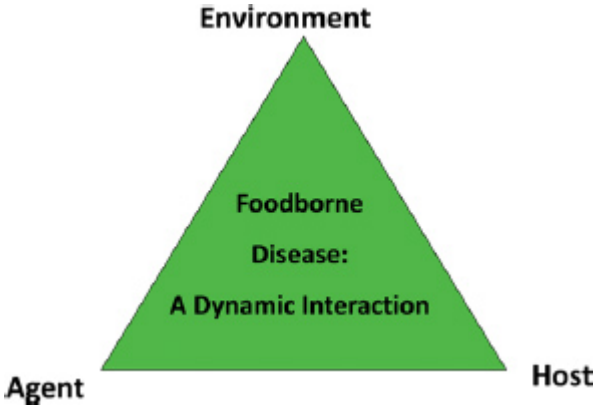

Figure 8.1 Illustration of the epidemiological triad, depicting the dynamic interaction of agents (i.e., bacteria, viruses, parasites), hosts (humans and animal reservoirs), and the environments leading to the occurrence of foodborne illnesses.

EPIDEMIOLOGY

Epidemiology is the study of events in populations. Events are usually thought of in terms of illnesses. For example, the CDC established an Active Surveillance Network for Foodborne Diseases (FoodNet) to determine how many laboratory-confirmed infections caused by *Campylobacter*, *Escherichia coli* O157:H7, *Salmonella*, and selected other pathogens occur in the populations under surveillance (https://www.cdc.gov/foodnet). By actively ascertaining all diagnosed infections in the FoodNet catchment area, FoodNet is able to establish reliable trends in the occurrence of these illnesses by age, gender, geographic area, and time. A second major FoodNet activity has been to conduct periodic surveys to provide an epidemiologic context that relates the specific foodborne pathogens under surveillance to the overall burden of diarrheal illnesses in the population. Population surveys have assessed how many diarrheal illnesses occur in the population and how often ill people seek medical care. Physician surveys have assessed how often and why physicians order diagnostic tests. Clinical laboratory surveys have assessed the availability and use of various laboratory test methods. By comparing the incidence and

proportion of specific diseases attributable to foodborne transmission with the frequency of medical evaluation and laboratory testing, it becomes possible to determine what proportion of diarrheal illnesses may be foodborne. These data provided the epidemiologic framework for the approach taken by Scallan and colleagues to determine that 48 million foodborne illnesses occur each year in the United States (1). Technical appendices to Scallan's landmark publication provide a rich compilation of information on disease characteristics and surveillance data for known foodborne pathogens.

Epidemiology also includes the study of factors associated with the occurrence of illnesses. The same population survey that FoodNet conducted to assess the frequency of diarrheal illness also surveyed the population to find out how often people have potential exposures, such as eating undercooked hamburger, eating sprouts, failing to wash their hands after handling raw chicken, or making a salad on the same cutting board they used to cut up raw chicken. Many of these factors are assessed in the context of outbreak investigations to enable identification of the factors actually contributing to the occurrence of an outbreak. FoodNet's compilation of these in their Atlas of Exposures (https://www.cdc.gov/foodnet/surveys/foodnetexposureatlas0607_508.pdf) has been an important resource for hypothesis generation in outbreak investigations, as described below.

Descriptive Epidemiology

The careful description of events in populations is generally called descriptive epidemiology. This process of determining characteristics of person, place, and time associated with illness occurrence forms the basis of all surveillance systems and outbreak investigations. The defining example of this process was the work of John Snow, during the London cholera epidemic of 1860. He located cases on a map of London, saw a cluster around the Broad Street pump, and pulled the pump handle. The contaminated water source was shut down, and the local outbreak ended. Such dramatic

examples of consequential epidemiology are not common. However, surveillance of foodborne disease, based on the principles of descriptive epidemiology, remains a cornerstone on which other food safety activities are built.

Surveillance of foodborne illnesses is a basic function of public health agencies. It involves the systematic collection and analysis of data on the cases and characteristics of the illnesses to guide public health actions, as described at length below. At the time of Snow's investigations, cholera was diagnosed by its typical clinical symptoms and disease progression. Thus, it represented a clinical syndrome rather than a microbiologically defined disease. As laboratory methods have developed, laboratory characteristics of the isolates have become important elements of descriptive epidemiology. In mid-September 1994, a nationwide outbreak of *Salmonella* illness associated with commercially distributed ice cream was detected when the Minnesota Department of Health's Public Health Laboratory noted an increase in the number of *Salmonella enterica* serovar Enteritidis isolates being identified. Initially, cases appeared to be clustered in southeastern Minnesota, and the full scope of the outbreak became apparent only after the investigation allowed cases to be linked to the outbreak based on their exposure to the nationally distributed food item.

In the mid-1990s, PFGE became a standard part of surveillance for *Salmonella*, *E. coli* O157:H7, and *Listeria monocytogenes*, and a national network of public health laboratories, PulseNet, was established. Because PFGE is more discriminant than genus, species, and serotype, PulseNet led to a marked increase in the number of outbreaks detected. This is turn led to a reduction in the number of sporadic cases of these illnesses that were reported. An evaluation of PulseNet's economic impact is a landmark demonstration of the value of increasing the sensitivity of public health surveillance (2). The current replacement of PFGE by WGS is leading to a similar gain of function for foodborne-disease surveillance and detection of clusters that likely represent outbreaks of foodborne illness.

As surveillance has evolved from detecting clusters of cases defined by clinical syndrome to microbiologic characteristics of genus, species, and serotype to molecular subtype defined by PFGE pattern and WGS, the size of detectable clusters has decreased, and the likelihood that cases within the cluster may share a common source of exposure has increased. Descriptive features of the cases in the cluster may provide important clues as to the source of the outbreak. Reviewing that descriptive epidemiology is the first step in hypothesis generation during outbreak investigations.

Analytical Epidemiology

In contrast to the mere description of events, the comparison of different rates at which they occur between groups is known as analytical epidemiology. This provides the means to test hypotheses about the source of an outbreak. For etiologic studies to determine the cause of an outbreak, the critical measure is the difference between the risk of illness among those exposed to the "contaminated" food and the risk of illness among those who were not exposed. This is customarily presented as an odds ratio or risk ratio, depending on the epidemiologic study design. As the development of molecular laboratory methods has transformed laboratory-based surveillance of foodborne illnesses, there has been a similar evolution in the development of epidemiologic methods to analyze outbreaks.

Community-Based Case-Control Studies

The classic tool of analytical epidemiology for foodborne diseases is the use of a case-control study. Comparing food exposures among cases in an outbreak to those among healthy control subjects has great power to identify foods that are associated with the illnesses. For example, in the nationwide outbreak of salmonellosis associated with ice cream, epidemiologists constructed a questionnaire to ascertain what foods individual patients had eaten in the 5 days before they became ill. The same questionnaire was used to interview healthy individuals of about the same age from

the same communities. By comparing the responses of the cases to the responses of the healthy individuals, who served as controls, it was rapidly determined that the outbreak was due to consumption of commercially manufactured ice cream. Ten (67%) of 15 cases, but only 2 (13%) of 15 controls, had eaten brand A ice cream (matched odds ratio = 10.0; 95% confidence interval [CI] = 1.4 to 434). While results of the case-control study implicated an exposure source within 3 days, regulatory testing to confirm the source of contamination required an additional 10 days.

The magnitude of the odds ratio is a measure of the strength of the association between illness and exposure (Table 8.1). The strength of this association left little doubt that the ice cream was the source of the outbreak. A public health intervention was initiated days before *Salmonella* was actually isolated from the suspected product. In addition, results of the case-control study suggested that the problem likely involved multiple ice cream flavors and days of production. In response, a nationwide product recall was initiated. Further investigation led to the determination that the ice cream premix had been contaminated by raw egg residues in tanker trailers used to haul the premix from two other suppliers. Ultimately, what initially appeared to be a regional outbreak in southeastern Minnesota involved an estimated 224,000 illnesses, with cases reported from 41 states. The published report of this investigation provides a useful model for how an outbreak investigation can identify the root cause of an outbreak and identify effective measures to prevent its recurrence (3).

Table 8.1 Evaluating the strength of association between illness and exposure in epidemiologic studies

Odds ratio or relative risk	Strength of association[a]
1	No association
2-5	Relatively weak
5-10	Relatively strong
>10	Very strong

[a]Other key factors to consider when evaluating the association include the following. Was time between exposure and illness onset consistent with a reasonable incubation period? Was a dose-response behavior observed? Do results of product tracing suggest a common source?

Although they may provide very useful information, large community-based case-control studies such as the one described above are no longer routinely conducted in outbreak investigations. Because of growing difficulties in identifying and interviewing suitable controls, they have become too expensive to conduct and are too slow to produce actionable results in a timely manner. However, smaller, focused case-control studies should be conducted when a subcluster of cases in a multistate outbreak share exposure to a common retail food establishment. As described below, an ingredient-specific case-control study among establishment patrons may be critical to identifying the cause of the larger outbreak. Because these case-control studies are limited in scope to foods served by the establishment, interviews are quicker and well meal companions can serve as controls.

Case-Case Comparisons

The development of molecular subtype-specific surveillance based on PFGE, and more recently WGS, has made it possible to compare cases caused by an outbreak-associated strain with cases caused by unrelated strains. Because the occurrence of an outbreak implies a common source, the cases caused by unrelated strains with many different likely sources of exposure make a very efficient control

group. This is particularly true when patients representing sporadic cases are routinely interviewed with detailed food exposure questionnaires. Case-case comparison studies have been critical for investigating *Listeria* outbreaks, where the risk for illness is dependent on underlying health conditions. For example, during the summer of 2011, an outbreak of listeriosis was identified by the Colorado Department of Public Health and Environment. Food exposures from reported cases were compared to aggregated exposures of nationally reported cases collected by the CDC's *Listeria* Initiative. Outbreak-associated case patients had much higher rates of consuming cantaloupes. Cantaloupe source tracing identified a common grower, and microbiological testing confirmed the contamination of the whole cantaloupes within a week of the outbreak's recognition. Similar methods are also being applied to outbreaks of *E. coli* O157:H7 and *Salmonella* infections.

Case-case comparisons produce the same measures of association as do case-control studies. Although there are theoretical reasons to believe that the unrelated cases used for comparison may have different exposure distributions than would a group of community controls, neither comparison group would likely share the common exposure that caused the outbreak. Thus, from a practical standpoint, these studies are interpreted in the same way. The increased stringency of WGS to discriminate outbreak-associated from unrelated cases makes case-case comparisons a desirable alternative to case-control studies when aggregate case exposure data are available.

Binomial Comparison Studies

A second derivation of case-comparison studies has become the *de facto* standard of practice for investigating clusters and outbreaks identified by pathogen-specific surveillance. The use of this method was pioneered by the late William Keene, an epidemiologist with the Oregon State Health Department and founder of the International Outbreak Museum (www.outbreakmuseum.com/). This approach requires interviewing cases with a detailed exposure

questionnaire, aggregating case exposure data, and comparing them to exposure data compiled from a suitable reference population. The proportion of cases with a particular food exposure can be compared to the population exposure proportion. However, the method does not produce an odds ratio or other measure of the strength of association. Keene developed a simple binomial calculator to test the significance of differences between the case and population exposure proportions. His use of this method in 2006 helped identify bagged spinach as the source of a large multistate outbreak of *E. coli* O157:H7 infections.

FoodNet's Atlas of Exposures has been the most commonly used source of population exposure data. However, there are several limitations to its use. The most recently published FoodNet exposure data are from 2006. Because dietary patterns change over time, novel food exposures may require validation form other sources. The FoodNet population survey was reinitiated in 2017. Similarly, FoodNet exposure data were aggregated across participating sites, and geographic differences in dietary patterns are also apparent. Thus, identifying local population exposure data is preferred.

As with other analytical epidemiology methods, the binomial comparison identifies associations that must be confirmed by product source tracing and corroborated by other investigation findings. In this regard, binomial comparisons should be considered more as advanced hypothesis generation than as hypothesis testing. Because binomial comparisons emulate very large case-control studies, there is an increased chance of producing spuriously significant results. Thus, the results must be cautiously interpreted to avoid errors in identifying the source of an outbreak.

Cohort Studies

A closely related tool of analytical epidemiology is the cohort study. In outbreak investigations, retrospective cohort studies are conducted when an entire group (or population) with a common

exposure can be identified. Individuals can be interviewed without prior knowledge of whether they were ill. Identifying groups based on their exposure status rather than their illness status allows direct calculation of a risk ratio for specific exposures. The risk ratio is the percentage of exposed persons who were ill divided by the percentage of unexposed persons who were ill.

Typical settings for cohort studies involve banquets, wedding receptions, and other events where a list of all persons attending can be obtained. For specific exposures, such as a particular food item, the percentage of persons who became ill after eating the food can be determined. Hence, in addition to implicating the food item, it is possible to determine the attack rate among persons who ate it. Information on attack rates may also help in evaluating the factors contributing to the occurrence of the outbreak. For example, for many bacterial foodborne agents, the attack rate may be related to the exposure dose. A high attack rate may imply high levels of contamination, such as may occur after prolonged temperature abuse.

For example, the CDC's *Morbidity and Mortality Weekly Report* recently reported on an outbreak of diarrheal illness and abdominal pain among employees who attended a catered Thanksgiving lunch that was reported to a local health department. An online survey was prepared and sent to all employees who attended the lunch. The use of the online survey allowed rapid collection of illness and exposure data, from which investigators simultaneously established a clinical case definition, estimated food exposure illness rates, and associated illness with consumption of turkey and stuffing that had been served together. Subsequent laboratory studies and environmental assessments confirmed that the outbreak was caused by *Clostridium perfringens* due to improper temperature control of the cooked turkey.

P Values and CIs

In both case-control and cohort studies, much attention is paid to the precision of the calculated estimate, as measured by the *P* value or 95% CI. Most conventions treat a *P* value of <0.05 as being significant. Similarly, 95% CIs are expected to exclude 1.0 when a significant exposure occurs. While these criteria have served as useful guides to data analysis over the years, it must always be noted that the main contributor to the *P* value and CI is the size of the sample. The larger the sample size, the more likely it is that a statistically significant result may be obtained. Investigators should not discard potentially important associations just because they fail to achieve a *P* value of <0.05. Conversely, "highly significant" results may be totally spurious. The concern is that bias in sampling may have introduced reasons other than contamination of food for the observed difference in risk of illness.

In particular, if food items are usually consumed together, one food item may be identified while the other is overlooked. Mistakes in the identification of the source of two large foodborne outbreaks appear to have resulted from this type of error. In 1996, outbreaks of illness caused by *Cyclospora* were initially associated with strawberries from California, while in 2008, a nationwide outbreak of *S. enterica* serovar Saintpaul infections was associated with tomatoes. In both outbreaks, subsequent epidemiologic analyses identified the actual vehicles: raspberries and jalapeno peppers, respectively. The harm done by this type of error to the affected producers and to confidence in the public health system may be substantial. However, when potential sources of bias are properly controlled and accounted for, epidemiologic methods have demonstrated an impressive ability to accurately identify the sources and contributing causes of foodborne outbreaks.

Limitations in the Use of Epidemiology

As powerful as epidemiologic methods are, they do have limitations. In an outbreak setting where everyone ate a contaminated food item, there may be no opportunity to demonstrate a difference in risk of illness between those who were exposed and those who were

not. Alternative approaches, such as looking at the amount eaten or when the food item was eaten, may allow some epidemiologic discrimination, but results are not likely to be "significant." For example, in two outbreaks of shigellosis in Minnesota that were associated with parsley from a common source, parsley was associated with illness at one restaurant, but not at the other. Chopped parsley was used on so many dishes at the second restaurant that most of the cases and the controls ate it. Thus, the absence of an association does not necessarily mean that the food item or exposure in question is safe.

AGENTS AND TRANSMISSION

Information about specific agents and their transmission is contained in their respective chapters. However, in discussing the epidemiology of foodborne illnesses, it is important to keep in mind the chain of infection. This includes the agent, the reservoir that contains the agent, a means of escape from the reservoir, a mode of transmission to a susceptible host, and a means of entry to the host. These elements contribute to the epidemiologic triad of agent, host, and environment interactions that results in the occurrence of illness.

Specific agents vary with respect to the types of illness they cause, from self-limited gastroenteritis associated with bacterial enterotoxins to invasive and life-threatening diseases associated with *L. monocytogenes*. Some agents, such as norovirus, are cleared from the gastrointestinal tract in a matter of days, whereas others, such as *Giardia*, may cause prolonged carriage, over several weeks. Infectious doses may range from ingestion of a few *E. coli* O157:H7 cells to hundreds of thousands of *C. perfringens* cells. Incubation periods range from a few hours for staphylococcal intoxication to weeks for viral hepatitis type A. Some agents, such as *Shigella*, infect only humans, whereas *Salmonella*, *Campylobacter*, and *E. coli* O157:H7 primarily originate from animal sources. Many agents are associated with typical food vehicles associated with their

animal reservoirs, such as *S.* Enteritidis with eggs and *E. coli* O157:H7 with ground beef, or with food vehicles susceptible to environmental contamination from the animal reservoir, such as leafy green vegetables and *E. coli* O157:H7.

The characteristics of specific agents affect the potential sources of contamination during food production and preparation and form the basis for hazard analysis for specific foods. Knowledge of these patterns contributes to hypothesis generation. It helps investigators focus on likely sources of transmission. However, most foodborne pathogens may be transmitted by multiple routes of exposure, and outbreak investigations are critical for identifying new food hazards and exposure pathways. As described at length below, the results of investigations into foodborne illness outbreaks are also increasingly being incorporated into food attribution models.

FOODBORNE ILLNESS SURVEILLANCE

Public health surveillance for foodborne illnesses is a governmental function that is specifically authorized by law. In the United States, foodborne illness surveillance is established within the framework of state and local communicable disease reporting rules. There is considerable variation in these rules with respect to what illnesses are reportable, how quickly they need to be reported, and whether isolates need to be submitted to the public health laboratory. While the Food and Drug Administration (FDA) and USDA's Food Safety and Inspection Service (FSIS) have regulatory authority over foods in interstate commerce, there is no corresponding authority over the multistate outbreaks that may result from the interstate shipment of contaminated foods. On a national level, the CDC coordinates surveillance activities and multistate outbreak investigations and compiles data from states. However, they have no authority to intervene in any state's investigation. The Council to Improve Foodborne Outbreak Response (CIFOR), which includes representation from local, state, and federal agencies' epidemiologists, environmental health specialists, and public health

laboratorians, has developed guidelines for foodborne disease outbreak response to establish effective outbreak investigation coordination and communication (http://cifor.us/products/guidelines). The CDC has played a key role in developing, improving, and promoting new laboratory methods and epidemiologic practices, as described below.

Purposes of Foodborne Illness Surveillance

Surveillance involves the systematic collection of data with analysis and dissemination of results. Surveillance systems may be passive or active and may be national or regional in scope or based on a sentinel system of individual sites designed to provide estimates that can be generalized. Types of systems, their use, and their limitations are discussed below.

There are four primary purposes for conducting foodborne disease surveillance:

- Identify, control, and prevent outbreaks of foodborne illness
- Determine the causes of foodborne illness to identify preventable hazards
- Monitor trends in occurrence and attribution of foodborne illness
- Quantify and reduce the burden of foodborne illness

“Pulling the pump handle” is the goal of all public health epidemiologists conducting foodborne disease surveillance. Hence, there is a sense of urgency in every investigation to rapidly identify the source of the outbreak and implement control measures to stop transmission and prevent additional illnesses. For products with a long shelf life, such as cured meat products, frozen foods, or cereals, even a relatively long investigation can identify a contaminated product quickly enough to remove it from the marketplace in time to prevent many illnesses. For highly perishable products, such as fresh fruits and vegetables, often the outbreak will have run its course before the food item can be implicated.

Even if it is impossible to directly intervene to control the outbreak, there is still value in determining the causes of foodborne illness. Identifying contributing factors and root causes can help prevent future outbreaks of foodborne illness. Under the Food Safety Modernization Act (FSMA), food manufacturers must establish preventive controls to abate food safety hazards in their operations. Many of these hazards, in terms of either specific agents, specific food ingredients, or various agent-food interactions, were originally determined as a result of foodborne illness surveillance. Because food sources and foodborne disease agents are constantly changing, hazard analysis is an ongoing process that requires continuous support from public health surveillance of foodborne diseases. Additionally, Scallan and colleagues' estimates of the burden of foodborne illness suggest that most foodborne illnesses are caused by unspecified agents. As the experience with *Cyclospora* illness outbreaks from Guatemalan raspberries reveals, foodborne disease surveillance may be the only way to identify both new causes of foodborne disease and potential foodborne hazards.

A third purpose for conducting foodborne disease surveillance is to monitor trends in occurrence and attribution of foodborne illnesses to specific commodities or production practices. This is important to identify priorities for new food safety activities and to monitor the effectiveness of existing programs. For example, Painter and colleagues at the CDC developed a detailed classification scheme for food commodities and used it to attribute sources of foodborne outbreaks from 1998 to 2008 (4). Their approach was the first to quantify the importance of fresh produce as a source of foodborne illnesses. They attributed 46% of outbreak-associated illnesses to produce. They also attributed more deaths to poultry than to any other commodity. Beyond indicating the need for efforts to prevent contamination of produce and poultry, they established a methodological framework that has been used by the CDC, FDA, and FSIS in their Interagency Food Safety Analytics Collaboration in their development of foodborne illness source attribution. They are

developing models to incorporate data from outbreak investigations, sporadic illnesses, and pathogen prevalence in animals and foods.

FoodNet surveys of the population, physicians, and clinical laboratories linked to active surveillance of laboratory-confirmed infections provide the most comprehensive data available from which to estimate the burden of foodborne diseases. These burden-of-illness estimates have been used as a basis for setting the public health priorities reflected in the Healthy People 2020 goals. FoodNet trend analysis for specific agents has been used for evaluating the effectiveness of prevention measures. These analyses have demonstrated the success of interventions to reduce *E. coli* O157:H7 in ground beef, *L. monocytogenes* associated with ready-to-eat meats, and *S. enterica* serovar Typhimurium overall. However, not every trend has demonstrated success. Several *Salmonella* serovars associated with produce and poultry have become more abundant. In addition, significant gaps remain in our knowledge base. Scallan and colleagues concluded that approximately 80% of estimated foodborne illnesses cannot be attributed to known agents. Moreover, timely estimates for the burden of illness associated with all major foodborne pathogens, not just those under FoodNet surveillance, are needed to improve our evaluation of prevention measure effectiveness.

Methods of Foodborne Illness Surveillance

Foodborne disease surveillance requires close collaboration between acute-disease epidemiologists, public health laboratories, and environmental health specialists to determine the likely sources of exposure and routes of food contamination. Methods of surveillance of foodborne illness have been changing in response to the development of new molecular diagnostic methods, including WGS, and rapid developments in information technology and social media. These advances have had important implications for each of the four primary components of foodborne disease surveillance (Table 8.2).

Investigation of Outbreaks Associated with Events and Establishments

Approximately three-quarters of foodborne outbreaks are reported to local or state health departments by ill persons who were part of the outbreak. These include the vast majority of outbreaks caused by norovirus, *C. perfringens, Staphylococcus aureus*, and other agents for which there has not been routine clinical laboratory testing. There is a bias towards detecting outbreaks at events such as a wedding, where a large group with a common exposure experiences illnesses and has some reason to discuss it later. People eating at a restaurant may never know that their illness was also experienced by other restaurant patrons, who are unknown to them. However, multiple independent complaints may identify the same establishment.

Foodborne illness complaints are usually collected by local environmental health programs or health departments. Most individual complaints identify the meal most recently eaten out of the home, usually within a few hours, as the suspected source of the illness. Because many foodborne illnesses have incubation periods in the 1-to 3-day range, collecting a 3-day food history increases the likelihood of identifying a relevant exposure. Entering this exposure information into an electronic database also increases the likelihood that a common exposure can be identified in relation to multiple complaints.

Table 8.2 Primary components of foodborne disease surveillance and surveillance systems and impact of recent developments in laboratory and epidemiologic methods

Component	Surveillance systems	Impact of recent developments
Investigation of outbreaks associated with events and establishments	NORS, NEARS	Database management of complaint systems and social media-based surveillance increase outbreak detection. CIDT of clinical, food, and environmental samples increases confirmation of etiology and contributing factors.
Pathogen-specific surveillance to identify clusters of cases	PulseNet, NORS	WGS increases sensitivity of outbreak detection, specificity of outbreak investigation, ability to link human, food, and environmental isolates. CIDT increases diagnostic testing but decreases sensitivity of outbreak detection and specificity of outbreak investigation. CIFOR, COE, FoodCORE, and FDA's RRT demonstrate and promote effective outbreak investigation measures.
Determining risk factors for sporadic cases of infection with common foodborne pathogens	FoodNet	Large community-based sporadic case-control studies limited by available resources. Case exposure aggregations through the *Listeria* Initiative and the COE Project Mercury leverage routine data collection.

Component	Surveillance systems	Impact of recent developments
Population surveillance to determine frequency of gastrointestinal illnesses, health care-seeking behavior, food consumption, and personal prevention measures	FoodNet	FoodNet population surveys are being reinstituted to provide context for interpreting results of other surveillance activities.

Several investigators have explored the potential use of social media to identify foodborne outbreaks. Restaurant reviews posted to social media sites such as Yelp!, Facebook postings, and Twitter feeds identifying symptoms of foodborne illnesses have all demonstrated potential to identify unrecognized foodborne outbreaks. For the most part, attempts to use these sources have required considerable effort for a small increase in outbreaks detected. Several cities have developed systems to identify suspicious Tweets and encourage the sender to report the illness to their conventional complaint system. Further development and refinement of machine learning algorithms could reduce the need for health department staff to review suspect messages and increase the usefulness of the approach. One organization has developed a system to promote crowd sourcing to identify foodborne outbreaks. Iwaspoisoned.com has developed a simple online complaint reporting interface and forwards complaints to local health departments. However, most complaints do not include detailed food exposures or complete contact information. Local health departments have raised concerns that this system could compete with their own complaint systems, leading to a net loss of information and missed opportunities for

public health interventions. Because independently operated complaint systems require the same individual-level awareness and motivation as do complaint systems run by local public health agencies, they are unlikely to fundamentally increase outbreak detection.

Outbreaks associated with events and establishments require prompt and thorough investigation to identify both the agent and the source. These outbreaks are usually recognized because of the occurrence of common symptoms, such as diarrhea and vomiting, and are reported to public health officials before a specific diagnosis has been established. With the development and use of norovirus testing by many state public health laboratories, the proportion of outbreaks with an unknown etiology has declined from 67% from 1998 to 2002 to 23% in 2015. However, the shift in attribution to norovirus was not solely due to improved access to laboratory testing. The proportion of outbreaks that were not confirmed but were suspected based on clinical and epidemiologic features increased from 0% from 1998 to 2002 to 27% in 2015. Such epidemiologic profiling of outbreaks is useful to guide laboratory testing as well, and has been incorporated into CIFOR Outbreaks of Undetermined Etiology Guidelines (http://cifor.us/products/oue-guidelines).

Although clinical laboratories and many public health laboratories have not historically tested for the presence of enterotoxigenic *E. coli* or other uncommonly reported foodborne pathogens, the development of new culture-independent diagnostic tests (CIDT) and multiagent test panels is transforming our ability to confirm the etiology of outbreaks. The use of CIDT in outbreak investigations may increase the proportion of outbreaks with a confirmed etiology and provide an important framework to evaluate the usefulness of the tests. Confirming CIDT results by culture in public health laboratories can identify potential concerns with sensitivity and specificity of the tests. It can also provide an opportunity to assess the importance of codetection of multiple pathogens within the same sample.

The investigation of outbreaks associated with events is the oldest form of foodborne disease surveillance and accounts for approximately three-quarters of reported foodborne outbreaks. These outbreak investigations are responsible for most of the contributing factor data reported to the National Outbreak Reporting System (NORS). Contributing factors and the environmental antecedents or root causes that precede them are necessary for foodborne attribution studies based on outbreak data. This is a new application for these data and warrants efforts to improve standardization of environmental assessment and reporting. The CDC's Environmental Health Branch has established the National Environmental Assessment Reporting System (NEARS) to complement outbreak data reported to NORS (www.cdc.gov/nceh/ehs/nears/). Moreover, these outbreaks remain the primary way to identify "new" foodborne pathogens that may not be identified by clinical laboratories.

Across much of the developing world, recognition of outbreaks associated with events or establishments, usually involving large groups and short incubation periods, is the extent of foodborne disease surveillance available. This basic level of foodborne disease surveillance requires very little public health infrastructure. However, the development of multipanel diagnostic kits and point-of-use testing will transform the utility of even this basic level of foodborne disease surveillance.

Pathogen-Specific Surveillance To Identify Clusters of Cases

Although most outbreaks are detected through complaints, most multistate and high-profile outbreaks caused by *Salmonella*, Shiga toxin-producing *E. coli* (STEC), and *L. monocytogenes* are detected through identification of clusters by pathogen-specific surveillance. Thus, improving pathogen-specific surveillance has been a major focus of public health agencies.

Laboratory advances

Twenty years ago, the standardization and widespread use of PFGE revolutionized surveillance for *Salmonella*, *E. coli* O157:H7, and *L. monocytogenes*. The introduction of PulseNet created a national framework for surveillance that enabled the detection of widespread outbreaks, even though few cases were reported from any individual state. PFGE greatly improved the investigation of outbreaks by distinguishing unrelated sporadic cases from the main outbreak-associated strain. PulseNet took advantage of the combined revolutions in molecular biology and information technology. Highly reproducible PFGE patterns were generated under standardized conditions, and the PFGE patterns were transmitted electronically between participating laboratories. PulseNet became the backbone of a public health surveillance system, providing truly national surveillance for a variety of foodborne pathogens in a manner timely enough to be an early warning system for outbreaks of foodborne illness. As a result of PulseNet activities from 1994 to 2009, it was estimated that 270,000 foodborne infections caused by *Salmonella, E. coli* O157:H7, and *Listeria* were prevented each year, with a net savings of $500,000,000 (2).

PFGE subtyping improved the specificity of the case definition and made it more likely that the source of the outbreak could be identified. However, PFGE was a relatively crude technique that provided no real information about the organism beyond the subtype pattern. The rapid development of genetic sequencing technology (known as next-generation sequencing) and informatics has made WGS a new standard method for public health surveillance of foodborne pathogens (5). Beginning in 2013, the CDC began using WGS for surveillance of *L. monocytogenes*. *Listeria* was the first pathogen chosen because it causes severe illnesses in a high proportion of cases, a *Listeria* initiative had been established to ensure that all clinical isolates would be forwarded to public health laboratories, and there were fewer than 1,000 cases annually reported in the United States. Almost immediately, the

benefits of routine WGS became apparent, with more clusters being detected, outbreaks being solved with fewer cases, and novel food vehicles being identified and linked to cases. WGS has entirely replaced PFGE for surveillance of *Listeria* in the United States. The transition of routine *Salmonella* surveillance from PFGE to WGS is now under way. While surveillance moves from PFGE to WGS, PulseNet will remain the public health network through which this surveillance is organized.

A key factor in the success of PulseNet was the ability to standardize laboratory procedures so that PFGE patterns in one laboratory could be reliably compared to those in another laboratory. To maintain this same functionality with WGS for *Listeria*, the CDC is developing core genome multilocus sequence typing (cgMLST) to provide a standard reference of gene loci for the core genome of the pathogen. With cgMLST surveillance, the number of allele, or gene, differences can be compared to the reference standard, allowing a strain-specific allele code to be generated. Isolates with the same or closely related allele code can be identified and compared to historic frequencies, similar to surveillance by PFGE pattern. This approach can be extended to the whole genome by including accessory genes in the analysis. In addition, sequence information codes for other important factors, such as genes associated with serotype, virulence factors, or antimicrobial resistance. Thus, the size and potential severity of the cluster can be simultaneously identified, to help establish priorities for investigation.

A complementary approach to WGS involves the analysis of high-quality single nucleotide polymorphisms (hqSNP). With hqSNP analysis, closely related isolates are compared to determine the number of SNP, or base pair differences, between isolates. This is a highly discriminatory practice that is useful to sort out relationships among isolates within an outbreak investigation. However, because results generated using different references cannot be directly compared, it may not be as generally applicable as cgMLST for routine surveillance. As with PFGE, there are common cgMLST

sequence types for which hqSNP analysis could provide further discrimination.

There are limitations to the use of WGS. Sequencing is not currently as rapid as PFGE. Thus, there may be delays in detecting clusters during the transition from PFGE to WGS. In addition, some *Salmonella* serotypes appear to diversify their genomes faster than others. Thus, inherent variability could affect cluster definitions. For outbreaks that extend over prolonged periods, outbreak-associated cases may have more differences than would cases in a point source outbreak. If an outbreak involves polyclonal contamination, outbreak-associated clusters may not be recognized. These are problems that also limited the usefulness of PFGE. However, the greater discriminatory power of WGS will lower the threshold of investigating clusters. This should largely compensate for these other shortcomings.

The other major laboratory development that impacts pathogen-specific surveillance is the increase in the use of CIDT. These are tests that detect the presence of the agent by identifying specific toxins, antigens, or gene sequences in clinical material without isolating the organism itself. They provide rapid results that are not very specific. A variety of CIDT have begun to be used in clinical laboratories for the primary diagnosis of diarrheal diseases. CIDT targeting STEC or specific parasites have been in use for several years. Positive CIDT results indicating the presence of STEC have required the secondary culture and isolation of the organism for confirmation and subtyping. This secondary culture of the original clinical sample that provided the positive CIDT result is known as a reflex culture. More recently, multipathogen panels have been developed and are becoming widely used in clinical laboratories. CIDTs are popular because they provide results in hours rather than days, which provides information to clinicians that they can use to manage patient care. Multipathogen panels provide results for a wider range of agents than conventional culture methods and require fewer trained microbiologists to use and interpret. Thus,

they may be cheaper to use, in addition to being faster and more informative.

However, the lack of a pathogen isolate to subtype represents a considerable challenge to surveillance. Much of the increased utility of WGS will be lost if CIDT results cannot be confirmed with culture. The CDC and state public health officials are making concerted efforts to have clinical laboratories perform reflex cultures themselves or to forward clinical samples to the public health laboratory for culture. In 2017, the CDC reported a 176% increase in CIDT-positive reports of *Salmonella*, compared to the numbers in 2014 to 2016. However, because of the high frequency and success of reflex cultures, only 9% could not be confirmed (6). For other agents, the loss of isolates was more pronounced, as 36% of *Campylobacter* and 27% of STEC isolates were either culture negative or not cultured. In addition, the process of reflex culture considerably delays the availability of useful subtype data and represents a large cost to both clinical and public health laboratories.

The changing patterns of CIDT use have considerably complicated the CDC's efforts to track trends in the occurrence of foodborne pathogens under surveillance. The dynamic nature of change in the frequency of use and characteristics of individual CIDT performance will need to be assessed to provide a framework to adjust incidence rates over time. On the positive side, if the benefits of CIDT result in more patients being tested and diagnosed, public health officials will see a net gain in surveillance data. While the approaches needed to understand the results from an epidemiologic perspective may change, more data should result in better surveillance and enhanced detection of outbreaks.

Epidemiologic advances

The public health utility of incorporating molecular subtyping into routine surveillance of *E. coli* O157:H7, *Salmonella*, and *Listeria* has been repeatedly demonstrated. However, many subtype cluster

investigations initiated on a national basis fail to identify a common source of exposure. This may reflect the difficulties in conducting timely multistate outbreak investigations. For example, in December 2017, an outbreak of *E. coli* O157:H7 illness was identified. Twenty-five cases across 15 states were identified, and the outbreak-associated strain was linked to a contemporaneous outbreak in Canada, which Canadian public health officials had linked to romaine lettuce. By the end of the outbreak, only 15 of 25 case patients in the United States had been interviewed to ascertain detailed food exposure histories. While leafy greens were suspected, no source could be identified.

In order to improve the level of performance for foodborne illness surveillance and outbreak investigations, the CDC and its state and local partners have initiated several coordinated activities. In 2006, the CDC, the Council of State and Territorial Epidemiologists, and the National Association of City and County Health Officials convened a working group representing local, state, and federal public health and food regulatory agencies. CIFOR began to develop a set of guidelines for foodborne disease outbreak response to standardize and improve outbreak investigation practices. The guidelines were originally published in 2009, and the third edition was published in 2018.

In 2009, the CDC developed a pilot program to explore how to improve disease surveillance and outbreak investigation practices in three states. In 2011, it was named the Foodborne Diseases Centers for Outbreak Response Enhancement (FoodCORE), which expanded to 10 centers by 2014. FoodCORE has promoted timely and comprehensive submission of clinical isolates to public health laboratories for molecular subtyping, rapid interviewing of reported case patients by teams of student workers using detailed food exposure questionnaires, and enhanced coordination and communication with environmental health specialists. The usefulness of many of these practices has been revealed over the past 20 years by the Minnesota Department of Health. Federal

support through the CDC is enabling other states to employ the same methods.

With the passage of the FSMA in 2011, Congress mandated that federal public health and food regulatory agencies work with state and academic partners to improve surveillance for foodborne illnesses. The FSMA established a network of Integrated Food Safety Centers of Excellence (COE) in five states to empower health departments and academic partners to assist other states improve their outbreak investigations. The COEs coordinate with foodborne illness surveillance programs at the CDC to evaluate the effectiveness of surveillance measures and provide training to build the public health workforce.

Following the passage of the FSMA, the FDA established the Coordinated Outbreak Response and Evaluation Network (CORE), a multidisciplinary team of FDA specialists charged with trying to assist the CDC and states to investigate multistate outbreaks. CORE coordinates with the FDA's rapid response teams (RRTs). These are multiagency, multidisciplinary teams that use Incident Command System principles to respond to human and animal food emergencies.

CORE and the RRTs have been particularly involved in product tracing activities. Although product tracebacks are frequently started only after a food item has been implicated, detailed product information is actually critical to epidemiologic analysis, and tracebacks intended to provide source information that can be used in epidemiologic analyses are critical to the identification of the contaminated food item. The importance of this point is further emphasized by the increasing occurrence of outbreaks associated with foods, such as salads and salsas, that routinely contain multiple ingredients. Had source tracing of tomatoes been pursued before tomatoes were implicated as the source of a large *S.* Saintpaul outbreak in 1998, the lack of convergence for tomato sources might have led to consideration of other produce items frequently combined with tomatoes. However, it is likely that

investigators were anticipating tomatoes to be identified as the source, given the frequency of tomato-associated outbreaks and the apparent strength of the association based on the results of an initial case-control study.

The importance of product tracing early in the course of outbreak investigations is emphasized by the major changes that are occurring in outbreak investigation methods. Increasingly, routine interviews of all patients with *Salmonella*, STEC, and *Listeria* illness are being conducted by teams of student workers using detailed hypothesis-generating questionnaires. As case clusters are being identified, frequencies of case food exposures are being compiled and compared to expected values from population surveys or sporadic case aggregations. The differences in these proportions are being tested by simple statistics, and likely exposure sources are being identified. Because most of these aggregated data sources do not contain fine product details, product tracing is conducted to ascertain a common source for the suspected exposure. This approach is proving efficient and reliable and will likely be the standard of practice for the foreseeable future.

Integration of surveillance on a global level

The Global Foodborne Infections Network has been established by the World Health Organization (WHO) to promote pathogen-specific surveillance for *Salmonella*, *Campylobacter*, and *E. coli* O157:H7 and provide training to international partners. Declining public health resources in developed and developing countries may severely limit the usefulness of this system and the international distribution of PulseNet. Building the capacity to conduct molecular subtype surveillance is necessary to detect widely dispersed outbreaks caused by common serotypes and to track the emergence of global food safety threats. Failure to invest in these advanced surveillance systems will consign developing countries to a basic level of surveillance.

Determining Risk Factors for Sporadic Cases of Infection with Common Foodborne Pathogens

Determining risk factors for sporadic cases of infection with common foodborne pathogens is a third major component of foodborne disease surveillance. Population-based case-control studies of sporadic infections are needed to supplement outbreak data for attribution studies. They can help identify targets for intervention and provide a basis to evaluate its effectiveness. Case-control studies of sporadic *S.* Enteritidis infections in the United States and Europe helped establish the role of grade A shell eggs in the epidemiology of these infections.

Case-control studies of *Campylobacter* infections helped establish chicken as a primary source of *Campylobacter*. Similarly, case-control studies of sporadic *E. coli* O157:H7 infections confirmed the importance of ground beef, particularly undercooked ground beef, as a source of the pathogen. However, case-control studies of this type are expensive to conduct and may require several years to complete. Thus, they may not be sensitive to rapid changes in patterns of food sourcing or consumption, both of which can shift over short time periods. In addition, because common foodborne pathogens may have many potential sources of exposure, these methods are inherently limited with regard to evaluation of exposure to commonly eaten food items.

FoodNet has conducted population-based, case-control studies for *E. coli* O157:H7, *Salmonella* serogroups B and D, *Campylobacter*, *Cryptosporidium*, and *L. monocytogenes*. These have provided updated and original estimates of the proportion of these infections that are attributable to specific food items. Results of sequential *E. coli* O157:H7 case-control studies revealed a decrease in the risk of *E. coli* O157:H7 infections associated with eating hamburgers at a fast-food restaurant. This validated the fact that fast-food restaurants were thoroughly cooking the hamburgers they serve. At home, or at table service restaurants, where consumers have a choice to order an undercooked hamburger, eating undercooked

hamburgers remained associated with illness. Case-control studies of *Campylobacter*, *S.* Enteritidis, and *S. enterica* serovar Heidelberg infections also revealed associations with eating out, not at home. Other interesting findings included associations between *S.* Enteritidis infection and chicken consumption, a finding that was subsequently documented through a series of outbreak investigations. Similarly, a FoodNet case-control study of sporadic *L. monocytogenes* infections identified eating melons at a commercial establishment as a risk factor for illness before the 2011 outbreak was associated with cantaloupe. Cantaloupe was included on food exposure questionnaires because of the results of the case-control study.

Population Surveillance

The final important component of foodborne disease surveillance is population surveillance to determine the frequency of gastrointestinal illnesses, health care-seeking behavior, food consumption, and personal prevention measures. This type of syndrome-specific surveillance is not usually conducted by state or local health departments. However, these measures formed the basis of the CDC's estimates that 48 million foodborne diseases occur each year in the United States. These data are also useful for understanding the results of active surveillance. By describing when and why people seek medical care when they are ill, these data can help to estimate how many illnesses occur for each one that gets a specific diagnosis. With the development and use of CIDT, this type of information is critical to understanding foodborne illness trends. Finally, the population-based food consumption data are being used to estimate the proportion of specific illnesses attributable to specific exposures in the FoodNet case-control studies, which are used to help develop foodborne illness attribution models.

Following models developed to build on FoodNet findings, international collaborations have been coordinated through the WHO to strengthen disease surveillance and to determine the global burden of acute gastroenteritis (7). The Foodborne Disease Burden

Epidemiology Reference Group (FERG) found that the most frequent causes of foodborne illness were norovirus and *Campylobacter* spp., with non-typhoidal *Salmonella enterica* being a leading cause of deaths. Forty percent of the burden of foodborne illnesses was borne by children under 5 years of age, with the greatest burden in Africa.

Results of the FERG study support integrating food safety policies into poverty reduction programs targeting food security and nutrition. Encouraging international investments to promote access to safe drinking water and sanitation in developing countries is a global public health issue. Reducing the burden of foodborne illness in these countries will provide global benefits through the reduced risk of contamination of foods imported into developed countries.

SURVEILLANCE FOR FOOD HAZARDS

Risk assessments for specific pathogens, such as *E. coli* O157:H7 in ground beef or romaine lettuce, *S.* Enteritidis in shell eggs or chicken meat, or *L. monocytogenes* in soft cheeses or frozen vegetables, require making measurements or assumptions about many parameters. At every step from farm to table, potential sources of contamination can be identified, measured, and modeled to determine the relative contribution to the overall risk of foodborne illness.

Environmental Monitoring

For many foodborne pathogens of public health importance, contamination of finished food products is a sporadic and rare occurrence. While end-product pathogen testing is difficult to justify as a primary prevention measure, it provides important information as part of a comprehensive quality assurance testing program. Given the scale of modern agriculture and food production systems, contamination levels below the statistical and microbiological threshold can still be large public health problems.

For example, internal contamination of eggs with *S.* Enteritidis is rare, occurring in an estimated 1 in 20,000 eggs on a national basis in the United States. Despite this sporadic occurrence, consumption of contaminated shell eggs is still an important cause of foodborne illness. For this reason, surrogate measures of contamination, such as identifying infected hens or environmental contamination in egg laying houses, have been widely accepted as being more efficient and effective than testing individual eggs.

Similarly, environmental sampling of generic *Listeria* spp. in food processing environments has been critical to manage and reduce the risk for contamination by *L. monocytogenes*. Identification of potential harborage areas for generic *Listeria* spp. has allowed manufacturers to target sanitation measures to eliminate potential source of contamination. Successful application of environmental monitoring in plants that process ready-to-eat meats, along with product formulations that inhibit growth of *Listeria*, has helped reduce the number of outbreaks associated with deli meat products. This has contributed to incidence rates of *Listeria* infections in the United States that are at all time low levels.

WGS is providing new opportunities to monitor patterns of environmental contamination in food manufacturing facilities. Environmental isolates can be subtyped and monitored over time to identify strains that may have taken up residence in the facility. Identifying these resident organisms may indicate the need for special corrective actions or sanitation measures to eradicate these persisting sources of contamination.

Finished-Product Testing

Although food manufacturers may avoid finished product testing, routine food testing is conducted as part of larger food safety verification programs operated by the FDA, FSIS, and state agriculture departments. WGS is routinely performed on these food isolates, with gene sequences uploaded to the National Center for Biotechnology Information (NCBI) at the National Institutes of

Health. These data are compared to human cases in the PulseNet database to identify potential links. This type of cross-referencing between food, environmental, and human isolates has become an important tool to identify previously unrecognized outbreaks and to generate hypotheses during cluster investigations. For example, *L. monocytogenes* isolated from an ice cream sample in South Carolina was traced to a manufacturing facility in Texas that was subsequently linked to a cluster of cases that occurred in a Kansas hospital in 2015. These isolates were all determined by WGS to be closely related. During the investigation of ice cream products at the Kansas hospital, an additional ice cream product from a separate manufacturing facility in Oklahoma was found to be contaminated with *L. monocytogenes*. The *Listeria* isolate from this second product was different from the original outbreak strain. However, a search of PulseNet identified five other cases from three states with onset of illness from 2010 to 2014 that were caused by closely related strains of *Listeria*. At least one of these case patients had a history of consuming ice cream from the source plant.

The example of the ice cream-associated listeriosis outbreak highlights several important considerations for food and environmental testing in the WGS era. Because results of WGS data can be stored electronically in searchable databases, links can be made across space and time with unprecedented ease. Once a record is established, it may be retrieved years later. In this outbreak, WGS linked cases that had occurred 5 years previously to a manufacturing source. However, the outbreak investigation provided an epidemiologic context to the link between cases and source. Just identifying an isolate from a case that is closely related to a food isolate by WGS does not imply that the food was the source of the illness. For every potential WGS link that is made between food or environmental isolates and human cases, an epidemiologic investigation must be conducted to establish the relationship between source and case.

Behavioral Risk Factor Surveillance

Behavioral risk factors for foodborne disease range from choosing to eat alfalfa sprouts or undercooked ground beef to failing to wash hands between using a toilet and making a salad. These factors are evaluated and can be identified during the course of outbreak investigations. The frequency of these behaviors in the general population can be assessed through surveys, such as those being conducted as part of FoodNet. Information of this type can provide important perspectives for understanding the occurrence of foodborne disease outbreaks and sporadic infections. It also serves as the basis for developing and modifying public education campaigns to improve food safety, such as the Partnership for Food Safety Education's national public education campaign, Fight Bac!.

Environmental Hazard Surveillance

Factors contributing to the occurrence of foodborne disease outbreaks are compiled by the CDC from national surveillance data and by individual states. National data are published in annual foodborne outbreak surveillance summaries. Leading contributing factors include bare-hand contact by a food worker who is suspected to be infectious and contamination of raw foods intended to be eaten raw. These factors are associated with norovirus transmission routes. Cross-contamination and food preparation practices that support proliferation were more frequently cited as contributing to *Salmonella* outbreaks. Unfortunately, contributing factors have been reported from only 50 to 60% of all outbreaks reported to the CDC. Bias in what is reported is the largest systematic problem for interpreting national foodborne disease outbreak surveillance data.

To address the lack of contributing factor information reported to NORS, NEARS, which collects outbreak data on restaurants and other retail food service establishments, collects data on environmental factors related to the occurrence of the outbreak and on the reasons that these factors occurred. Relating contributing factors to their environmental antecedents may provide a better understanding of corrective actions that can be applied to help food service operators prevent foodborne illness in their establishments.

NEARS is intended to be a companion to NORS, so that information on the same outbreaks can be reported to both and linked. The ability to link outbreaks between NORS and NEARS creates a unique analytical resource that can be especially useful to explore the role of restaurants in the epidemiology of foodborne illnesses.

The improvements that NEARS will bring to contributing factor reporting highlight a critical need for addressing likely food hazards: first, to determine the proportion of illnesses and outbreaks attributable to the hazard, and then to estimate the predictive value of the hazard for causing disease. In a restaurant setting, we may know how many times bare-hand contact with foods or failure to wash hands is identified as a contributing factor in an outbreak of foodborne illness, but what is the frequency of this failure in restaurants? The FDA began to address these data needs in 1997 with the creation of the FDA Retail Food Program Database of Foodborne Illness Risk Factors. This was followed by surveys in 2003 and 2008 to assess trends (8). Results of these surveys revealed better compliance with hand washing in fast-food restaurants than in full-service restaurants. Both fast-food and full-service restaurants increased compliance with provisions regarding bare-hand contact with ready-to-eat foods. While both fast-food and full-service restaurants improved on holding times and temperatures, these were out of compliance in approximately half of full-service restaurants. Approximately one-third of full-service restaurants had potential contamination issues. These studies provide data to address important environmental questions using epidemiologic methods applied to surveillance for the hazards. Current attribution models focus on commodity-level attributions. However, since more than 50% of outbreaks occur in restaurant settings, a better understanding of how restaurants modify commodity-level risks is imperative.

FOODBORNE DISEASE SURVEILLANCE AND ATTRIBUTION

Public health surveillance of foodborne disease is critical to the performance of food safety systems that are based on HACCP (hazard analysis and critical control point) plans. Surveillance is required to identify new hazards. It also provides the ultimate feedback on the efficacy of HACCP plans. In the 1994 outbreak of salmonellosis due to commercial ice cream, cross-contamination during transportation was identified as a hazard that had not been addressed in the manufacturer's HACCP plan.

As noted earlier, case-control studies of sporadic outbreaks of *E. coli* O157:H7 infection revealed that public health recommendations regarding thorough cooking of hamburgers appeared to reduce the risk of eating hamburgers in fast-food restaurants. Following the 2002 FSIS notice to manufacturers of raw ground beef products that they must consider *E. coli* O157:H7 a potential hazard in their HACCP plans, the percentage of positive samples at retail decreased markedly, and the incidence of *E. coli* O157:H7 infections decreased as well, achieving Healthy People 2010 goals.

The FoodNet surveillance network was established, in part, to provide a tool to evaluate the public health impact of the USDA's implementation of meat processing plant HACCP systems. FoodNet sites provide population-based measures of the incidence of illnesses caused by several important foodborne pathogens. The reductions in the occurrence of *E. coli* O157:H7 infections demonstrated the success of coordinated activities by ground beef producers, FSIS, and public health officials to reduce the risk of infections associated with ground beef. Currently, while overall rates of salmonellosis have remained stable for the past 20 years, there have been considerable declines in *S.* Typhimurium and *S.* Heidelberg infections over the past 10 years. This is important because these were among the serotypes targeted by the poultry industry and FSIS measures. Furthermore, the declines in numbers of human cases correlate with declines in numbers of positive chicken meat samples. Thus, these results suggest that these coordinated activities have reduced the burden of disease associated with these food-pathogen pairs.

As noted above, food attribution models being developed by the Interagency Food Safety Analytics Collaboration incorporate outbreak data using a standardized food categorization scheme. This model is being updated to incorporate statistical modeling approaches to evaluate temporal changes in attribution estimates. Given the examples of changes observed by FoodNet, having attribution models that can be updated to reflect current conditions in the food system is critical to maintaining effective food control. In addition, because attribution measured at the point of processing may have different results than attribution at the point of service, efforts are being made to estimate food source attribution along the farm-to-table continuum. In this regard, restaurant operations will be a particularly important focus area. The final area of great effort is to incorporate WGS and case exposure data for food source attribution. The high degree of granularity with WGS may allow more stable associations between specific clonal groups of pathogens and food animal or environmental reservoirs. Initial efforts to characterize source associations with *S.* Enteritidis illnesses may serve as a model that can be expanded into a larger range of serotypes.

SUMMARY OF MAJOR ADVANCES IN THE EPIDEMIOLOGY OF FOODBORNE ILLNESS

Humans remain the ultimate bioassay for low-level or sporadic contamination of our food supply. Epidemiologic methods of foodborne disease surveillance are powerful tools because they take advantage of events that are occurring throughout the population. This population-based lens, focused by advances in molecular subtyping and information technology available to public health laboratories, is particularly well suited to dealing with foodborne diseases associated with mass-produced and widely distributed food products.

WGS is becoming the standard for public health surveillance. It offers greater sensitivity for outbreak detection and greater specificity for outbreak investigation than previously used methods. Public health officials will be challenged to provide the epidemiologic resources to investigate and solve the anticipated growth in small outbreaks. WGS links between cases and foods or environmental samples will require exposure assessment. Ascertainment of detailed information on food source and production is needed to confirm the cause of the outbreak and identify contributing factors.

In contrast, CIDT threaten public health surveillance with a loss of case specificity, requiring that the local cluster of illnesses, such as that caused by *Salmonella*, be recognized based on a common exposure to a retail food establishment. The increased use of CIDT by clinicians may offset the loss of specificity in the test result by increasing the numbers of cases reported.

Streamlined approaches to outbreak investigations focused on detailed exposure assessment and comparison to expected values, followed by product tracing to confirm the source, will increase efficiency, but the results need careful evaluation to avoid spurious associations.

Better outbreak investigation methods, including environmental assessments, will provide more useful data to evaluate the effectiveness of food safety policies and improve food attribution models. Improving the science base for policy development should lead to more effective food control activities.

The same methods of observation and analysis that form the basis of foodborne disease surveillance in the United States are also being practiced across the world in developed countries and are being adapted for use in many developing countries. Since national food supplies are rapidly becoming global in origin, the need for an international system for foodborne disease surveillance exists as well. Models such as PulseNet provide opportunities to conduct multinational surveillance for at least the major bacterial foodborne

disease agents. Because foodborne disease problems imported into one country may represent disease problems endemic to the food-producing country, growing awareness of these problems could stimulate investment in interventions that improve public health in both countries. In particular, the global trade in fresh produce, spices, aquacultured fish and seafood, and seed stock requires safe water distribution and sanitary sewage disposal systems wherever these products are handled.

Salmonella

CHARACTERISTICS OF THE ORGANISM

Salmonella, a rod-shaped facultative anaerobic member of the family *Enterobacteriaceae*, is a ubiquitous microorganism able to infect a multitude of hosts, including animals, plants, and protozoa, and colonize diverse environments. The versatility of this pathogen resides in its ability to swiftly adapt to broad shifts in temperature, pH, water activity, and oxygen concentrations (1). These bacteria are generally motile and are peritrichous, except for the nonflagellated serovars *Salmonella* Pullorum and *Salmonella* Gallinarum (2). Some metabolic traits of the species of this genus that distinguish it from other Gramnegative rod-shaped enterobacteria are production of catalase, the absence of the cytochrome *c* oxidase, and the inability to ferment lactose and produce urease and indole.

The unique *Salmonella* environmental pervasiveness, its ability to cause disease in humans and animals, and the multiple routes of infection make this pathogen a public health threat that cannot be eradicated, only identified and contained. In developed and industrialized countries, *Salmonella* spp. contaminate mainly animal products and produce, whereas, in developing countries, waterborne transmission and person-to-person transmission play a more important role. There are as many as 130 million cases of nontyphoidal salmonellosis worldwide each year, and of those, about 80 million are foodborne. Considering that there is an estimate of 2.8 billion diarrheal diseases worldwide, this makes *Salmonella* responsible for 3% of them (3). In the United States, *Salmonella* is responsible for approximately 1.02 million illnesses and more than 378 deaths each year. These estimates make nontyphoidal *Salmonella* (NTS) serovars the leading cause of bacterial foodborne illness (4).

CLASSIFICATION AND TAXONOMY

Nomenclature

The first microorganism belonging to the genus now called *Salmonella* was first isolated in 1884 by Theobald Smith, a trained physician working at the time as inspector with the U.S. Bureau of Animal Industry, and described by Daniel E. Salmon, who was the veterinary surgeon chief of the Bureau and the first recipient of a degree in veterinary medicine in the United States. The bacillus-shaped microorganism was isolated from porcine intestines during an outbreak of what was thought to be hog cholera and, as a result, named *Bacillus choleraesuis*. In 1900, the director of the National Institute of Bacteriology in Buenos Aires, Argentina, Jose Leon Marcel Lignières, first proposed placing all the bacteria causing hemorrhagic septicemias into a single group, called *Pasteurelloses* (5). However, the following year, recognizing that such a general classification was too vague, he proposed separating the group into two taxa, *Pasteurella* and, to honor the lead discoverer, *Salmonella* (6).

In 1923, Bergey first physiologically (7) defined the members of this genus as follows: “Motile forms occurring in the intestinal canal of animals in various types of acute inflammatory conditions. Attacks numerous carbohydrates with the formation of both acid and gas. In general, does not form acetyl-methyl-carbinol.” This definition was modified in 1930 to exclude lactose, sucrose, and salicin from the fermented carbohydrates and again in 1934 to further restrict the genus definition to organisms that form acid only in carbohydrate media (8). In 1934, *Salmonella* was recognized as a genus by the *Salmonella* subcommittee of the Nomenclature Committee of the International Society for Microbiology. The committee also decided that the most efficient way to classify the members of this

new genus was through the discriminating criteria based on serotyping first proposed by Bruce White in 1929 and expanded by Fritz Kauffmann in 1931.

Based on this system, each new serological type identified by O (somatic) and H (flagellar) antigen characterization received a name according to the disease caused, the animal affected, or the name of the place of its first occurrence. These serological varieties (serovars) were to be considered different species if they showed distinctive cultural characteristics. In 1966, Kauffmann proposed the one serovar-one species concept by which every serovar should be considered a separate species (9). Kauffmann also divided the genus *Salmonella* into four subgenera (I to IV) based on biochemical characteristics without making a formal nomenclature proposal (10). This proposal was only one of several classification systems used for epidemiological purposes, but, if adopted, it would have resulted in more than 2,500 different species. At the same time, phenotypic studies and numerical taxonomy showed that *Salmonella* serovars within each subgenus were biochemically indistinguishable. As a result, Kauffmann's subgenera were considered species: "*S. kauflmannii*" (subgenus I), "*S. salamae*" (subgenus II), *S. arizonae* (subgenus III), and "*S. houtenae*" (subgenus IV) (11). In the early 1970s, the development of new DNA-based techniques allowed new approaches to understanding the taxonomy of the *Salmonella* genus and its nomenclature.

In 1973, Crosa et al. determined by DNA-DNA hybridization that virtually all the serovars of *Salmonella* were highly related from the genetic standpoint and supported the classification of all the *Salmonella* serovars and species and all serotypes of the genus *Arizona* thus far identified as one species (12). This genetic similarity, however, conflicted with the broad biochemical and serological variability, host range, and pathogenicity characteristics of the genus. As a result, Crosa et al. supported the three-species system proposed by Ewing in 1972, consisting of *Salmonella choleraesuis*, *S. typhi*, and *S. enteritidis* (13). Because "choleraesuis" as a designation denoted a species as well as a serovar, thus possibly leading to classification confusion, "*Salmonella enterica*" was suggested in 1986 as the designation of the *Salmonella* type species by the Subcommittee of Enterobacteriaceae of the International Committee on Systematic Bacteriology at the XIV International Congress of Microbiology (14). In 1987, Le Minor and Popoff proposed dividing *Salmonella* into seven subspecies: *S. enterica* subsp. *enterica* (I), *S. enterica* subsp. *salamae* (II), *S. enterica* subsp. *arizonae* (III), *S. enterica* subsp. *houtenae* (IV), *S. enterica* subsp. *bongori* (V), and *S. enterica* subsp. *indica* (VI) (15). Subsequently, biochemical and genetic differences led to the split of subspecies III into *S. enterica* subsp. *arizonae* (IIIa) and *S. enterica* subsp. *diarizonae* (IIIb) and gave *S. enterica* subsp. *bongori* (subspecies V) separate species status. Specifically, the latter decision was based on DNA relatedness studies and multilocus enzyme electrophoresis techniques (16).

This system was accepted by several organizations across different countries, including the American Society for Microbiology, the World Health Organization (WHO), and the Centers for Disease Control and Prevention (CDC), but it was rejected by the Judicial Commission of the International Committee of Systematic Bacteriology. The rejection was based on the possibility of overlooking the clinical importance of the serovar *Salmonella* Typhi by making it a serovar of *S. enterica* subsp. *enterica*. More importantly, the changes proposed by Le Minor and Popoff implied a restructuring of the taxonomy of the genus, and the commission did not and does not have the authority to rule on such changes.

In 2002, the commission reconsidered the nomenclature proposal by Le Minor and Popoff and, after considering recent taxonomic analyses and subsequent requests for changes submitted by several scientists, issued an opinion (Opinion 80) that was made official in 2005 and clarified by Tindall et al. (17). Based on this opinion, the type species of the genus *Salmonella* Lignieres 1900 is *S. enterica*, and the epithet *enterica* should be conserved over all earlier epithets that may be applied to this species (e.g., *choleraesuis*). The ruling recognized that *S. enterica* should be divided into six subspecies: *S. enterica* subsp. *enterica*, *S. enterica* subsp. *S. enterica* subsp. *salamae*, *S. enterica* subsp. *arizonae*, *S. enterica* subsp. *diarizonae*, *S. enterica* subsp. *houtenae*, and *S. enterica* subsp. *indica*. It also implicitly accepted the taxonomic proposal by Reeves et al. (16), thus establishing two species, *S. enterica* and *Salmonella bongori*.

Serovars

In most bacterial species, a serovar is defined by a combination of surface antigens that produce serological reactions, leading to an antigenic formula (e.g., *Escherichia coli* O157:H7). In *Salmonella* species and subspecies except *S. enterica* subsp. *enterica*, antigenic formulae are assigned using the simplified Kauffmann-White-Le Minor scheme based on the O and H antigens. In *Salmonella*, the H antigens of flagellin can undergo rapid mutations and switch immunologic reactivity, in a phenomenon called phase variation. This is a method deployed by this and other pathogens to evade the immune response. For this reason, the antigenic formula includes antigen classification for H in phase 1 and 2. According to this scheme, the subspecies name is written in roman numerals (e.g., II, IIIa, IIIb, IV, and VI), including the species *S. bongori* (V) (mainly for consistency with the formula system) followed by a space, the O antigens (separated by a comma if needed) followed by a colon, H antigens from phase 1 followed by a colon, and H antigens in phase 2, whenever present (for example, *Salmonella* serotype II 6,7:Z_6:1,7 refers to *S. enterica* subsp. *salamae*, O antigens 6 and 7, H antigen Z_6 in phase 1, and H antigens 1 and 7 in phase 2). The official serological classification system is maintained by the WHO and is published in *Antigenic Formulae of The* Salmonella *Serovars* (18).

S. enterica subsp. *enterica* has the largest number of serovars (more than 2,500), and most them are of human relevance. For this reason, using the antigen formula for their identification could cause confusion. Therefore, the modern nomenclature rules assign names to serovars of this subspecies based on the name of the geographic area where a serovar was first isolated. There are a few exceptions where the historical names based on the illness caused or the habitat or host of the serovar are still maintained (i.e., Typhimurium, Typhi, Paratyphi, and Gallinarum).

Concerning proper naming in publications and official documents, the first mention of a serovar should contain the full species name (*Salmonella enterica*) followed by the subspecies (*enterica*), which must be italicized (*Salmonella enterica* subsp. *enterica*). This is then followed by the word "serovar" along with the name of the serovar (e.g., *Salmonella enterica* subsp. *enterica* serovar Agona). Note that the name of the serovar is given in roman letters with the first letter capitalized. Subsequent mentions of the name can be condensed to "*Salmonella*" followed by just the serovar name, for example, *Salmonella* Agona. In scientific writing, abbreviation of a genus name in front of anything but a species epithet is strongly discouraged, as it could lead to confusion of that name for a species. Therefore, a serovar name should not follow an abbreviated genus (e.g., *S.* Agona) (18, 19).

Isolation

Isolation of *Salmonella* from foods and surfaces can often be challenging because of low cell numbers and the competing microbiota present. The variety of foods that can be contaminated by this foodborne pathogen, including eggs, candies, spices, and pig ears, makes the development of a standard isolation method particularly challenging. Currently, the U.S. Food and Drug Administration (FDA) publishes a laboratory methods manual that contains the procedure accepted for food and environmental testing (20). Sampling and homogenization of the food is always dependent on the type of food considered and can vary substantially between foods. However, for most of them, there are different specific broths (i.e., lactose broth, Trypticase soy broth enriched with ferrous or potassium sulfate, tetrathionate broth, and universal pre-enrichment broth) used to resuspend, homogenize, and pre-enrich the sample. This first preenrichment is generally followed by enrichment in a slightly acidic and hyperosmotic medium, Rappaport-Vassiliadis (RV) broth, and tetrathionate broth. If the presence of *Salmonella* Typhi is suspected, selenite cysteine broth is used instead of RV broth, as this serovar is inhibited in RV. Both enrichments are streaked for single colonies on three selective and differential media: bismuth sulfite (BS), xylose lysine deoxycholate (XLD), and Hektoen enteric (HE) agar. Following incubation for 24 h, typical *Salmonella* colonies look brown, gray, or black with sometimes a metallic sheen and a brown or black halo on BS, pink with or without black centers on XLD, and blue-green to blue with or without black centers on HE. If present, two typical *Salmonella* colonies are picked from each plate for subsequent analysis. Occasionally there can be atypical colonies that should also be recognized and characterized. Some *Salmonella* strains can produce green colonies with little or no halo on BS agar or yellow colonies with or without black centers on HE and XLD agars. These colonies typically grow more slowly than normal and should also be collected for identification.

At this point, colonies from the plates are usually characterized for their reaction on triple sugar iron (TSI) slants and lysine iron agar (LIA). In TSI, *Salmonella* typically produces an alkaline (red) slant and acid (yellow) butt, with or without production of H_2S and blackening of agar. In LIA, *Salmonella* usually produces an alkaline (purple) reaction at the bottom of the tube. Only a clearly yellow butt of the tube should be considered acidic and, therefore, negative, as other shades or colors can still be indicative of *Salmonella*. The LIA reaction is the most important in this phase for the identification of *Salmonella*. As a result, all the isolates that are positive for the LIA test should be kept for subsequent analyses, regardless of the TSI results. The presumptive *Salmonella* isolates should be tested for urease activity (negative), dulcitol fermentation in red phenol tubes (positive with gas formation), inability to grow in KCN broth, negative malonate broth reaction (green or unchanged color), and negative indole test (no deep red/pink color at the top of the tube). These cultures should be also serologically tested for flagellar type. Any culture either positive in the indole test and negative in the serological flagellar (H) test, or positive in the KCN test and negative in the lysine decarboxylase test, is not *Salmonella* and is discarded. Table 9.1 provides a list of biochemical reactions distinctive for *Salmonella* species.

Table 9.1 Biochemical and serological reactions of *Salmonella* (reproduced from reference 20)

	Result		
Test or substrate	**Positive**	**Negative**	***Salmonella* reaction[a]**
Glucose (TSI)	Yellow butt	Red butt	+
Lysine decarboxylase (LIA)	Purple butt	Yellow butt	+
H_2S (TSI and LIA)	Blackening	No blackening	+
Urease	Purple-red color	No color change	–
Lysine decarboxylase broth	Purple color	Yellow color	+
Phenol red dulcitol broth	Yellow color and/or gas	No gas; no color change	+[b]
KCN broth	Growth	No growth	–
Malonate broth	Blue color	No color change	–[c]
Indole test	Red color at surface	Yellow color at surface	–
Polyvalent flagellar test	Agglutination	No agglutination	+
Polyvalent somatic test	Agglutination	No agglutination	+
Phenol red lactose broth	Yellow color and/or gas	No gas; no color change	–[c]
Phenol red sucrose broth	Yellow color and/or gas	No gas; no color change	–
Voges-Proskauer test	Pink-to-red color	No color change	–
Methyl red test	Diffuse red color	Diffuse yellow color	+
Simmons citrate	Growth; blue color	No growth; no color change	v

[a] +, 90% or more positive in 1 or 2 days; —, 90% or more negative in 1 or 2 days; v, variable.

[b] The majority of *Salmonella* Arizonae cultures are negative.

[c] The majority of *Salmonella* Arizonae cultures are positive.

Core Genome versus Pangenome

Biochemical and serological characterizations are useful and effective when determining the identity of isolates that have already been characterized. However, only after the development of genome-based phylogenetic reconstruction was it possible to clearly define the members of a genus. This shows that in bacteria, these identification techniques based on phenotypic characteristics lack taxonomic accuracy and, consequently, are not appropriate for identifying the relationship of a new, unknown strain to others. This inadequacy is mainly due to the genetic nature of the traits used by serological and biochemical tests. In fact, these phenotypic characters are linked to genes that have high levels of mutations (e.g., flagellar genes) or horizontal transfer between congeneric species (21).

DNA-based methods such as DNA-DNA hybridization, 16S rRNA gene sequencing, pulsed-field gel electrophoresis, multilocus sequence typing, and other molecular-marker-based techniques have been developed to make identification more reliable and better linked to the taxonomy of this genus (21, 22). Over the past 2 decades, the development of cost-effective high-throughput sequencing techniques and the exponential increase of computational power have produced an ongoing paradigm shift that challenges our definition of species. This is particularly true for prokaryotes, as these microorganisms have generally smaller genomes than eukaryotes and a high frequency of horizontal transfer that calls into question our concept of cohesive species (23). The comparison of the genomes of different strains of *E. coli* and other well-known bacteria has shown that certain chromosomal regions and the genes contained therein are highly conserved at different taxonomic levels, whereas other sections appear to be highly variable and sometimes uniquely linked to a single species or population (23). The genes that are common to all the species members of a genus are defined as part of the core genome of that genus (e.g., the *Escherichia* core genome accounts for about two-thirds of any species genome belonging to it). Similarly, the genes shared by all the subspecies or populations of a species constitute the core genome and define that species genetically (e.g., *S. enterica* has an estimated core genome comprising 3,200 gene families over an average genome size of 5,000 genes [23]). Conversely, the genes that are present in only some of the taxa of a certain group are considered "accessory genes." The sum of all the accessory genes across all the members of a taxonomic group and the core genome is the pangenome of that group. Usually the taxonomic ranks considered for the identification of core and pangenomes in bacteria span genus to serovar (24).

The addition of new complete genomes has shown that certain species have a "closed" pangenome. This means that the species is confined to a homogeneous group of strains with a relatively large core genome and a restricted number of accessory genes. Variation among these strains is usually limited to genetic mobile elements and single nucleotide polymorphisms (25). *S. enterica* and *S. bongori*, with large stretches of shared virulence factor-carrying genomic islands (*Salmonella* pathogenicity islands [SPI]), belong to this group of organisms, with an estimated core genome of about 2,800 genes and a pangenome of 10,000 genes (26). Other bacterial species have what are called "open" pangenomes; these groups have very variable genome sizes, generally small core genomes, and an ever-expanding number of unrelated accessories. Although closely related to *Salmonella* spp., *E. coli* is a good example of a species with an open pangenome. The difference between open and closed pangenomes does not depend on the number of sequenced genomes available, as the phenomenon is still significant even when the relative number of genomes analyzed per species is taken into account.

The fact that two closely related genera, such as *Salmonella* and *Escherichia*, represent a closed and an open pangenome indicates that horizontal gene transfer mechanisms are not directly responsible for this difference, as both genera rely on the same mechanisms. In all bacterial genomes, there is a certain level of redundancy and repeated sequences that inflate the genome size. However, the number of functional genes and pathways that are present correlates well with the diversity of growth conditions an organism can endure. Therefore, an intriguing possibility is that *Salmonella*'s success as an animal pathogen is based on a fine balance between trading sources of genomic variability and niche expansion for specialization and adaptation to specific hosts.

PHYSIOLOGY

Salmonella normally grows at temperatures between 5.5 and 45°C, depending on the specific serovar and the environmental conditions. It needs a pH ranging between 6.5 and 7.5 for optimal growth; however, it is able to grow at a much broader range of pH values (3.99 to 9.5) by using pH-dependent acid resistance (AR) mechanisms that are specific to the stationary phase or a low-pH acid tolerance response (ATR) that can be induced in stationary or exponential phase (27–30). This response is characterized by the specific expression of several proteins, mostly membrane related, regulating the growth rate of the cells and the pH balance within the cell. These changes have been shown to induce protective mechanisms against other stresses, such as low water activity (a_w) and heat stresses. Exposure to sublethal temperatures of less than 50°C for 15 to 30 minutes can provide increased tolerance to higher temperatures in *Salmonella*, completely independent of ATR (28, 29). Similarly to the ATR, heat pretreatment also induces the expression of heat shock proteins that can increase the heat resistance of the cells. This stress response system involves several general stress transcriptional regulators and might have a crossover protection effect against other environmental conditions as well.

Desiccation Resistance

One of the most important challenges that *Salmonella* encounters in environmental habitats, such as soil and lowmoisture foods, is water loss through evaporative drying or through the matric potential generated by the adhesion of water to small particles present in soil. These processes decrease the water available to participate in chemical reactions and, ultimately, lower the water activity in the environmental system. *Salmonella* achieves protection against low a_w by slowing the evaporation of water and preventing complete desiccation by specific mechanisms that protect membranes and proteins from the denaturation caused by the loss of water. Although the genetic and physiological responses to desiccation stress in *Salmonella* have not been thoroughly studied, there are strong indications that they overlap with other stress response networks triggered by similar chemophysical signals (e.g., osmotic, thermal, and oxidative stress) (31).

On the surface of the bacterial cell, there is usually a layer of exopolysaccharides and associated proteins, forming an extracellular matrix, referred to as the glycocalyx. This surface structure is known to have a variety of protective functions, including preventing complete desiccation by holding water and limiting the amount lost through evaporation. Also, extracellular cellulose associated with curli amyloid fiber has been shown to play a major role in desiccation resistance and survival in *Salmonella* Typhimurium (32). This extracellular cellulose has been shown to be modified by a phosphoethanolamine. The presence of this modification makes the polymer a zwitterion, or inner salt, which is an overall neutral molecule bearing positive and negative ionic groups. Ionic charges increase water retention of this modified cellulose. The enzymes responsible for the formation of this modified cellulose are encoded by the *bcsEFG* operon. Mutants with mutations in any of these genes are unable to form a fully structured biofilm and lose their community behaviors (33).

Loss of water is harmful to bacteria because it causes denaturation of proteins by allowing the exposure of hydrophilic amino acids and disrupting the bilayer structure of the membranes. Disaccharides like trehalose and betaine not only act as solutes, thus counterbalancing the osmotic pressure, but also maintain the structure and function of proteins and membrane lipids under conditions of extreme desiccation by replacing water and acting like glass in a process called vitrification (34). This process lowers the diffusion rates within the cell, thus preventing the diffusion of harmful reactive oxygen species generated by the stress (35). Trehalose has also been shown to protect *Salmonella* against other forms of stress associated with desiccation (e.g., thermal stress and oxidative stress). Trehalose biosynthesis involves the enzymes trehalose-6-phosphate phosphatase and trehalose-6-phosphate synthase, encoded by the genes *otsB* and *otsA*, respectively. The *otsBA* operon is controlled by the general stress response sigma factor σ^S, which also controls a wide range of physiological functions necessary for resistance to osmotic stress, temperature stress, and oxidative stress (31, 34).

Osmotic stress can be seen as a consequence of dehydration, where the water loss begets an increase in solutes concentration. Bacterial cells must maintain the appropriate turgor pressure during osmotic

upshifts or downshifts, and they achieve this goal through increases or decreases in the concentration of solutes in the cytosol and/or periplasm. First, immediate countermeasures are deployed to quickly balance the osmotic pressure, and then they are replaced by long-term readjustment if the osmotic conditions are sustained in the surrounding environment. Within only a few minutes, a loss of turgor pressure or increases in intracellular ionic strength induce the transcription of the *kdpABC* operon, encoding a high-affinity K^+transport system. Potassium transport is followed by an increase in glutamate, as a counterion. This first temporary mechanism is followed and replaced by an accumulation of organic compounds known as compatible solutes (e.g., proline, glycine betaine, ectoine, or trehalose) that can be obtained from the extracellular environment or synthesized *de novo* (34).

It has been observed that desiccation and high osmolality elevate the upper limit of growth temperature of bacteria and increase their survival at otherwise lethal temperatures and that mutations in *otsAB* increase the sensitivity of *Salmonella* to higher temperatures (21). Recently, a group of virulence genes was found to be involved in desiccation tolerance by using RNA sequencing, and mutants in *sopD*, a virulence effector, and *sseD*, a component of the injectisome, were unable to form a proper biofilm, thus highlighting the importance of this extracellular structure (36).

Thermal Resistance

Although treatment with heat has deep historical roots—for instance, ancient Romans used to preserve quince fruits by soaking them in honey and cooking them to a hard paste—the systematic use of thermal treatments in food processing is relatively recent. The use of heat to preserve food was first published in 1810 by Nicolas Appert. Appert was a French confectioner and distiller who started experimenting with ways to preserve foods using reinforced jars sealed with waxed corks in 1795. This specific way to thermally treat foods preceded pasteurization, the process invented by Louis Pasteur, by several decades. It became a strategic asset for the Napoleonic army, as it allowed the transport of food over longer routes and times. For this reason, Nicolas Appert could not make his invention public until 1810 (37). Thermal treatment is one of the main technologies that is currently used to inactivate spoilage and pathogenic bacteria in food and favored by international regulatory agencies. There is a clear distinction between treatment based on the intensity of the heat used and its goal (e.g., sterilization or reduction of the load of spoilage organisms). Food sterilization differs from medical sterilization, as it does not imply the complete removal of microorganisms present in the food. For instance, thermophilic bacteria are usually not removed because they do not have any impact on public health. This process generally employs temperatures higher than 100°C and direct or indirect exposure to the heat source, and it is usually performed in the final container. The heat can either be dry or wet, and the product can be held at high temperatures for a short time or at low temperatures for a long time. Sterilization usually allows a prolonged shelf life (3 months to a year). Treatment at mild temperatures for prolonged times is typical for pasteurization and provides a stable food product that will last for a few weeks under refrigeration. Thermal processing of foods is a field unto itself and beyond the scope of this chapter (38). For this reason, we focus on *Salmonella*'s response to thermal stress.

In *Salmonella*, thermal stress elicits a cytoplasmic heat shock response under the control of the heat shock sigma factor σ^H and an extracytoplasmic response regulated by the sigma factor σ^E. The σ^H regulon includes more than 30 heat shock proteins, which function as molecular chaperones and proteases to decrease the heat-induced denaturation of proteins. The intracellular concentration of σ^H is regulated at the translational level. Elevated temperatures (42°C) denature the secondary structure of *rpoH* mRNA, allowing ribosomal binding and translation. Increased levels of σ^H inhibit the cytoplasmic heat shock response in a negative feedback loop that leads to the overexpression of heat shock proteins. Expression of *rpoH* is also under the control of σ^E, allowing a coordinated response to thermal and, possibly, envelope stress (39, 40).

The alternative sigma factor σ^E (encoded by *rpoE*) controls multiple cell envelope, or extracytoplasmic, functions that mitigate the effects (e.g., accumulation of misfolded proteins) of high temperatures on

the extracytoplasmic compartment as well as other factors causing envelope stress. Members of the σ^E regulon include periplasmic chaperones (e.g., SkpA, SurA, and DegP), peptidyl-prolyl isomerases (e.g., SurA and FkpA), (serine) proteases (e.g., DegP), and other factors involved in outer membrane biosynthesis and function (41).

Continuous osmotic and/or heat stresses induce several genes belonging to the oxidative stress response network. These genes include *sodC* (superoxide dismutase), *katE* (catalase), *osmC* (peroxidase), *puu* genes (putrescine catabolism), and *cusCFBA* (copper efflux system). At least nine genes, mainly iron related, are induced by the two stresses combined: *acnA* (aconitase A), *bfr* (bacterioferritin), *ibpA* (heat shock chaperone), and *degP* (heat shock serine protease) genes. Also, proteomic studies confirmed that the Dps, KatE, AcnA, and OsmC proteins are induced during the initial phase of osmotic adaptation. A number of genes, including the *suf-ABCDSE* operon (which encodes components of a secondary pathway of iron-sulfur cluster assembly), are induced when both stresses are applied but not by one stress only (42).

Acid Resistance

Salmonella is an enteric bacterium and, like many bacteria that transit through the human gastrointestinal tract, is a neutralophile with optimal growth within a pH range of 7.00 to 7.50. However, depending on the characteristics of other environmental factors (e.g., temperature, salinity, and presence of organic or inorganic acids), the pH range allowing the growth of this pathogen can be much broader, from 3.99 to 9.5. This wide range reflects the variety of environmental pH conditions this pathogen encounters. For example, in the gastrointestinal tract, proton concentrations can range from mildly acidic in the saliva (pH 6.3 to 7.3) to extremely acidic in the stomach (pH 1.5 to 3.5). The difference in proton concentration between those two body sites ranges between a thousand-and a million-fold (27–29).

In food, the ability to avoid the damage caused to proteins and DNA by low pH is also extremely important. The consumption of fermented foods is an ancient, common, and widespread practice among humans. Acidic fermentation of food products (e.g., milk, meat, fish, grains, fruits, and vegetables) containing different end products, such as lactic acid, propionic acid, carbon dioxide, and ethanol, improves organoleptic characteristics, digestibility, and bioavailability of several nutrients. Furthermore, it has been particularly important for food preservation from spoilage and contamination because it limits the growth of the local microbial communities or possible pathogenic contaminants.

Similar to *E. coli*, *Salmonella* can deploy for its protection from low pH AR and ATR mechanisms (28). However, differently from *E. coli*, the AR mechanisms do not include a glutamate-dependent response (AR2) but rely instead on arginine, ornithine, and lysine decarboxylase systems. Comparative studies of these decarboxylase systems have shown that the arginine decarboxylase is mainly involved in the response to extreme pH, but its activity is negligible under moderately acidic conditions. The ornithine decarboxylase system is not important for survival and is active under anaerobic and mildly acidic conditions, whereas lysine decarboxylase has a broad impact on survival, being essential at pH of 2.3 and supporting growth at 4.5. Lysine and ornithine decarboxylase systems are also involved in controlling the intracellular pH (43, 44).

The ATR is a network of mechanisms that are induced by growth in mildly acidic conditions (habituation) or by exposure to moderately low pH (adaptation). Physiological conditions have a large impact on the ways these mechanisms are activated and mainly can be divided into log-phase and stationary-phase ATRs. Regardless of the physiological phase of the bacterium, several types of acid shock proteins are induced to prevent or repair the macromolecular damage caused by acid stress. Most of these proteins are involved in cellular regulation, molecular chaperoning, energy metabolism, transcription, translation, synthesis of fimbriae, regulation of the cellular envelopes, colonization, and virulence (45, 46).

During the logarithmic phase, ATR is mainly regulated by σ^S, Fur, and the two-component system PhoPPhoQ. The σ^S sigma factor is encoded by *rpoS*, regulates several oxidative stress genes, and controls the expression of at least 10 different acid shock proteins in the log-phase ATR; most of these

are of unknown function except SodCII, which is a periplasmic Cu^{2+}/Zn^{2+}-superoxide dismutase (1, 47). Fur is a negative regulator that mainly controls iron homeostasis, and therefore, its role during oxidative stress has been well characterized and is dedicated to preventing the production of hydroxy radicals through the Fenton reaction. Recently, a clear link between different Fur-regulated antioxidant enzymes, such as Mn superoxide dismutases and catalases, and resistance to the deleterious effects of organic acids was shown (48). Indeed, Fur has also been shown to directly regulate a subset of acid shock proteins in an iron-independent manner, contributing to ATR under organic acid stress (44). Acid stress caused by weak organic acids is particularly damaging for the cell, as their undissociated form can easily diffuse through the membrane, through either passive or active transport, and dissociate within the cell, thus lowering the intracellular pH. This characteristic is extremely important in the food industry, as it is one of the reasons that organic acids such as lactate and acetate are widely used in preventing spoilage of several food products.

PhoPQ is a two-component system where PhoP is the response regulator and PhoQ is the sensor kinase. At low extracellular Mg^{2+} concentrations, PhoQ can be activated by autophosphorylation and transphosphorylation of PhoP, which regulates genes for Mg^{2+} transport and virulence. At high Mg^{2+} concentrations, PhoPQ can be induced by moderately acidic pHs, possibly sensing the acidic pH by conformational changes induced by H^{+}at the Mg^{2+} ion-binding site. PhoQP activation is essential for *Salmonella* Typhimurium resistance to inorganic acid stress and survival within macrophages (44, 47).

PATHOGENICITY AND VIRULENCE FACTORS

Immune Response to *Salmonella* Infection

Upon ingestion, *Salmonella* can survive the low pH of the stomach and travel to the distal ileum of the small intestine. Once in the small intestine, the bacteria must penetrate the mucus layer to make contact with the intestinal epithelium. This mucus layer, composed of mucin glycoproteins, is secreted by epithelial goblet cells and, in addition to being a barrier to the epithelium, also contains antimicrobial peptides secreted by epithelial and Paneth cells (49). Figure 9.1 presents a schematic representation of *Salmonella* Typhi infection in humans.

Increased production of some antimicrobial peptides and mucin by goblet cells is induced by the host inflammatory response to the detection of pathogen-associated molecular patterns (PAMPs) by pattern recognition receptors. Typical microbial PAMPs expressed by *Salmonella* include lipopolysaccharide, type III secretion systems (TTSS), fimbriae, and flagellin. However, *Salmonella* is capable of combating antimicrobials such as lipocalin-2, which sequesters bacterial siderophores, thus starving microbial invaders of needed iron (50). To evade iron starvation, *Salmonella* expresses *iroBCDE* and *iroN*, which encodes an enzyme to alter its siderophore enterobactin so that it can no longer be sequestered by lipocalin-2 (51). In addition to the *iro* locus, *Salmonella* also contains the two-component regulator PhoPQ, which can sense cationic antimicrobial peptides and upregulate mechanisms to modify lipid A by either acylation or attaching an amino-arabinose moiety to confer resistance to these antimicrobials (52–54).

Once *Salmonella* makes contact with the epithelium, the bacteria invade intestinal epithelial enterocytes and M cells. *Salmonella* can then colonize the lymphatic tissue of the intestines called Peyer's patches through the invasion of epithelial M cells. Once in the Peyer's patches, *Salmonella* can travel to the mesenteric lymph nodes, where many phagocytic cells reside (55–57). Gastroenteritis is caused by a localized *Salmonella* infection of the intestinal mucosa and mesenteric lymph nodes and is associated with an intestinal inflammatory response and an increase in intestinal fluid secretion (58).

The detection of PAMPs by pattern recognition receptors also induces the expression of proinflammatory cytokines and chemokines that activate and recruit neutrophils and macrophages to the infected tissue as a part of the innate immune response. Host complement proteins and antibodies are opsonins that can coat the bacterium to promote phagocytosis of the bacterium by phagocytes such as neutrophils, macrophages, and dendritic cells (59). Once the bacterium is engulfed, it resides inside

a phagosome that is designed to destroy the microbial invader. However, *Salmonella* is an intracellular pathogen that can survive after being phagocytized within modified phagosomes known as *Salmonella*-containing vacuoles (SCV) by altering its environment to more favorable conditions and inducing a dormant state. *Salmonella* can survive intracellularly within host macrophages by increasing the expression of important virulence genes in response to the acidification of the intracellular environment within the membrane-bound compartment of the phagosome (60). For further reading, Broz et al. provide a detailed review of the innate immunity against *Salmonella* infection (61).

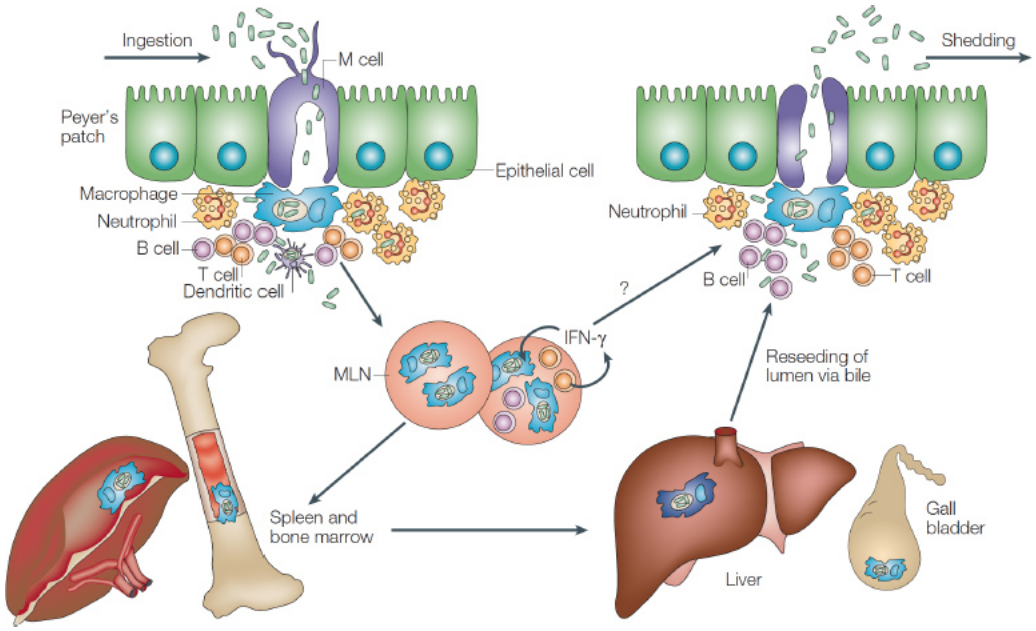

Figure 9.1 Schematic representation of persistent infection with *Salmonella* Typhi in humans. Bacteria invade the M cells of the Peyer's patches of the intestinal tract mucosal surface. This induces the inflammatory response, including recruitment of neutrophils and macrophages, phagocytosis of bacteria, and deployment of T and B cells. In systemic *Salmonella* infections, such as typhoid fever, the pathogen targets host cells, such as dendritic cells and/or macrophages, which allow systemic spread through the lymphatic and blood circulatory systems to the lymph nodes present in the mesenteries. This then leads to transport to the spleen, bone marrow, liver, and gallbladder. Bacteria can colonize all these tissues and organs and periodically can restart shedding from the mucosal surface. $IFN_{-\gamma}$, which can be secreted by T cells, has a role in maintaining persistence by controlling intracellular *Salmonella* replication. Interleukin 12, which can increase $IFN_{-\gamma}$ production, and the proinflammatory cytokine tumor necrosis factor alpha also contribute to the control of persistent *Salmonella* (not shown).

Production of the cytokine gamma interferon ($IFN_{-\gamma}$) by macrophages, neutrophils, and lymphoid cells is also an early form of cell-mediated innate immune defense against *Salmonella* infection (62). $IFN_{-\gamma}$ is detected by most host immune cells with specific $IFN_{-\gamma}$ receptors and causes an increase in the major histocompatibility complex (MHC) class I and class II molecules. MHC class I molecules present antigens from intracellular microbes on the surfaces of antigen-presenting cells to $CD8^+$ cytotoxic T cells. $CD8^+$ cytotoxic T cells can then produce cytokines to this $IFN_{-\gamma}$ and tumor necrosis factor alpha. In addition to cytokines, $CD8^+$ cytotoxic T cells produce cytotoxic granules and cause the activation of the caspase cascade, both of which lead to apoptosis of the infected cell (63). However, it has long been known that *Salmonella* is adept at preventing the fusion of the lysosome to the phagosome (64), which leads to the destruction of the bacterium and the release of the microbial antigens needed for MHC class I presentation. In addition to induction of MHC molecule expression, $IFN_{-\gamma}$ also upregulates the expression of inducible nitric oxide synthase and promotes antigen presentation by macrophages (63).

B cells can recognize extracellular antigens with their B-cell receptors, take up the antigen through endocytosis, and degrade it. Once degraded, the antigen is presented on the surface of the B cell on MHC class II molecules to $CD4^+$ helper T cells, which can then activate the B cell and initiate an adaptive immune response. Through this mechanism, Th1 helper T cells and B cells have been shown to play an important role in clearing *Salmonella* infection (65). Th1 helper T cells also produce $IFN_{-\gamma}$, which will stimulate undifferentiated $CD4^+$ T cells to differentiate into Th1 helper T cells, creating a more robust immune response.

If the infection is not contained within the lymphatic tissues in the intestines, *Salmonella* can then disseminate throughout the body by using the lymph system and reach the blood (causing bacteremia) and systemic tissues. These types of systemic infections are common in immunocompromised individuals with nontyphoid serovars of *Salmonella* and in otherwise healthy individuals with *Salmonella* Typhi and *Salmonella* Paratyphi A to C. The well-known disease typhoid fever is a systemic infection caused by *Salmonella* Typhi or *Salmonella* Paratyphi A to C. During systemic infection, the salmonellae spread to the spleen, liver, and bone marrow, where the pathogen can be engulfed by resident phagocytes. As *Salmonella* Typhi and *Salmonella* Paratyphi A to C have host specificity only for humans and other higher primates, *nramp1*-deficient mice infected with the related pathogen *Salmonella* Typhimurium are used as models of infection for typhoid fever. Nramp1 (natural resistance-associated macrophage protein 1) is a cation transporter in late phagolysosomes of macrophages, neutrophils, and dendritic cells. During *Salmonella* infection, Nramp1 reduces intracellular iron levels to limit the availability of free iron to internal pathogens (66). Other animal models of *Salmonella* infection are reviewed by Santos et al. (67).

SPI and TTSS

As described above, the abilities to invade the intestinal epithelium and to survive intracellularly within phagocytes are major factors for the pathogenicity of *Salmonella*, and these abilities are mediated by TTSS encoded on SPI. Pathogenicity islands are mobile clusters of genes encoding a collection of virulence factors that are typically located near tRNA regions and are present in pathogenic bacteria but absent in their nonpathogenic relatives (68–70). It is hypothesized that pathogenicity islands were acquired through horizontal gene transfer, because the G+C contents of the pathogenicity islands diverge from that of the surrounding DNA (71). Figure 9.2 shows the organization of SPI-1 through SPI-5.

Currently, 21 SPI have been discovered and include genes for important virulence factors, such as TTSS and effector proteins that aid in invasion and persistence of *Salmonella* in its host (72, 73). TTSS are needle-like bacterial membrane structures that create a translocon pore in host cells to inject effector molecules into host cells. SPI-1 and SPI-2 encode TTSS-1 and TTSS-2, respectively, and are found in all serovars of *S. enterica* (74). TTSS-1 is required for the invasion of nonphagocytic intestinal epithelial cells and causes intestinal inflammation. The SPI-1-encoded transcription factor HilA regulates the needle-like component of TTSS-1 as well as the SPI-1-encoded transcription factor InvF, which in turn regulates SPI-1-encoded effectors. The TTSS-1 translocases SipB, SipC, and SipD are effectors that aid in the attachment of bacterial TTSS-1 to the host cell. Once the bacteriumhost cell connection is established, effectors can then be injected into the host cell. Secretion of the effectors SipA, SipC, SopB, SopE, and SopE2 into the host cell by *Salmonella* induces membrane ruffles by host actin rearrangement and results in the internalization of the bacterium (75, 76). Once inside nonphagocytic cells, the TTSS-1 effector SptP returns the host cell's actin structure to its original state. In addition to the SPI-1-encoded effectors, several TTSS-1 effectors are encoded on other SPI, such as SopE, encoded on SPI-7, and SopB, encoded on SPI-5 (75, 77).

Besides aiding in *Salmonella*'s internalization by intestinal epithelial cells, several TTSS-1 effectors also induce an inflammatory response. SopE, SopB, and SopE2 induce the expression of proinflammatory cytokines, SipA and SopA induce the expression of chemokines to recruit phagocytic cells to the site of infection, and SipB activates the caspase cascade. Once inside the SCV, the bacterium secretes additional effectors, such as SspH1, AvrA, SpvC, and SseL, to inhibit NF-κB-regulated apoptosis of the

infected cell. Other effectors such as SopB, SopD, and SipC help form the SCV and prevent its fusion with lysosomes. Once the SCV is formed, effector SptP interacts with the SCV and induces bacterial proliferation (73, 76, 78).

SPI-2-encoded TTSS-2 is important in the invasion of phagocytic cells, such as macrophages and dendritic cells, and the subsequent intracellular survival of the bacterium. Experiments with green fluorescent protein and luciferase promoter fusions have shown several genes in SPI-2 that are upregulated in not only the intracellular environment of macrophages but also epithelial cells (79, 80). The SPI-2-encoded two-component system SsrA-SsrB responds to signals within the intracellular environment, such as the acidification of the SCV, and upregulates the TTSS-2 genes and the associated SPI-2-encoded effectors. Expression of the SPI-2-encoded translocases SseB, SseC, and SseD aids in the formation of the TTSS-2 translocon, which is needed to secrete effector proteins out of the SCV into the host cell's cytosol. The TTSS-2 secretes the effectors SseF, SseG, SifA, and SpiC, which aid in the repositioning of the SCV to the perinuclear region adjacent to the Golgi apparatus and the maintenance of that position. At this location, the effectors SifA, SseJ, and SopD2 assist in the formation of tubular structures known as *Salmonella*-induced filaments that fuse the SCV with Golgi-derived vesicles for the acquisition of nutrients. There are many more TTSS effectors that are important for the virulence and survival of *Salmonella*, and these effectors are reviewed by van der Heijden and Finlay (81).

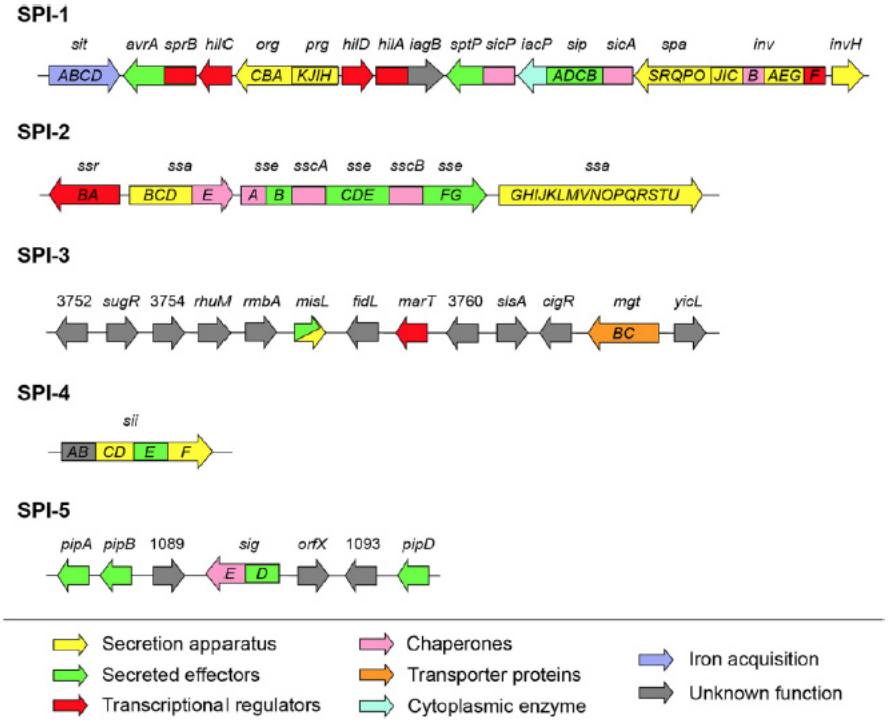

Figure 9.2 Schematic representation of the genes carried within the five SPIs and their putative virulence-related functions.

Although SPI-1 and SPI-2 are the most conserved and most extensively characterized SPI, other SPI play a role in the virulence of *Salmonella*. The *mgtC* gene encodes an inner membrane protein, MgtC, that is highly induced when *Salmonella* is inside a macrophage and is a required virulence factor for intracellular survival and growth in low-Mg^{2+} environments. The *mgtC* gene is within the *mgtCBR* operon on SPI-3 that also encodes an Mg^{2+} transporter (MgtB) and a peptide that promotes the degradation of MgtC (MgtR). It has been shown that inactivation of *mgtC* attenuates the virulence of *Salmonella* in a murine model (82), while the prevention of the degradation of the *mgtC* transcript causes hypervirulence in *Salmonella* (83). This indicates that the levels of MgtC must be carefully controlled during *Salmonella* infection.

SPI-7 is a large excisable pathogenicity island that is found in *Salmonella* Typhi and *Salmonella* Paratyphi C and some *Salmonella* Dublin strains. SPI-7 contains genes encoding type IVb pili, which have a role in macrophage infection, the TTSS-1-secreted effector protein SopE, and the Vi capsular antigen. The Vi capsule is a polysaccharide that inhibits the complement system and opsonization of the bacterium and is important for systemic infection by *Salmonella* Typhi (84–86).

In addition to encoding effectors that are secreted by TTSS-1 and TTSS-2, other pathogenicity islands contain genes for other important virulence factors, such as the SPI-4-encoded type I secretion system. This secretion system secretes SiiE, which aids the bacterium in adhering to epithelial cells (87). Besides the SPI-2 genes, SPI-11 carries *pagD* and *pagC*, whose products have a role in the survival of *Salmonella* within macrophages (88). As already mentioned, the SopB TTSS-1 and TTSS-2 effector is encoded on SPI-5, but also on this pathogenicity island is the SopB chaperone SigE (89). SPI-6 encodes the first discovered type VI secretion system in *Salmonella* (72) along with the fimbrial gene operons *saf* and *tcf* and the *pagN*-encoded invasin (90, 91). SPI-16 has been associated with murine intestinal persistence, though the genes within this island have yet to be characterized (92). Region of difference 21 (ROD21) is also an excisable pathogenicity island that is present in *Salmonella* Enteritidis, *Salmonella* Gallinarum, *Salmonella* Dublin, and *Salmonella* Typhi. This pathogenicity island contains genes encoding the TlpA protein, which is known to interfere with Toll-like receptor signaling, a potential type IV pilin, and genes involved in conjugation (93, 94).

Virulence Plasmids

Besides the TTSS and other virulence factors encoded on pathogenicity islands, some serovars of *S. enterica* contain a large (50-to 285-kb) virulence plasmid that has been shown to be important for bacterial multiplication in the reticuloendothelial system. Many clinically relevant *S. enterica* serovars contain a virulence plasmid, such as *Salmonella* Enteritidis, *Salmonella* Typhimurium, *Salmonella* Choleraesuis, and *Salmonella* Dublin. However, some notable serovars, such as *Salmonella* Typhi and *Salmonella* Paratyphi A and B, lack virulence plasmids altogether (95). Some larger (~140-kb) virulence plasmids also include antibiotic resistance genes. For plasmid-containing serovars, the curing of the plasmid reduces overall virulence, as was shown in strains of *Salmonella* Typhimurium (96). However, the virulence of serovars that do not natively include a virulence plasmid does not seem to benefit from their being transformed with a known *Salmonella* virulence plasmid (97, 98).

On the *Salmonella* virulence plasmid, the highly conserved *Salmonella* plasmid virulence (*spv*) region carries five virulence genes split into two operons, *spvR* and *spvABCD*. SpvR is a positive regulator of these genes, including its own gene, and is homologous to the LysR regulator family. SpvB, SpvC, and SpvD are effector proteins exported by the SPI-1-and SPI-2-encoded TTSS, and SpvA is an outer membrane protein with an undefined function. During intracellular infection, SpvB modulates the formation of the *Salmonella*-induced filament tubular structures on the surface of the SCV by inhibiting actin polymerization by ADP-ribosylation. SpvC is a phosphothreonine lyase that removes phosphate groups from mitogen-activated protein kinases to inhibit proinflammatory signaling. Likewise, SpvD also inhibits proinflammatory signals by inhibiting the upregulation of promoters by NF-κB (99). Though all the *spv* genes are regulated by SpvR, their expression levels are upregulated at different times of infection. The genes *spvR* and *spvA* are upregulated in the early stages of intracellular infection (100), while expression of the effector genes *spvB* and *spvC* is higher during the later stages of intracellular infection (101). On the other hand, the gene *spvD* was shown to be expressed constitutively during intracellular infection (101).

In addition to the *spv* genes, these virulence plasmids also contain the fimbrial *pef* and *fae* operons and *tra* conjugation genes. *Salmonella* fimbriae have been shown to induce the proinflammatory response, aid in cell adhesion to epithelial cells, and play a role in biofilm formation. Some *Salmonella* virulence plasmids contain an intact *tra* operon, such as pSTMV of *Salmonella* Typhimurium, which allows the plasmid to be horizontally transferred through conjugation. However, as a result of sequencing of several virulence plasmids from different serovars combined with the variation in plasmid size among different serovars, it has been concluded that most *Salmonella* virulence plasmids have been inherited through vertical transfer from parent to daughter cell rather than through horizontal means, such as

conjugation (95). This appears to be true partly because of the degradation of the *tra* operon within these nontransmissible plasmids. The large size variation between virulence plasmids appears to be due to the inclusion, or lack thereof, of these fimbriae and conjugation operons.

Toxins

In addition to the lipopolysaccharide lipid A endotoxin, which is common to Gram-negative pathogens, *Salmonella* species can produce several exotoxins during the course of an infection. There is only a limited understanding of *Salmonella*'s exotoxins, which are known to include several different cytotoxins and an enterotoxin.

Salmonella cytotoxins were first identified by their ability to lyse a specific line of mammalian cells (Vero cells derived from African green monkey kidney) and first thought to belong to the same group as the Shiga toxins. However, although they share some traits (e.g., they are heat labile and trypsin sensitive), they were not neutralized by antibodies against the *Shigella* Shiga toxin or *E. coli* Shiga-like toxins I and II (102). A *Shigella dysenteriae* 1-like toxin has been reported in *Salmonella* Enteritidis, *Salmonella* Kapemba, and *Salmonella* Thompson and was shown to be neutralized by antibodies against *S. dysenteriae* 1 toxin (103). It is now clear that several *Salmonella* serovars can produce toxins belonging to the same class of toxins as Shiga toxins. All the members of this class possess a catalytic A subunit linked to a pentameric B subunit (AB_5) and are classified into four groups according to the homology of the A subunit sequence, their catalytic activity, and the structural organization of the holotoxin. The B subunit pentamer attaches to specific glycan receptors on the host cell surface, allowing the internalization of the holotoxin. The most recently identified AB_5 toxin family is the subtilase cytotoxin B subunit-like proteins (104). The homologs for the B subunit of this toxin are present in different serovars of *S. enterica*, and the putative AB5 toxin has been named ArtAB (ADP-ribosylating toxin) (105). Although no cytotoxic phenotype has been detected for ArtAB, its homolog from *Salmonella* Typhi (also referred to as PltAB) has been reported to associate with a cytolethal distending toxin (CDT) (CdtB) and deliver it to target cells from an intracellular host compartment by autocrine and paracrine pathways (106).

The *Salmonella* CDTs are cytotoxins that cause DNA damage that results in cell cycle arrest, cellular elongation, and apoptosis in affected host cells (107). Typical CDTs need three subunits to be completely functional. The A subunit, CdtB, is the actual source of the toxic effects, while the B subunit, composed of CdtC and CdtA, aids the A subunit with gaining entry into the target cell. Interestingly, the typhoid toxin produced by *Salmonella* Typhi is a CDT that contains only CdtB with no associated subunit for toxin transport. In *Salmonella* Typhi, the expression of CdtB is induced after the bacterium in engulfed and internalized into the target phagocytic cell (108, 109).

Low-passage-number clinical *Salmonella* isolates have been reported to have hemolytic activity for the salmolysin encoded by *slyA*. The *slyA* gene was found to be homologous to genes in *Shigella* and enteroinvasive *E. coli*. The *slyA* gene encodes a positive regulator of *clyA*, which itself encodes a pore-forming cytotoxin that is present only in *Salmonella* Typhi and *Salmonella* Paratyphi A (110).

The *Salmonella* gene *stn* is thought to encode an enterotoxin that is found encoded in the genomes of all known *S. enterica* serovars and appears to be unique to *Salmonella*. However, the questions of whether this gene product is an enterotoxin and what its exact role in pathogenesis is are controversial. In a few studies, Stn was shown to induce fluid secretion in rabbit (111) and murine (112) ileal loop models, supporting the claim that Stn is an enterotoxin that causes diarrhea in the host. However, in another study, it was shown that a *stn* mutant was not deficient in its ability to invade or survive intracellularly in macrophages and retained its ability to induce fluid secretion in a murine ileal loop model (113). The same group did show that Stn can interact with the outer membrane protein A (OmpA) directly in order to aid in the localization of OmpA and stabilize membrane integrity (113). Overall, the specific role of Stn in *Salmonella* pathogenesis is unclear.

Other Factors that Contribute to Virulence

Examples of other important virulence factors of *Salmonella* are the abilities of this bacterium to form biofilms, convert to a persister state, and scavenge free iron from the environment. The formation of a biofilm is an important phase of growth for pathogenic bacteria and, through several different mechanisms, aids in the organism's resistance to antibiotics. Biofilm formation in *Salmonella* has been shown to improve the pathogen's survival in nutrient-limiting, acidic, and low-and high-temperature environments. Proteinaceous curli fimbriae and exopolysaccharide cellulose are the major components of *Salmonella*'s extracellular matrix and are important for the pathogen's ability to form biofilms (114). Carriers of *Salmonella* Typhi often have an infection of the gallbladder containing gallstones. It has been shown *in vitro* that *Salmonella* Typhi and *Salmonella* Typhimurium can form biofilms on human gallstones and that biofilm formation is bile dependent (115), showing how biofilm formation can possibly play a role in the persistence of the carrier state.

Persister cells are cells that can survive many different antibiotic treatments by virtue of the fact that these cells are not actively growing. Persisters play an important role in a biofilm's resistance to antibiotic treatment and can cause relapsing infections. It has been shown that *S. enterica* cells produce a subpopulation of persister cells outside biofilm formation when they are engulfed by macrophages. This persister state is regulated by a class II toxin-antitoxin mechanism (116) where a stable nonsecreted toxin arrests growth and, under certain conditions, an unstable antitoxin is produced to resume growth.

The procurement of iron is an important part of the survival and virulence of *Salmonella* within its host. In response to infection, the host sequesters free iron to starve microbial invaders by proteins such as Nramp1 (see above). However, *Salmonella* produces iron chelators called siderophores to scavenge iron and transport it to the bacterium. The importance of the *S. enterica* siderophores enterobactin and salmochelin has been shown in *Salmonella* Typhi. Leclerc et al. showed that enterobactin and salmochelin are upregulated in *Salmonella* Typhi within host macrophages and are important for virulence (117). This group also showed the importance of the Fur regulator of these iron siderophores and the regulation of siderophores during infection is discussed in the next section. In addition to the virulence factors discussed here, *Salmonella* also has other important virulence factors that include production of flagella within macrophages for the purpose of escape (118), the use of superoxide dismutase to combat host-produced reactive oxygen species (119, 120), and the uptake of other important metal ions, such as K^+ and Zn^{2+}, which have been shown to be important for intracellular survival (121, 122).

Virulence Gene Regulation

Salmonella has several important regulatory mechanisms to control the expression of its virulence factors. As mentioned above, PhoPQ is a two-component regulator that senses extracellular cationic antimicrobial peptides produced by the host immune system. However, PhoPQ can also sense low concentrations of divalent cations and low pH, which are both indicative of the SCV intracellular environment. In response to its regulatory signals, the sensor kinase PhoQ phosphorylates the DNA-binding response regulator PhoP. PhoP represses the expression of SPI-1 genes, including the SPI-1 regulator gene *hilA*, and upregulates genes involved in intracellular survival, such as the *mgtCBR* operon on SPI-3, SPI-2 genes, and the *spv* operon on the virulence plasmid (123, 124). PhoPQ upregulates the expression of the SPI-2 genes through the upregulation of the SPI-2-encoded two-component positive regulator SsrAB (123).

Expression of *srrAB* has also been shown to be regulated by another global two-component system, OmpREnvZ. EnvZ is the sensor kinase that detects the low osmolarity and pH of the SCV, and OmpR functions as its response regulator. Both OmpR-EnvZ and PhoPQ are required for optimal expression of *ssrAB* once the bacterium has reached the intracellular environment of the host cell (125, 126). OmpR-EnvZ is also known to upregulate *Salmonella* biofilm development through binding to the promoter region of the biofilm regulator *csgD* (127).

As mentioned in the previous section, biofilm formation is an important component of *Salmonella* virulence. The ability to produce biofilms is regulated by CsgD (curli subunit gene D), a transcriptional

regulator that upregulates both curli fimbria expression and cellulose biosynthesis. CsgD upregulates *adrA* transcription, which expresses AdrA, a diguanylate cyclase that generates the signaling molecule cyclic di-GMP. Cyclic di-GMP then activates cellulose biosynthesis. CsgD is also a positive regulator of *bapA* (biofilm-associated protein A) and of its own operon, *csgDEFG*, which includes genes for curli fimbria production (128).

In addition to its regulation by PhoPQ, the intracellular survival virulence factor gene *mgtC*, carried on SPI-3, is also upregulated by the presence of high levels of cytosolic ATP. This ATP is sensed by the leader region of the *mgtC* mRNA, and mutation of this leader region leads to reduced expression of *mgtC* and attenuates virulence in a mouse model (129).

Iron uptake homeostasis is also an important regulatory signal in *Salmonella*. This signal is sensed by the transcriptional repressor ferric uptake regulator (Fur). Fur binds DNA and represses the associated gene when Fe^{2+} is bound. In an iron-limiting environment, there is not enough free Fe^{2+} to bind Fur; Fur releases the DNA, and the associated gene is activated. In response to sensing low Fe^{2+} concentrations, Fur derepresses the production of siderophores such as enterobactin and salmochelin that bind free Fe^{2+} and genes involved in iron transport and storage (130, 131).

The alternative sigma factor RpoS is a stationaryphase regulator that plays an important role in the regulation of *Salmonella* genes during stress response to starvation, oxidative stress, osmotic pressure, heat, and low pH. Many of these environmental stimuli sensed by RpoS are present within the phagosomes of macrophages. First discovered in *E. coli* as a regulator of the catalase gene *katE* and named KatF (132), the RpoS sigma factor has also been shown to be important for virulence (133) and also responds to the expression of cationic antimicrobial peptides produced by the host immune system (134). Some of the many genes that are a part of the RpoS regulon include the virulence factor gene *csgD*, the virulence plasmid genes *spvRABCD*, and the superoxide dismutase gene *sodCII* (135). The expression of *rpoS* itself is regulated by the small RNAs RprA, DsrA, ArcZ, and OxyS posttranscriptionally (136–138). These small RNAs with the RNA chaperone Hfq target the 5′ untranslated region of the *rpoS* transcript in order to regulate its expression. The small RNAs RprA, DsrA, and ArcZ upregulate *rpoS* expression by stabilizing the transcript and aiding in the initiation of translation. On the other hand, the sRNA OxyS is a negative regulator of *rpoS*. There are many more regulators of *Salmonella* virulence, which are reviewed in detail by Fabrega and Vila (139).

CHARACTERISTICS OF DISEASE

Routes of Infection

Salmonella is typically spread through contaminated water or food via the fecal-oral route. While infection with *Salmonella* can occur via contact of open wounds or mucosal parts of the body with contaminated products, surfaces, or water, the primary cause of *Salmonella* outbreaks in developed countries remains food. Routes of infection tend to be associated with specific serotypes of *Salmonella* based on their ecology (140). For example, *Salmonella* Enteritidis is found among egg-laying poultry and has been the cause of illness outbreaks associated with shell eggs. While the ecology of many serovars of *S. enterica* remains unknown, a list of serovars, known ecologies, and associated outbreaks can be found in Table 9.2 (140). This table also highlights the flexibility of *S. enterica* serovars in particular to be associated with a primary host or ecology (i.e., chickens or pigs) and yet cause infection indirectly through food or other animal species unassociated with the primary host/ecology.

Environmentally, *Salmonella* serotypes have been detected in surface water, water storage tanks, piped water systems, irrigation water, and soil (141, 142). The level of prevalence depends on source of fecal contamination, distance from the contaminated site, frequency of contamination inputs into the site, efficiency of decontamination procedures, and flow between site and the source of contamination, which might be mediated by climatic factors such as rain, flooding, or human and animal interactions. Within the human-built environment, control of *Salmonella* has been particularly difficult in hospital settings. It has been detected on equipment, supplies, soiled laundry, hospital kitchens, and even the

hospital water supply (143). Ecology, human and animal movements, and the natural and human-built environments all serve to facilitate transmission and infection with *Salmonella* serovars globally.

Once *Salmonella* has entered the human body, the initial site of attachment is the intestinal epithelium of the small intestine, with invasion into nonphagocytic cells. Invasion can be mediated via two mechanisms, termed the trigger and zipper mechanisms. The trigger mechanism is carried out by a TTSS located on SPI-1 and involves cytoskeletal rearrangement and membrane ruffling. The zipper mechanism is TTSS independent, involves the Rck locus, and is host receptor mediated. The mechanisms differ in their mode of activation: the trigger mechanism is activated by bacterial effectors delivered by secretion systems from inside the cell, whereas the zipper mechanism is activated through host cell receptors on the outside of the cell (144, 145). Figures 9.3 and 9.4 illustrate the dissemination of infection of *Salmonella* in the human body and the trigger and zipper mechanisms of invasion of the cell by *Salmonella*.

Infectious Dose

The infectious dose is defined as the minimum number of bacteria required to cause illness. This can be dependent on current medications, the susceptibility of the host, the food matrix ingested, and virulence factors, which are often serovar dependent. Early studies using volunteers suggested that an infectious dose of 10^6 organisms was necessary to illicit infection; however, recent work has revised this estimate to an average of 10^3 to 10^4 CFU. It has been suggested through outbreak modeling that as few as 10 to 36 CFU can cause infection, depending on outbreak conditions and host susceptibility. Additionally, the probability of illness or attack rate has been shown to be linked to infectious dose. In 2002, the WHO estimated that the probabilities of illness given average doses of 1, 10, and 100 organisms were 0.2%, 2.2%, and 13%, respectively (146). While no study has established a gold standard of infectious dose for *Salmonella*, it is generally agreed that higher levels of *Salmonella* are more likely to cause infection. Research is ongoing to develop and evaluate methods to quickly enumerate *Salmonella* in environmental samples and food products to identify samples or products with a high bacterial load.

Symptoms and Treatment

The incubation time following successful invasion of the cellular tissue by *Salmonella* prior to manifestation of symptoms varies from a few hours to 2 days. Inflammatory gastroenteritis (salmonellosis) is the most common result of NTS infection, with symptoms including nausea, vomiting, abdominal cramps, diarrhea, fever, chills, headache, and blood in the stool. Symptoms can last 2 to 7 days, with diarrhea lasting up to 10 days. Though symptoms resolve, it may take months before the bowels return to normal. NTS infection can manifest without gastrointestinal symptoms in both adults and children, instead presenting as a febrile illness. Respiratory infection, anemia, and hepatosplenomegaly may be useful in diagnosing NTS; however, these clinical features are also seen in a variety of infections caused by other pathogens (147). This nonspecific clinical presentation makes diagnosis and treatment challenging, especially in settings where resources are limited. NTS infections can be diagnosed using blood or bone marrow cultures, PCR, or enzyme-linked immunosorbent assay (past infections). Treatment of NTS infections primarily consists of electrolyte replacement and rehydration (supportive care). Antimicrobial treatment is challenging and typically discouraged now that there is increasing prevalence of antibiotic-resistant serotypes and strains (see “Antibiotic Resistance” below). Currently, there are no vaccines licensed for human use for NTS; however, current vaccines for livestock and poultry are available and more are being tested (148).

Table 9.2 *S. enterica* serovars found in human Samples[a]

Serovar	Resistance type[b]	Ecology or host[c]	Vehicle of outbreak	Country and year(s)[d]

[a] Listed are serovars with known ecologies and two or more documented outbreaks.

[b] Antibiotic resistance types represent all antibiotics for which, at some point in time, resistance has been detected in one or more isolates from humans (bold), animals only (not bold), food (italics), or the environment (underlined). A, ampicillin; Ag, aminoglycosides; Ak, amikacin; Amc, amoxicillin-clavulanic acid; Apr, apramycin; Atm, aztreonam; Azi, azithromycin; Bl, β-lactams; C, chloramphenicol; Caf, ceftazidime; Car, carbenicillin; Cb, carbapenems; Cef, ceftiofur; Cep, cephalothin; Cfx, cefotaxime; Cfz, cefazolin; Cin, cinoxacin; Co, colistin; Cp, ciprofloxacin; Cpm, cefepime; Ctx, ceftriaxone, D, doxycycline; E, enrofloxacin; Eo, enoxacin; Ert, ertapenem; Ery, erythromycin; F, florfenicol; Fox, cefoxitin; Fr, furazolidone; Fs, fosfomycin; G, gentamicin; I, imipenem; K, kanamycin; L, levofloxacin; M, minocycline; Ma, macrolides; Me, meropenem; N, nalidixic acid; ND, no data; Neo, neomycin; Net, netilmicin; Nit, nitrofuran; No, norfloxacin; O, ofloxacin; P, polymyxin B; Pef, pefloxacin; Pip, piperacillin; R, rifampin; S, streptomycin; Sp, spectinomycin; Su, sulfonamide compounds; Sxt, trimethoprim/sulfamethoxazole; T, tetracycline (including derivatives); Tic, ticarcillin; Tob, tobramycin; Tzp, piperacillin-tazobactam; V, vancomycin.

[c] Unk, unknown.

[d] Ranges indicate several outbreaks occurring within each year in the range, not a single outbreak lasting the duration of the range.

[e] Shares the antigenic formula 6,7:c:1,5 with *Salmonella* Choleraesuis and *Salmonella* Typhisuis, so outbreaks may be identified under a different serovar.

[f] Kratom (also known as thang, kakuam, thom, ketum, and biak) is a plant consumed as a stimulant and can be used as a substitute for opioids.

[g] Inferred from the presence of SGI-1; no resistant isolates detected to date.

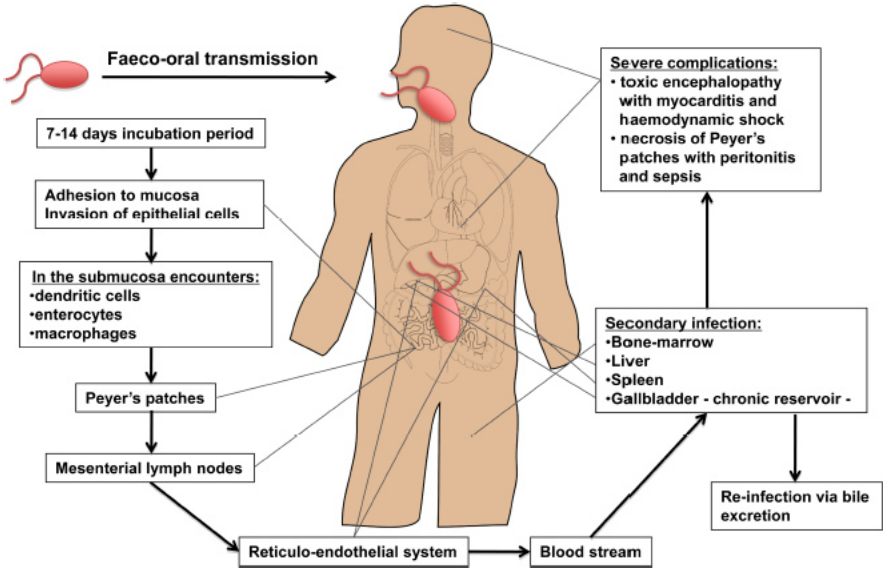

Figure 9.3. Diagram showing how *Salmonella* Typhi moves through the body during systemic infection.

After ingestion of *Salmonella* Typhi and *Salmonella* Paratyphi, which cause typhoid fever, an asymptomatic period follows lasting 7 to 14 days, and fecal shedding of the bacterium can occur during this time. Symptoms include fevers ranging from 39 to 40°C (103 to 104°F), weakness, abdominal pain, headache, loss of appetite, and in some cases a rash or flat, rose-colored spots. Additional symptoms may include a slightly distended abdomen with a "doughy" consistency or pain and tenderness in the right iliac fossa, suggestive of appendicitis or peritonitis (147). If the illness is left untreated, patients can experience complications including gastrointestinal bleeding, intestinal perforation, and encephalopathy. While definitive diagnosis is made through culturing of blood, bone marrow, or stool samples for *Salmonella* Typhi or *Salmonella* Paratyphi, assays have been developed for detection and diagnosis of typhoid fever using PCR, antigen-and antibody-based techniques, tube tests, and test strips, which are less invasive and purported to be as accurate as traditional culturing techniques (149). Once infection has occurred, treatment includes supportive therapy and antibiotics. For prevention, currently, there are two typhoid vaccines available within the United States, Ty21a (live-attenuated, oral vaccine) and the parenteral Vi vaccine. There are also several conjugate vaccines in development and in various stages of testing around the world, including TyVac, Typbar TCV, Vi-rEPA, and Vi-CRM.

Foodborne Outbreaks

NTS serotypes infect 1 in 10 people globally per year, with an estimated 33 million "healthy life years" lost and with inflammatory gastroenteritis being the most common result of *Salmonella* infection (150). For *Salmonella* Typhi and *Salmonella* Paratyphi, which cause typhoid fever, an estimated 11 to 22 million people are infected, resulting in 128,000 to 161,000 deaths per year (150). In 2016, a survey of 10 U.S. states found 7,554 confirmed *Salmonella* cases, and the most common serovars were *Salmonella* Enteritidis, *Salmonella* Newport, and *Salmonella* Typhimurium. In the same year, 94,530 confirmed human cases of salmonellosis were reported in the European Union (151, 152). In Asia, incidence data are limited for salmonellosis across the continent, but estimates from studies conducted in Southeast Asia and India suggest an incidence rate ranging from 7.2 to 525 cases per 100,000 persons per year within the continent (153, 154). In Africa, information on the incidence of *Salmonella* disease is also limited; however a study conducted between 2010 and 2014 for 13 sites across Africa which analyzed 13,431 blood samples found that of the noncontaminant bacteria isolated from febrile patients, 24% were *Salmonella* Typhi and 17% were NTS. The estimated burden from the 2010–2014 study in Africa for typhoidal and nontyphoidal fever was 100 cases per 100,000 person-years of observation (155).

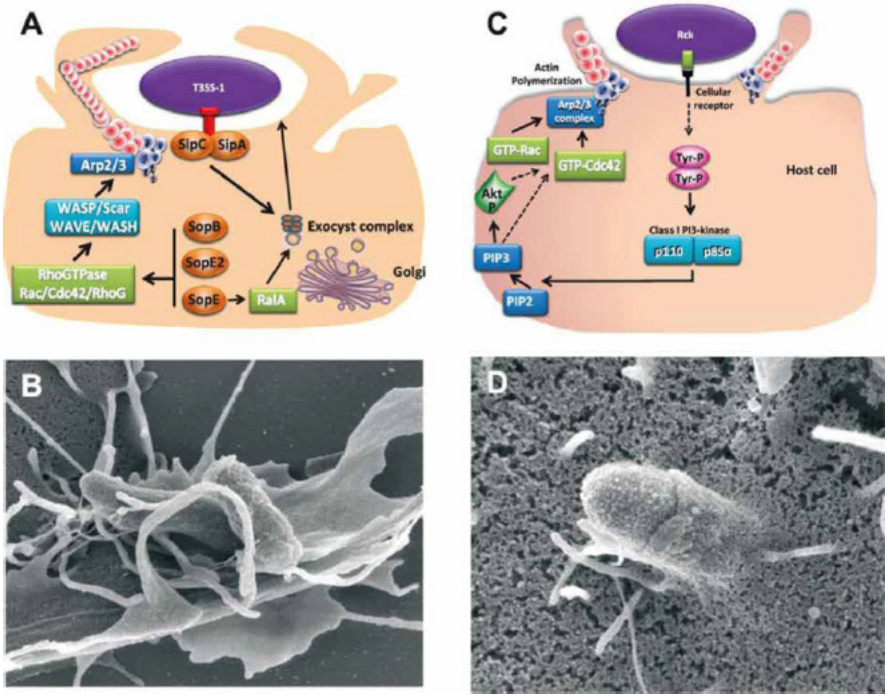

Figure 9.4. Diagrams and micrographs showing how *Salmonella* uses the trigger (A and B) and zipper (C and D) mechanisms to enter cells. (A) Diagram of the trigger mechanism. Using a TTSS, *Salmonella* effector proteins (SipA, SipC, SopB, SopE, and SopE2) are injected into the cell. SopE, SopE2, and SopB activate the Rho GTPases Rac, Cdc42, and RhoG to allow rearrangement of the actin cytoskeleton using the cellular proteins WASP, Scar, WAVE, and WASH, which activate the Arp2/3 complex. SipA and SipC bind to the actin. SipC and SopE, in concert with the Ras-related protein RalA, mediate formation of membrane ruffles and the recruitment of the exocyst complex. (B and D) Scanning electron microscopy images of *Salmonella* entering cells using the trigger and zipper mechanisms. Large membrane ruffles can be seen at the entry site. (C) Diagram of the zipper mechanism. Phosphorylation of tyrosine kinase is mediated by the Rck invasin protein expressed on the *Salmonella* outer membrane when it interacts with its receptor on the host cell membrane. The class I phosphatidylinositol 3-kinase is activated and induces phosphatidylinositol(3,4,5)-trisphosphate formation, using Akt activation. GTPase Rac1 and GTPase Cdc42 trigger actin polymerization via the Arp2/3 nucleator complex. The mechanism controlling Cdc42 during Rck-induced signaling is still unknown. Dotted arrows represent possible signaling events and/or interactions.

Approximately, 85% of all illnesses ascribed to *Salmonella* are foodborne, leading to ~155,000 deaths/year (3). Table 9.2 lists many of the notable foodborne outbreaks by serovar for *S. enterica* as investigated or described from 1967 to 2018. *Salmonella*'s unique ability to survive on substrates with high and low water activities facilitates its colonization and its correlation with outbreaks associated with dry products, wet products, and ecological hosts.

Salmonella serovars activate several mechanisms to combat desiccation, cold and heat shock, chemicals used for sanitation, and drops in pH. *Salmonella* Senftenberg, *Salmonella* Typhimurium, *Salmonella* Enteritidis, and *Salmonella* Bedford have all been shown to be heat resistant or to be able to adapt to heat shock, sometimes upregulating virulence genes in the process, thereby lowering infectious dose required for illness. *Salmonella* Tennessee, *Salmonella* Enteritidis, and *Salmonella* Typhimurium activate cold shock proteins to facilitate survival in cold environments, including refrigerated food. *Salmonella* serovars survive desiccation by forming biofilms and activating genes involved in fatty acid modification that facilitate survival by increasing osmotolerance or facilitating osmoprotection. Phenotypic changes in response to desiccation include *rdar* morphology (red, dry and rough), filament production, and cell shrinkage. *Salmonella* Senftenberg, *Salmonella* Enteritidis,

Salmonella Typhimurium, and *Salmonella* Mbandaka have shown very high survival in dry conditions, surviving for up to 30 months (156), and *Salmonella* Tennessee was found to survive for 182 days in cookie and cracker filling (157). A summary of *Salmonella* cellular responses to low-moisture environments is illustrated in Fig. 9.5.

Of final note is the cross-tolerance effect. Many virulence factors in *Salmonella* are regulated by the PhoPPhoQ system. Interactions or differences in regulation of genes associated with this system, such as *rpoS* and *fur*, have shown that induction of one stress (e.g., heat) can confer resistance to other stresses, such as low pH (*Salmonella* Enteritidis, *Salmonella* Mbandaka, and *Salmonella* Typhimurium), organic and inorganic acids, desiccation, UV, and chemical disinfectants (*Salmonella* Enteritidis, *Salmonella* Newport, *Salmonella* Infantis, and *Salmonella* Typhimurium) and/or can result in upregulation of virulence if pH decreases (*hilA*; *Salmonella* Senftenberg, *Salmonella* Heidelberg, *Salmonella* Mbandaka, *Salmonella* Montevideo, and *Salmonella* Infantis) (156).

Impact on the Host Microbiome

Since the advent and increased accessibility of high-throughput sequencing, there has been a surge in human and animal gut microbiome studies. The human gut contains 500 to 1,000 different species of bacteria, primarily belonging to three bacterial groups: *Firmicutes*, *Bacteroidetes*, and *Actinobacteria*. The gut microbiome plays a role in protecting the epithelia from invasion by producing toxins and by cross talk between different regions of the gut, which can allow the gut microbes to suppress growth of *Salmonella*, optimize the immune response, compete with *Salmonella* for nutrients, and mediate clearance of pathogens. *Salmonella* serovars and their associated virulence factors, in turn, have been shown to exploit aspects of the human gut to support their growth and compete with other microbes, such as using the gut inflammatory response to create a novel nutrient niche (158) or harnessing respiration from fermenting microbes via the generation of new electron acceptors (159). Characterization of the gut microbiome during infection is opening up a new area of research in microbiota-based therapies to remedy *Salmonella* infections in both humans and food animals. Currently, the main treatment for *Salmonella* infection is antibiotic administration. However, if infection is not completely cleared or there is antibiotic resistance, this treatment can reduce the bacteria within the gut, resulting in *Salmonella* expansion and causing prolonged disease, fecal shedding, and carrier status (159).

Antibiotic Resistance

As discussed above, the main prevention for typhoidal *Salmonella* infection is vaccination; however, once illness is acquired, supportive therapy and antibiotics are the main treatments offered. The WHO states that through the overuse and misuse of antibiotics as well as poor infection prevention and control, antimicrobial resistance is fast becoming one of the "biggest threats to global health, food security and development today" (160). Prior to the 1970s, chloramphenicol was the major treatment prescribed for enteric fever (typhoid) (161–163); however, isolates resistant to chloramphenicol were appearing before 1970 (163, 164). By the early 2000s, multi-drug (ampicillin, chloramphenicol, and trimethoprim-sulfamethoxazole)-resistant *Salmonella* Typhi and *Salmonella* Paratyphi were common globally. *Salmonella* Typhi is considered endemic in developing countries now, especially in Southeast Asia (147). With the rise in multi-drug-resistant *Salmonella* Typhi and *Salmonella* Paratyphi, antibiotic treatment has included the use of fluoroquinolones (e.g., ciprofloxacin), azithromycin (macrolide antibiotic), and extended-spectrum cephalosporins (e.g., ceftriaxone and β-lactams); however, within a couple of years, resistant strains were already emerging globally, and a concurrent resistance to nalidixic acid was also observed (147, 165, 166). Figure 9.6 shows a map of the resistance profile of *Salmonella* Typhi.

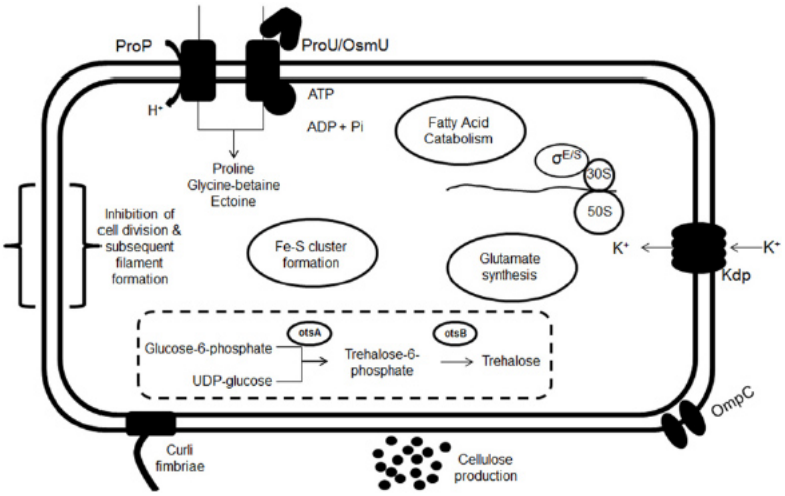

Figure 9.5 Diagram of proposed cellular responses to transition to a low-moisture environment. Responses include K^+ uptake by the Kdp transporter, osmoprotectant transport (ProU, ProP, and OsmU), glutamate synthesis, trehalose biosynthesis, upregulation of fatty acid catabolism and RpoE and RpoS regulators, Fe-S cluster formation and filament formation, and an increase in the number of OmpC porins. There may also be a role for cellulose and curli fimbriae in survival in low-moisture environments.

Vaccination is not an option for NTS, so, when supportive therapy fails, one of the most effective treatments for NTS infection has been (for the past 70 years) and continues to be the use of antibiotics (167, 168). In recent years, NTS has been showing increasing resistance to fluoroquinolones, β-lactams, chloramphenicol, penicillins, and trimethoprim-sulfamethoxazole; much of this resistance has been linked to agricultural use of these antibiotics in food animals (147, 165, 168–170). As of 2016, one of every four *Salmonella* infections was caused by bacteria resistant to three or more antimicrobials commonly used in human and animal medicine, and four countries reported for the first time extendedspectrum-β-lactamase-producing *Salmonella* Kentucky with high resistance to ciprofloxacin in humans (171).

As with *Salmonella* Typhi and *Salmonella* Paratyphi, the spread of resistant phenotypes has occurred globally, with ampicillin, chloramphenicol, streptomycin, sulfonamide, and tetracycline (ACSSuT) (Table 9.2) resistance having been detected in the United States, Europe, Canada, Israel, Turkey, and Japan, primarily associated with *Salmonella* Typhimurium (172–175). Quinolone (nalidixic acid) and fluoroquinolone (ciprofloxacin) resistance has been detected in serovars, including *Salmonella* Enteritidis, *Salmonella* Typhimurium, *Salmonella* Virchow, and *Salmonella* Hadar, found in Denmark and Southeast Asia. Serovars resistant to β-lactam drugs (e.g., cephalosporins; isolates harboring β-lactamases or AmpC-type enzymes) were first detected in North Africa in the mid-to late 1980s (176–178). Since then, cephalosporin resistance has been reported in Southeast Asia, Europe, Canada (associated with *Salmonella* Typhimurium and *Salmonella* Newport), and the United States (*Salmonella* Typhimurium, *Salmonella* Newport, and *Salmonella* Heidelberg). Serovars documented as having extensive drug resistance (resistance to more than six antimicrobial agents) include *Salmonella* Typhimurium and *Salmonella* Kentucky. These isolates have mostly been detected in Southeast Asia (China, Malaysia, Vietnam, and Thailand) (147, 179).

Resistant phenotypes are encoded by specific genes found on plasmids or genomic islands prone to horizontal gene transfer via transposons or conjugation between isolates and serovars. Antibiotic resistance genes on plasmids or other pieces of genetic material can also be transferred via uptake from the environment (transformation) or via phage (transduction). For example, *Salmonella* Typhimurium has been associated with definitive phage type 104 (DT104) (147), which confers resistance to the first-line antimicrobials ACSSuT (Table 9.2). For the ACSSuT resistance type, many of the genes encoding resistance are located on a genomic island (SGI-1) which was first identified in *Salmonella*

Typhimurium (180) but since has been detected in *Salmonella* Agona, *Salmonella* Albany, *Salmonella* Cerro, *Salmonella* Derby, *Salmonella* Dusseldorf, *Salmonella* Emek, *Salmonella* Haifa, *Salmonella* Infantis, *Salmonella* Kentucky, *Salmonella* Kiambu, *Salmonella* Kingston, *Salmonella* Meleagridis, *Salmonella* Newport, *Salmonella* Paratyphi B, and *Salmonella* Tallahassee (181–183). SGI-1 is a 14-kbp region bracketed by two integron structures which contain the antimicrobial resistance genes bla_{PSE-1}, *floR*, *aadA2* (streptomycin), *sul1*, and *tetG* (tetracycline) (Fig. 9.7) (147).

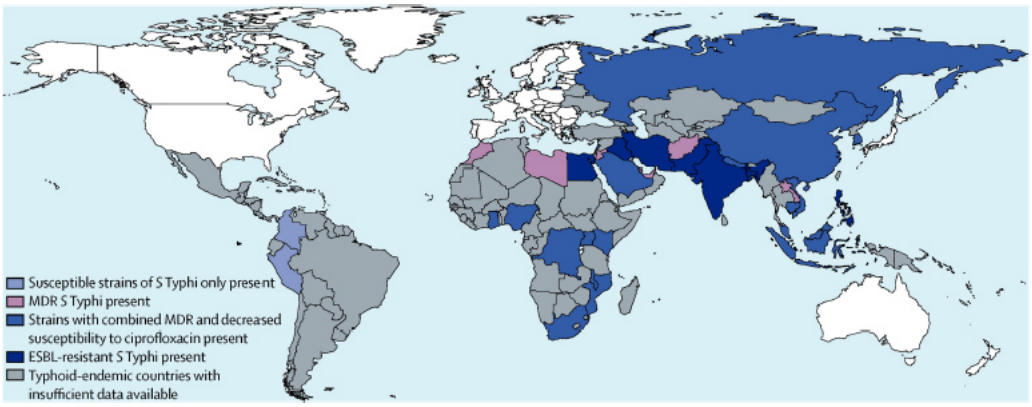

Figure 9.6 Global distribution of antimicrobial drug resistance in *Salmonella* Typhi. MDR, multi-drug resistant; ESBL, extended-spectrum β-lactamase. Reprinted from reference 147.

Resistance to penicillins and cephalosporins can be mediated by β-lactamase enzymes such as Bla_{PSE} and Bla_{TEM} (extended-spectrum β-lactamases), carbapenemases, AmpC-type enzymes, and β-lactamases, which are the most common mode of cephalosporin resistance in NTS (i.e., cephamycinases, encoded by bla_{CMY} genes). Cephalosporins typically target penicillin-binding proteins, disrupting cell wall synthesis. Genes conferring resistance are usually found on mobile genetic elements, such as plasmids, transposons, and integrons; thus, horizontal gene transfer is common between isolates and serovars.

Resistance to chloramphenicol can occur via chloramphenicol acetyltransferases (types I and III) or the nonenzymatic resistance genes *cmlA* or *floR*. Trimethoprim and sulfamethoxazole inhibit folate pathways, preventing synthesis of DNA, so any gene acquired that encodes folate pathway enzymes that do not bind to these drugs can provide resistance. Additionally, dihydrofolate reductase (*dfr*) facilitates resistance to trimethoprim, and the *sul* genes (*sul1* or *sul2*) mediate resistance to sulfamethoxazole.

Fluoroquinolones target DNA gyrase and topoisomerase IV, encoded by *gyrA*, *gyrB*, *parC*, and *parE*. Mutations in the quinolone resistance-determining regions of any of these genes have the potential to confer resistance. For instance, a single point mutation in *gyrA* corresponding to amino acid position 83 (serine to phenylalanine or tyrosine) or 87 (aspartic acid to asparagine or glycine) will result in resistance to nalidixic acid and decreased susceptibility to ciprofloxacin. Resistance to fluoroquinolones can also be acquired via a plasmid-mediated quinolone resistance mechanism [*qnrA*, *qnrB2*, *qnrS1*, and variants *aac(6′)-lb-cr*, *qepA*, and *oqxAB*].

Resistance to azithromycin (macrolide antibiotic) was first documented in 2010 in *Salmonella* Paratyphi A and has been spreading since (152, 184). Macrolides prevent protein synthesis by binding to the 50S ribosomal subunit. The plasmid-borne gene *mphA* (macrolide-2′-phosphotransferase) has been implicated in conferring resistance to azithromycin. Typically found in *E. coli*, the *mphA* gene has also emerged in *Shigella sonnei*, demonstrating intergenus transfer and validating concerns of further transfer to other *Shigella* and *Salmonella* spp. (147, 185).

Antimicrobial resistance has been exacerbated by the overprescription or misuse of antibiotics by medical professionals. Additionally, in many developing countries, antibiotics are available over the counter without a prescription or in substandard versions (expired or counterfeit) and are readily

consumed. In agriculture, antibiotics are used prophylactically to promote growth and reduce illness in food animals, often promoting the spread of antibiotic resistance into the food supply via human-animal interactions or environmental contamination. Efforts at control need to be focused on education of medical professionals and the public about the misuse or overuse of antibiotic therapies. Available antibiotics need to be managed at all levels to mitigate continued spread of resistant bacterial phenotypes. Finally, research in the area of alternative therapies, such as immunity-modulating agents, bacteriophage lysins, antimicrobial peptides, pro-, pre-, and synbiotics, plant extracts, and inhibitors targeting pathogenicity, need to be explored more fully in both animals and humans (186–188).

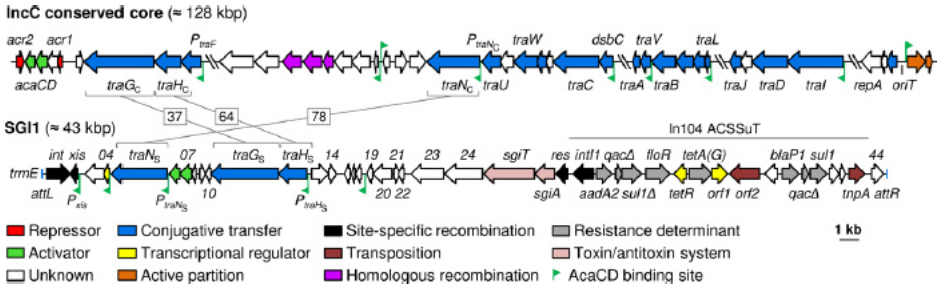

Figure 9.7 Diagram of the core sequence of IncC plasmids and SGI-1. The positions and orientations of open reading frames are indicated by arrowed boxes. Function was determined by BLAST comparisons and is indicated by colors. AcaCD binding sites are indicated by green flags. SGI-1 is flanked by the *attL* and *attR* attachment sites for integration into the 3′ end of the *trmE* gene in the chromosome of *Salmonella* Typhimurium DT104.

Interventions and Preventative

Controls in Foods

Salmonella is ubiquitous in our environment. Indeed, Table 9.2 lists the variety of ecological animal host reservoirs from which serovars have been isolated; however, some of the outbreaks listed there have also been due to consumption of, or exposure to, contaminated water (i.e., *Salmonella* Chester, *Salmonella* Typhi, and *Salmonella* Weltevreden). Additionally, many *S. enterica* serovars involved in prominent foodborne outbreaks, such as *Salmonella* Baildon, *Salmonella* Chester, *Salmonella* Hartford, *Salmonella* Manhattan, *Salmonella* Panama, *Salmonella* Rubislaw, *Salmonella* Weltevreden, and *Salmonella* Urbana, have no reservoir currently identified. As previously mentioned, *S. enterica* serovars have been detected in surface water, water storage tanks, piped water systems, irrigation water, and soil and in hospital environments within the water supply or on equipment in developed and developing countries alike. *S. enterica* serovars that are not mentioned in Table 9.2 but have been implicated in rare outbreaks in humans with environmental or nonfood animal reservoirs include *Salmonella* Agbeni, *Salmonella* Coeln, *Salmonella* Haifa, and *Salmonella* Potsdam (178, 189–192). Still other serovars interfere with agricultural practices by being carried by wild birds or waterfowl, whose excrement can contaminate crops and produce (192–194). The diversity of *Salmonella*'s hosts, ecologies, survival, and virulence strategies has contributed to its continued persistence in the food chain and given rise to the need for multipronged approaches to prevention and control.

The main source of foodborne disease caused by *Salmonella* continues to be poultry-derived products and eggs (195). Programs for the control of *Salmonella* in poultry and eggs date back to 1935 with the National Poultry Improvement Plan, which was established by an act of Congress and based on recommendations developed from meetings between the government, the International Baby Chick Association, and industry partners. It also established statewide breeding programs with uniform terminology. In the early 1990s, the outbreak traceback program dictated that laying flocks would be tested for *Salmonella* Enteritidis and the eggs would be processed at pasteurization plants (196). In 1996, the U.S. Department of Agriculture (USDA) Food Safety Inspection Service (FSIS) issued the Hazard Analysis and Critical Control Point (HACCP) Systems Final Rule. The HACCP Final Rule, with the goal of reducing the occurrence of pathogenic microorganisms on meat and poultry products,

required that all establishments (i) develop and implement standard operating protocols, (ii) require regular microbiological testing to validate prevention and removal protocols during slaughtering, (iii) establish pathogen reduction standards for *Salmonella*, and (iv) design and implement preventive controls to improve the safety of their products (197). The USDA also provides documents and guidelines for food defense planning and food safety assessments, as well as meat, poultry, and processed-egg-product inspection videos. In 2001, the USDA released a report highlighting the effectiveness of these programs, showing a 50% reduction of *Salmonella* presence in samples compared to pre-HACCP implementation (198). By 2010, the prevalence of *Salmonella* contamination in U.S. broiler chickens was 6.7% (198), and in 2014 this percentage dropped to 3.7% (199), highlighting the continued effectiveness of programs such as the HACCP system for controlling *Salmonella* in broiler chickens.

Control efforts have also extended to standardizing practices for the control of *Salmonella* on shell eggs. The risk assessment for *Salmonella* Enteritidis was initiated in 1996 and was followed by the Egg Safety Action Plan. By 1999, the number of cases per 100,000 people had dropped to 1.98, and FSIS continues to guide the development of standards for egg and egg products. In 2010, a large outbreak of *Salmonella* Enteritidis resulting in 1,470 illnesses and the recall of ~500 million eggs occurred during the FDA's establishment of the Egg Safety Final Rule (200). The Egg Safety Final Rule established (i) monitoring conditions and testing for eggs; (ii) limitations on visitors and establishment of practices to reduce cross-contamination; (iii) monitoring and reduction of pests and debris; (iv) cleaning and disinfection, including the removal of visible manure, dust, feathers, and old feed, followed by fumigation or another disinfection method; and (v) refrigeration at or below an ambient temperature of 45°F beginning 36 hours after laying.

Despite these policies, however, controlling *Salmonella* contamination on shell eggs continues to be a complex problem due to the number of variables that have to be considered, such as flock size, flock age, stress, feed, vaccination, and cleaning routines. Egg washing combined with pasteurization and/or irradiation continues to be the most effective method for *Salmonella* control. Pasteurization by heat treatment using a water bath at 57°C for 25 minutes followed by hot air at 55°C for 57 minutes resulted in a 1.9-log reduction in *Salmonella* (201). The minimum level of radiation required to inactivate *Salmonella* is 1.5 kGy (201). Recently, the merits of chlorine dioxide gas in combination with mild wet heat were explored, and this study demonstrated that 5.9 log/CFU/egg of *S. enterica* could be inactivated on the surfaces of egg shells within 4 hours (202). Standard guidelines for consumers include cooking eggs to an internal temperature of 160°F (70°C), use of pasteurized eggs whenever possible, and not storing eggs or foods made with eggs at room temperature for more than 2 hours. Recently, an outbreak occurred, resulting in 45 illnesses and the recall of over 200 million shell eggs from a farm in Indiana (200, 203); however, since the implementation of the Egg Safety Final Rule in concert with state-implemented egg quality assurance programs, the overall incidence of *Salmonella* on shell eggs has gone down significantly. As of 2017, the U.S. prevalence of *Salmonella* in pasteurized egg products was 0.14% (204–206).

Chlorine and ionizing radiation have been evaluated in the control of *Salmonella* in seafood. Studies found that the interferences of organic matter, the potential for carcinogenic by-products, and incomplete inactivation (leaving cells viable and infectious though not culturable) have resulted in limited use of chlorine as a bactericidal wash (207, 208). The use of ionizing radiation has been more promising in seafood, as it has been found that 0.43 to 0.71 kGy could inactivate 1 log of bacterial pathogens such as *Salmonella* in a variety of frozen seafood products, compared to frozen meat products, which required 0.98 to 1.26 kGy (209, 210).

For fresh produce, good manufacturing practices are important in the control of bacterial pathogens. Of the food imported into the United States, ~50% is fruits and vegetables, and the amount of food imported is rising. A survey of outbreaks of *Salmonella* disease associated with foods imported into the United States from 1996 to 2014 found that although the total number of outbreaks associated with imported food was small, the number has increased (211). Multicountry outbreaks have also occurred in Europe due to food imports (212–214). Many of the exporting countries may not use harvesting or processing practices that meet minimum standards, thereby facilitating contamination. Practices such

as irrigation with wastewater, fertilization with sludge or sewage, washing produce with contaminated water, handling of produce by local workers, and cross-contamination during drying and packaging in unregulated facilities all contribute to the movement of *Salmonella* contamination globally in our imported food supply. Establishment of global partnerships in the control of *Salmonella* is of great importance, considering that the amount of food imported, particularly in the United States, has risen over the past 20 years. Globally, systematic *Salmonella* control programs have yet to gain ground in Southeast Asia, Latin America, Africa, and some parts of Eastern Europe (215–218). In Brazil and Japan, there are widespread vaccination programs to reduce *Salmonella* impacts on poultry (219, 220) but, to date, no specific initiatives targeting *Salmonella* reduction in produce or food exports. *Salmonella* control programs, however, have been implemented in the United States (Food Safety Enhancement Act [2009] and Food Safety Modernization Act [2011]) and Europe (EU directive 2160/2003), and they have been integral in reducing *Salmonella* disease within the population as well as *Salmonella* contamination of foods both grown and manufactured in-country and exported (212, 221–223).

As discussed above, *Salmonella*'s success as a foodborne pathogen and its global ubiquity are due to its genomic and physiological plasticity, conferring the ability to survive in different hosts and environments. The potential for illness outbreaks associated with food animals, aquaculture, or produce is not altogether unexpected, since the vehicles of transmission have been shown to be animals and water and since cross-contamination even after sanitization is not uncommon. However, there have been a number of outbreaks involving low-moisture food, such as nuts, peanut butter, spices, and most recently tahini and dried coconut (Table 9.2) (224–226). It was mentioned above that as few as 10 to 36 CFU can cause a productive infection and that *Salmonella* can survive desiccation through putative stress response networks triggered by chemophysical signals (e.g., osmotic, thermal, and oxidative stress; see "Infectious Dose" and "Desiccation Resistance" above). Laboratory experiments that have shown inactivation of *Salmonella* on dry foods include the use of dry-and moist-air convection heating, propylene oxide or ethylene oxide fumigation, low-energy X-ray irradiation, freeze-drying or supercritical CO_2 drying, and cold plasma (227, 228). Misconceptions play a role in the persistence of bacterial pathogen contamination in food products as well. For instance, typical thermal treatments are 165°F and 158°F for turkey and beef, respectively, to ensure reductions in numbers of *Salmonella*. The public may assume that these temperatures are sufficient for nuts as well, when in fact, according to the Almond Board of California's Technical Expert Review Panel, oil roasting temperatures of 260°F for 2 minutes and blanching temperatures of 190°F are required for adequate reduction of *Salmonella*. The efficacy of each technique is impacted by the food matrix, specific water activity, and *Salmonella* strain used; control processes may not be effective across types of food products (i.e., dry food products versus fish or fresh produce).

Outreach, education, proper training tools, and industry and government initiatives such as HACCP or current good manufacturing practices are the best line of defense in the control of bacterial pathogen dissemination in our food supply. This is the foundation for the manufacturing of safe food, covering proper facility conditions, control and storage of food stuffs, processing protocols, personal hygiene, routine testing, and cleaning and sanitation practices. It is a complex and challenging issue, especially in developing nations, where regional cultural practices or unavailability of financial or training resources can interfere with compliance with food safety regulations. On farms, vaccination, pest control, adequate ventilation, disinfection, limiting animal contact, control of feed handling, hatchery management, and use of antibiotics can help control levels of *Salmonella*. In food processing plants, control has to be initiated at several levels: (i) evaluation and testing of the initial ingredients sourced from different suppliers within the processing chain, (ii) proper training of personnel in good microbiological and decontamination procedures, (iii) proper disinfection of equipment and treatment of water, (iv) proper thermal treatment of foods, (v) ensuring effective pest control, and (vi) consideration of adopting a positive-pressure air system in plants processing food items to reduce bacterial contamination in the air of processing plants. Continued end-point sampling and establishment of an effective environmental monitoring program encompassing checkpoints for all variables listed above should reduce *Salmonella* contamination on food products (147).

Eleven *Campylobacter* Species

Campylobacter is regarded as a leading cause of bacterial foodborne infection in many areas of the world. *Campylobacter jejuni* and, to a lesser extent, *Campylobacter coli* are important causes of human diarrheal illnesses, even surpassing *Salmonella* in importance in many countries (1, 2). Although human illnesses are usually self-limiting, the associated morbidity and cost are significant. In Europe, the burden of human campylobacteriosis is estimated to be between 8 and 100 times higher than the annually reported number of cases, which has approximated 200,000 in recent years (3). Such a high incidence of *Campylobacter*-related diarrhea has significant socioeconomic impacts, making this pathogen a priority for public health and food safety researchers. This chapter highlights the important bacteriological and epidemiologic issues related to contamination by thermotolerant *Campylobacter* spp. (*C. jejuni* and *C. coli*) in the human food supply chain.

Since no single review can be comprehensive, the reader is encouraged to refer to several excellent recent books and reviews for additional information (1, 2, 4, 5).

THE GENUS *CAMPYLOBACTER*

The genus *Campylobacter* belongs to the family *Campylobacteraceae* together with the genera *Arcobacter* and *Sulfurospirillum*. The genus was established in 1963, and its taxonomic structure has been revised over the years (6, 7). In 2017, the genus *Campylobacter* contained 29 species, 5 of which have been further divided into 11 subspecies (8). These species can be traced to a variety of animal and environmental sources. In veterinary medicine, *Campylobacter fetus* subsp. *venerealis* is an important cause of epizootic bovine infertility, and *C. fetus* subsp. *fetus* is most often associated with spontaneous abortion in cattle and sheep. However, limited information can be found regarding isolation of *Campylobacter* species from wildlife. There is a recent report of isolation of *Campylobacter lari* subsp. *concheus* and *Campylobacter volucri*s from penguins in the Antarctic region (9). In human oral medicine, the species *Campylobacter concisus*, *C. curvus*, *C. hominis*, *C. sputorum*, *C. rectus*, *C. showae*, and *C. gracilis* are predominantly important (7, 10). However, from a wider public health and food safety perspective, *C. jejuni*, *C. coli*, *C. lari*, and *C. upsaliensis* are important species causing foodborne and zoonotic illnesses, of which *C. jejuni* and *C. coli* are the most significant. These four species are often referred to as thermotolerant campylobacters, as most strains of these species exhibit optimal growth at 41 to 43°C. Relevant biochemical properties of these thermotolerant *Campylobacter* species are summarized in Table 10.1.

The species *C. jejuni* comprises two subspecies: the first, *C. jejuni* subsp. *jejuni*, is one of the most common causes of human gastroenteritis worldwide (7, 11), whereas the second, *C. jejuni* subsp. *doylei*, is less well defined as a human pathogen. It is isolated infrequently from human clinical samples and has been associated with infants' bacteremia and pediatric diarrhea in developing countries (12). The distinction between the two subspecies is rarely considered in public health and food microbiology laboratories. However, a multiplex PCR method has been described for the differentiation between the two *C. jejuni* subspecies (13). For simplicity, throughout this chapter, *C. jejuni* refers mainly to *C. jejuni* subsp. *jejuni*.

C. coli is regarded as the *Campylobacter* species isolated second most frequently from human diarrheal samples. It was first isolated from pigs with infectious dysentery and is still the *Campylobacter* species most frequently isolated from pork and swine farms (2). Nevertheless, *C. coli* can also be found in poultry, cattle, and dogs (10). This species is closely related to *C. jejuni*, having a large set of genes in common with *C. jejuni*. This likely explains the problematic differentiation between *C. jejuni* and *C. coli* that occurs in biochemical and phenotypic tests (14). To circumvent this problem, a number of PCR tests have been developed that can differentiate *C. jejuni* and *C. coli* (15, 16). Despite their being closely related, genetic evidence indicates that *C. coli* strains are less diverse and more clonal than *C. jejuni* strains (17–19).

C. lari strains have been isolated from seagulls, wild birds, poultry and products thereof, cattle, and shellfish and from untreated water (20–22). In humans, *C. lari* has been occasionally isolated from individuals with diarrhea (23). *C. lari* strains are primarily distinguished from *C. jejuni* and *C. coli* by their resistance to nalidixic acid (2); however, Endtz et al. (20) have described nalidixic-susceptible variant groups. *C. upsaliensis* is a catalase-negative thermotolerant *Campylobacter* species (7, 10), and its natural hosts appear to be pet dogs and cats (24), although it has been isolated from sporadic and outbreak cases of human enteric illness (25).

Table 10.1 Biochemical and growth characteristics of thermotolerant *Campylobacter* spp. causing human foodborne campylobacteriosis[a]

Characteristic	C. *jejuni*	C. *coli*	C. *lari*	C. *upsaliensis*
Growth at 25°C	–	–	–	–
Growth at 35-3JDC	+	+	+	+
Growth at 42°C	+	+	+	+
Nitrate reduction	+	+	+	+
3.5% NaCl	–	–	–	–
H2S, lead acetate strip	+	+	+	+
H2S, TSI	–	D	–	–
Catalase	+	+	+	–
Oxidase	+	+	+	+
MacConkey's agar	+	+	+	–
Motility (wet mount)	+	+	+	+
Growth in 1% glycine	+	+	+	+
Glucose utilization	–	–	–	–
Hippurate hydrolysis	+	–	–	–
Resistance to nalidixic acid	s[b]	s	R	s
Resistance to cephalothin	R	R	R	s

[a] +, 90% or more of strains are positive; –, 90% or more of strains are negative; D, 11 to 89% of strains are positive. R, resistant; S, susceptible; TSI, triple sugar iron.

[b] Nalidixic acid-resistant *C. jejuni* strains have been reported.

BACTERIOLOGICAL ASPECTS OF *CAMPYLOBACTER*

Characteristics and Growth Conditions

Campylobacters are Gram-negative, oxidase-positive, non-spore-forming bacteria. The name *Campylobacter* is derived from the Greek word "*kampylos*," which means curved, reflecting to a certain extent its morphology under the microscope. Log-phase cells have a characteristic spiral, curved, or occasionally straight rod shape, with pleomorphic size ranging from 0.2 to 0.8 μm in width and 0.5 to 8 μm in length. As *Campylobacter* cells begin to age, they tend to be coccoid. The cells are highly motile by means of a single flagellum or occasionally multiple flagella at one or both ends, which gives them a very characteristic darting, corkscrew-like motility and may serve as an important feature in pathogenesis. Campylobacters are relatively inactive biochemically, obtaining their energy from amino acids or tricarboxylic acid cycle intermediates (rather than carbohydrates) (2, 7, 26).

These microaerobic organisms grow best in an atmosphere containing 5 to 10% carbon dioxide and 3 to 5% oxygen. Most *Campylobacter* strains grow at 37°C; the optimum growth temperature for *C. jejuni* and *C. coli* ranges from 41 to 43°C, and the organisms do not grow at <30°C. These two characteristics restrict the ability of campylobacters to grow outside the host, and consequently, unlike most bacterial foodborne pathogens, campylobacters are not normally capable of multiplication in food during processing or storage (2, 7).

Responses to Unfavorable Environments

There is debate as to the extent to which *Campylobacter* is sensitive to unfavorable environmental stresses. Despite being widely prevalent in the human food chain and diarrheal cases, numerous well-established bacterial stress response genes are noticeably absent from the sequenced *C. jejuni*, *C. coli*, and *C. lari* genomes, for example, those encoding the stationary-phase and stress response sigma factor RpoS, the oxidative stress response regulatory elements SoxRS and OxyR, and osmotic shock regulators BetAB (27). *Campylobacter* spp. survive poorly under dry or acidic conditions and in sodium chloride concentrations above 2%. Survival in foods is better at chill (4°C) than ambient (25°C) temperatures; for instance, survival has been recorded in milk and water at 4°C after several weeks. Freezing reduces the cell numbers of *Campylobacter*, but even after freezing (−20°C) for several weeks, low levels of *Campylobacter* can be still detected on contaminated poultry (2, 28, 29). Adding to that, *Campylobacter* species are relatively sensitive to heat (the time for 1 log10 reduction [90% inactivation of the population] at 55°C is 2.5 to 6.6 min) and irradiation and can readily be inactivated during proper cooking (30, 31).

Valuable insights on mechanisms by which *C. jejuni* overcomes stressful environments are based on findings from laboratory stress models. The tolerance response of *C. jejuni* to several stressors, such as aerobic exposure and acid stresses, after mild laboratory adaptation has been reported (32, 33). Adding to that, it has been determined that challenging *C. jejuni* strains under aerobic conditions can enhance their acid tolerance response (34). Such a cross-protection response from one stress to another has also been determined, as genes involved in heat shock response in *C. jejuni* NCTC 11168 were upregulated in response to acid stress (35). Additionally, it has been revealed that starved *C. jejuni* cells are able to withstand heat stress (36). Some studies also showed that strain-to-strain differences in stress response may be a reflection of the genotypic diversity within the *Campylobacter* population (37, 38).

CAMPYLOBACTER DIVERSITY AND SUBTYPING

Insight into Diversity via Genomic Analysis

According to the literature, the genetic diversity of *C. jejuni* is greater than that of *C. coli*, which is responsible for a more stable population within a broiler flock (39, 40). In other words, the high frequency of genomic variation can be due to the high diversity of *C. jejuni* (41) or to the subsequent introduction of the bacterium (42). The

publication of the complete genome sequence of *C. jejuni* strain NCTC 11168 was crucial in understanding the molecular basis for the genotypic diversity of this pathogen (43). This opened the opportunity for in-depth molecular investigations. For instance, comparative genomic hybridization analysis of 11 *C. jejuni* clinical isolates (of various heat-stable serotypes) revealed low levels of genome plasticity among these strains; approximately 84% of the 1,654 genes analyzed were common to all strains tested. These "core genes" appeared to encode housekeeping functions, such as biosynthesis, metabolic, cellular, and regulatory processes. On the other hand, strain-specific gene differences were involved in the biosynthesis and modification of cell surface structures, including flagella, lipooligosaccharide (LOS), and capsular polysaccharide (44).

In line with this study, Leonard et al. (45) utilized *C. jejuni* DNA microarray technology to investigate genetic diversity among five clusters of epidemiologically related isolates. The authors observed a similar variability in genes involved in surface modification, such as the LOS, capsule, and flagellin loci. Hence, the presence of several dozen phase-variable genes in surface antigen biosynthesis loci provides *C. jejuni* with exceptional diversity for interactions with different niches, including immune evasion in the human host and survival in other reservoirs (46). This can be further elaborated from the study of On et al. (47), in which a whole-genome microarray was used to detect *C. jejuni* cytolethal distending toxin and hemolysin activities, along with survival under aerobic conditions. The strains tested were grouped into two clusters, of which one showed better viability during aerobic incubation. Sixty-seven genes were present in this cluster but were missing from the other one. Most of these variable genes were localized within the gene associated with surface structures, including flagella, LOS, and membrane transport protein. These studies provide a molecular basis for the correlation between *C. jejuni* genomic content, particularly in surface-coding regions, and its diversity and environmental survival potential.

Other elements that contribute to *C. jejuni* diversity are its natural competence and recombination ability. It has been determined that *C. jejuni* is naturally competent, as it can take up DNA from the environment. This leads to recombination between strains, which allows the generation of even more genetic diversity. *In vitro*, *C. jejuni* has a marked preference for DNA from *C. jejuni* strains, as opposed to DNA from other species (48, 49). Frequent recombination and intrachromosomal rearrangements in *C. jejuni* can affect the entire chromosome as well as individual loci, such as flagellin genes (43). Another feature of the *C. jejuni* genome that contributes to its diversity is the presence of homopolymeric tracts (short DNA intervals in which the same base is tandemly repeated) that can provide a window to genes that slip in and out of frame (44). According to van Belkum et al. (50), such phase-variable genes can enable key determinants to switch on and off depending on the environmental selective pressure to which *C. jejuni* is exposed.

Overview of Selected Molecular Subtyping Methods

As discussed in the section above, *C. jejuni* has considerable genetic diversity. According to Wassenaar and Newell (51), a combination of subtyping methods might

be required for studying *C. jejuni*, because diversity and recombination levels might render the use of a single typing method of limited value when applied in an epidemiologic context. Since the 1980s, subtyping of *C. jejuni* for public health and food safety purposes has benefited from the emergence of various genotypic typing methods. Table 10.2 highlights the main features of some of the commonly used genotypic typing methods for *C. jejuni*.

Contribution of Subtyping to Understanding *Campylobacter* Epidemiology

Over the past 2 decades, molecular subtyping of *Campylobacter* spp. has provided valuable clinical and epidemiologic insights, some of which are described below.

Discriminatory Power of Typing Methods for *C. jejuni* and *C. coli*

Overall, pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST) generated typing results that had a better correlation with the geographic location of the isolates in comparison to other typing methods summarized in Table 10.2. PFGE and MLST exhibited a better discriminatory power for *C. coli* isolates than repetitive extragenic palindromic PCR or restriction fragment length polymorphism of the *flaA* gene (*flaA*-RFLP) (52). Duarte et al. (53) compared five different typing methods, i.e., MLST, *flaA*-RFLP, antimicrobial resistance profiling, determination of the presence or absence of five putative virulence genes, and, exclusively for *C. jejuni*, determination of LOS class for use in the monitoring of *C. jejuni* and *C. coli*. It was shown that MLST was individually the most discriminative typing method for both *C. jejuni* and *C. coli*, whereas the most discriminative method for both *C. jejuni* and *C. coli* was obtained by combining MLST with *flaA*-RFLP. This approach of combining MLST with variable gene sequence typing had been described before (17). Another study demonstrated that although multiple-locus variable-number tandem-repeat analysis has slightly higher discriminatory power than MLST, it is better to use this method as a prescreening method in epidemiology before employment of MLST for analyzing a large population of *C. jejuni* (54).

Recently, multiplex ligation-dependent probe amplification–binary typing (MBiT) was used as a novel method for subtyping of *C. jejuni* and *C. coli*. This study revealed that MBiT not only is a time-saving method (results produced within 6 h) but also is more rapid and cost-effective than both PFGE and MLST. Moreover, it has been found that MBiT is more discriminatory than MLST and requires only basic molecular biology equipment and skills (55). Instead of using fragment-based typing methods (such as PFGE or *flaA*-RFLP) or sequence-based typing methods (such as MLST), nowadays whole-genome sequencing (WGS) and subsequent bioinformatic analysis are being introduced into molecular epidemiological studies. The WGS approach has the ability to provide nearly complete genotype information for the isolates analyzed. The data are not limited to revealing the presence or absence of virulence factors or antimicrobial resistance genes but can provide insights into the molecular evolutionary forces behind these very important genotypes.

Table 10.2 Molecular subtyping assays for *Campylobacter*

Method	Typeability	Discriminatory power	Convenience	Practical considerations
flaA-RFLP	Almost 100%	Fair; can be enhanced by combining patterns of restriction enzymes (e.g., DdeI with HinfI).	Quick (<24 h) and simple PCR-based (equipment is becoming widely available) High-throughput analysis	Targets one polymorphic gene; thus, the technique is widely criticized for being vulnerable to genetic instability. Of important value in outbreak investigations, and could be used to predict MLST clonal complexes Internationally standardized protocol is available.
PFGE	95–100%; DNA methylation and DNase activity in some isolates can limit the action of restriction enzymes.	Good, and better than *flaA*-RFLP Using KpnI in addition to SmaI enhances PFGE discriminatory power.	Time-consuming (3 to 5 days; however, a 24-h protocol has been published) Low-throughput analysis Need specialized and expensive (initial setup) equipment	Analysis of results is difficult and includes the use of specialized software in combination with visual examination of bands on gel. Some reports indicate that PFGE is vulnerable to *C. jejuni* genetic instability, including point mutation, transformation, and plasmid acquisition or loss, which can lead to minor changes in band profile. Internationally standardized protocols are available.

Method	Typeability	Discriminatory power	Convenience	Practical considerations
MLST	100%	High	Automatable and high throughput Needs highly skilled operator and sequencing facility (failure on first run is frequently encountered) Costly; however, the price is rapidly declining.	Involves analysis of the DNA sequence for each isolate on a standardized panel of genes (seven for *Campylobacter*) that are chosen because they have an essential function (housekeeping genes) and are present in the vast majority of isolates Web-based free software is available for ease of result analysis and interpretation. Freely accessible online database is available. Direct comparison between different laboratories and different isolate collections is possible, which emphasizes its epidemiological importance.
MBiT	100%	Higher than MLST	Results produced within 6 h, more rapid and cost-effective than both MLST and PFGE	

Outbreak Investigations

PFGE has been useful in including or excluding cases of *Campylobacter* enteritis from outbreaks (56, 57). The most extensive use of PFGE to support outbreak investigation of *Campylobacter* enteritis has been within PulseNet, in which more than 2,500 profiles have been identified using standardized methods (58). Applying MLST to *Campylobacter* isolates from several outbreaks has been less discriminatory than PFGE in identifying which cases are outbreak related and which are not (59, 60). As of ca. 2015, next-generation WGS has also been shown to be a powerful tool for determining the relatedness of bacterial isolates in foodborne illness detection and outbreak investigations. However, WGS has rarely been used in smaller local outbreaks, such as those that often occur with *Campylobacter* spp. There was one study comparing PFGE, which since the inception of the CDC PulseNet program is the method of choice for bacterial “fingerprinting,” to WGS and a reference-free

bioinformatic analysis for retrospectively analyzing a specific outbreak of *C. jejuni* associated with raw milk in Utah (61).

The results of WGS and subsequent bioinformatic analysis correlated well with the PFGE and epidemiological outbreak investigation results. However, it was shown that PFGE has limitations compared to WGS. PFGE cannot indicate the phylogenetic relationships of isolates. PFGE lacked the resolution to determine the outbreak relatedness of all isolates, whereas the genomic approaches in the latter study indicate the phylogenetic relationships of the isolates, as well as providing nearly complete genotypic information for each isolate. A significant benefit of the selected WGS bioinformatic analysis in the latter study was that a reference genome sequence was not needed. This reference-free analysis removes the critical step of selecting the genome sequence of a closely related organism, which can dramatically affect the outcome of an analysis (62). Additionally, the bioinformatic analysis used is not reliant on curated MLST databases. As such, the selected reference-free approach not only allowed the resolution of relationships between highly similar bacterial isolates but also allowed the analysis of isolates that may not have representation in an MLST database or highly divergent strains that may not have an available reference genome sequence. The reference-free analysis allows the addition of historical sequence data and other known sequences to provide context for the analysis. The addition of these historical or known sequences allows the surveillance of pathogens associated with foodborne illnesses, the detection of possible outbreak clusters, and the surveillance of outbreaks over long periods and in relation to known sources of contamination. The genotypic information generated by WGS can be further exploited to gain insights into virulence factors, antimicrobial resistance, and molecular evolution for outbreak-associated isolates (61, 62).

Host Association

Recent findings from MLST-based studies have provided evidence for possible association of certain *C. jejuni* subtypes with specific hosts. Interestingly, the association between *Campylobacter* subtypes and certain hosts has shown a robustness to even large geographic distances. For example, relationships have been observed between clonal complex 61 (CC-61) and cattle, CC-257 and poultry, and CC-403 and pigs and also, perhaps less stringently, between CC-45 and poultry and wild birds and between CC-42 and sheep (2, 63–65). Despite the fact that some *C. jejuni* clonal complexes show consistent associations with certain hosts, others, such as CC-21, are widely distributed in multiple hosts (e.g., farm animals, humans, pets, wild birds, and environmental samples). Differences in the composition of intestinal mucin in various hosts play a significant role in the result of *Campylobacter* infection of these hosts (66).

Source Attribution

The philosophy behind the source attribution approach is that control of *Campylobacter* in the reservoir will prevent subsequent human exposure, regardless of the transmission route or vehicle identity. DNA-based subtyping studies, especially

those considering regional and temporal aspects in the study design, provided important insight into sources of clinical strains of *C. jejuni*. For example, in a study in New Zealand it was observed that *C. jejuni* PFGE subtypes of human origin closely matched subtypes from chicken meat, compared to isolates from other veterinary and environmental sources (67). Also, in Finland, Hänninen et al. (68) concluded that, based on PFGE typing, chicken meat was the most important source of human infection over 3 consecutive years in the Helsinki region. In the same study, certain PFGE types persisted throughout the 3-year period, suggesting that common Finnish *C. jejuni* genotypes from selected lineages are able to colonize both humans and chickens and that these genotypes persist from one year to another. Furthermore, findings of other DNA-based typing studies suggest a role of farm animals and wildlife hosts in *Campylobacter* infection of humans and colonization of broiler flocks (69–71).

Despite the value of DNA-based subtyping studies, conclusions from these studies are limited to a crude and qualitative indication of an overlap between clinical cases and infection source strains of *Campylobacter*. Some model-based approaches are increasingly being considered to quantify source attributions of *C. jejuni* clinical strains based on MLST data. For example, Wilson et al. (72) developed an evolutionary probability model to trace the sources of 1,231 human campylobacteriosis cases in England based on MLST data. The assignment probability estimated that chicken is the source of infection in most (56.5%) of the cases, followed by cattle (35.0%) and sheep (4.3%). Additionally, Mullner et al. (73) used MLST data as prior information in a Bayesian modeling approach to estimate the contribution of *C. jejuni* from different food animals to human illness in New Zealand. They estimated that of the 474 human cases, 379 (80%) were attributable to poultry, 48 cases (10%) to bovines, 44 cases (9%) to ovines, and 4 cases (1%) to the environment. These models highlight the fact that source contribution can vary widely depending on the geographical location and modeling approach. In addition, these models reveal that MLST provides a good degree of subtyping resolution that can be used in source attribution of *Campylobacter* enteritis.

Reservoir attribution of human *Campylobacter* enteritis can provide guidance to risk managers and policy makers on the implementation and evaluation of control strategies for major reservoirs of *Campylobacter* (74). It has been estimated that cecal contents of domestic and wild birds, as the main reservoir of *Campylobacter*, carry up to 10^{10} CFU *Campylobacter* per g, which can be transmitted from the intestines of poultry to meat during processing (75–77). Moreover, water is one of the main sources of *Campylobacter*. Although this pathogen can survive in water for long periods, especially at 4°C, finding modeling data to predict the survival characteristics of these organisms in water seems necessary (78).

CAMPYLOBACTER ASSOCIATION WITH FOODS

Campylobacter enteritis in humans is characterized by a large number of sporadic cases rather than single-source outbreaks. Infection can be acquired by a number of routes. However, *Campylobacter* enteritis in humans is considered to be mainly

foodborne. Campylobacteriosis has been attributed to the consumption of several kinds of food, including raw or undercooked meat, especially poultry meat, raw milk, contaminated water, and seafood. Additionally, other risk factors, including cross-contamination during preparation of ready-to-eat foods like vegetables, as well as direct contact with feces from infected animals, including domestic pets, have been reported as the sources for human campylobacteriosis (2, 79, 80).

As a common inhabitant of the gastrointestinal tract of warm-blooded animals, *Campylobacter* can contaminate foods in different ways. *Campylobacter* contaminates meat when carcasses (e.g., poultry and beef) come into contact with intestinal contents during slaughter and evisceration (11, 81). According to the European Food Safety Authority (82), the proportion of human campylobacteriosis cases attributed by microbial subtyping to chicken as a reservoir ranges between 50 and 80%. In comparison, attribution of human cases during case-control studies suggests that a lower proportion, 24 to 29%, can be attributed to the consumption of chicken meat. The apparent discrepancy between the results of these different attribution methods could be associated with several factors. Case-control studies assign attribution at the point of exposure, while subtyping studies assign it at the reservoir level. Molecular subtyping studies (often based upon MLST genotyping) may overestimate the importance of chicken due to incomplete data on other reservoirs, such as pets and wild birds. If more data on the diversity of strains in such reservoirs became available, a larger proportion of human cases might be linked to these reservoirs. Furthermore, strains from the chicken reservoir may reach humans by pathways other than via meat (e.g., via the environment or direct contact), and poultry-associated strains can also colonize other hosts, such as cattle, pigs, and pets. Conversely, case-control studies may underestimate the true attributable risks due to inaccurate exposure assessment and to confounding by acquired immunity. Still, among food sources, chicken and other poultry (in particular undercooked meat and meat in restaurants) constitute an important risk factor.

In the European Union, in 2016, few member states reported monitoring the presence of *Campylobacter* in food; if analysis was performed, it considered mainly fresh meat from broilers and turkeys and their meat products. In these foods, the occurrence was, respectively, 36.7% and 11% in fresh meat from broilers (n = 11,495) and fresh meat from turkeys (n = 1,505). The occurrence of *Campylobacter* was comparable between milk products and cheeses and was reported to be around 1% (n = 1,616) (83). Milk can be contaminated with *Campylobacter* as a result of fecal contamination on the farm. Most cases of *Campylobacter* enteritis attributed to milk or cheese have involved raw milk or homemade unpasteurized fresh or soft cheeses, because *Campylobacter* cannot survive proper pasteurization (84). Thoroughly processed dairy products (e.g., hard cheese and powdered milk) pose a limited threat due to the low resistance of *Campylobacter* to conditions of reduced pH and water activity.

Eggs do not appear to be an important source of *Campylobacter*, despite its frequent occurrence in poultry (85). The dry surface of the egg does not favor *Campylobacter* survival, and egg albumen has been shown to exhibit bactericidal properties. Results of some surveys on the presence of thermotolerant *Campylobacter* strains in different

food categories are presented in Table 10.3. In a European Union baseline survey carried out in 2008, *Campylobacter* was found in the intestines of 71% of chickens, indicating that they were already colonized when alive, and on 76% of sampled carcasses, which suggests some further contamination during slaughtering (86). But many studies have shown that much of the world's poultry meat is often contaminated with campylobacters.

Table 10.3 Examples of surveys on the prevalence of thermotolerant *Campylobacter* in different foods

Food source	Country (reference)	Sampling	No. positive/no. tested (%)
Poultry meat	Belgium (156)	Chicken meat preparation, processing	315/656 (48.02)
	England (203)	Chicken carcass, retail	199/241 (83.0)
	Ethiopia (204)	Chicken carcass, retail	160/220 (72.7)
	France (15)	Poultry meat, retail	53/70 (75.7)
	Germany (105)	Chicken fillet, retail	87/100 (87.0)
	Iran (205)	Chicken carcass, slaughter	186/336 (55.4)
	Japan (206)	Chicken meat and products, retail	110/170 (64.7)
	New Zealand (207)	Poultry meat, retail	204/230 (89.1)
	Poland (139)	Poultry carcass, slaughter	464/625 (74.2)
	The Netherlands (208)	Broiler breast skin, slaughter	1,447/3,680 (39.6)
	Turkey (209)	Chicken products, retail	106/127 (83.4)
	United Kingdom (210)	Chicken carcass, retail	616/877 (70.2)
	United States (211)	Broiler carcass, slaughter	1,094/4,200 (26)
	Estonia (151)	Chicken carcass, retail	98/517 (18.9)
	Philippines (212)	Chicken carcass, retail	57/120 (47.5)
	Italy (213)	Poultry meat, slaughter and retail	161/472 (34.1)
	Brazil (214)	Chicken carcasses, retail	18/92 (19.56)
	United States (215)	Chicken livers and gizzards, retail	136/202 (67)
	Iran (205)	Chicken carcass, processing	186 of 336 (55.4)
	Iran (216)	Poultry meat, retail	106/260 (40.8)
Raw milk	Ireland (217)	Raw cow's milk, bulk tank sampling	1/62 (1.6)
	Pakistan (218)	Raw cow's milk, bulk tank sampling	13/127 (10.2)
	Spain (219)	Raw cow's milk, bulk tank sampling	35/98 (36.0)
	Switzerland (220)	Raw goat's milk, bulk tank sampling	0/344 (0.0)

Food source	Country (reference)	Sampling	No. positive/no. tested (%)
	United States (221)	Raw cow's milk, bulk tank sampling	5/248 (2.2)
	Iran (216)	Raw cow's milk	7/80 (8.7)
	United States (222)	Raw cow's milk, bulk tank sampling	27/234 (11.5)
	Tanzania (223)	Raw cow's milk, vendors selling milk and bulk tanks	38/284 (13.4)

The concept of poultry meat being the prime source of human campylobacteriosis has been only partially supported by indirect epidemiologic evidence, because most human cases are sporadic and difficult to trace to a specific source. In Belgium, poultry was withdrawn from the market during the summer of 1999 in response to dioxin contamination in the preharvest sector. Subsequently, there was a 40% reduction in human cases of campylobacteriosis enteritis (87). Furthermore, in The Netherlands, during an avian influenza outbreak in 2003, 1,300 commercial and >17,000 noncommercial poultry flocks (more than 30 million birds) were culled. Concurrently, there was a 40% reduction in human campylobacteriosis enteritis cases during the months of culling compared to the same period in prior years (88).

Campylobacters extensively colonize the poultry cecum, large intestine, and cloaca but are generally restricted to the mucus layer in the crypts of the intestinal epithelium at these locations (89). The nature of the association between *Campylobacter* and poultry can be attributed to certain adaptation mechanisms. First, it has been suggested that the microaerobic nature of *Campylobacter* is probably a reflection of the limited oxygen concentration encountered in the avian gut (11). Second, the optimal growth temperature of the thermotolerant campylobacters (42°C) mirrors that of the avian gastrointestinal tract, which differs considerably from that of the mammalian gut (37°C) (11, 49). Third, the motility and chemotactic behavior of *C. jejuni* play a role in colonization of the chick gastrointestinal tract, because the organisms are preferentially attracted to fucose components of the chick's intestinal mucin. Fourth, campylobacters might have evolved mechanisms to overcome nutritional limitations while colonizing the avian gastrointestinal system. One of these mechanisms is the ability to acquire iron from both the avian host and the gastrointestinal flora. *C. jejuni* is able to utilize host-derived hemin and hemoglobin, and some *C. jejuni* strains have transport systems that enable them to scavenge siderophores (high-affinity iron compounds) generated by other members of the gastrointestinal flora (90, 91). Although there are several reports indicating a common presence of *C. jejuni* in *Campylobacter*-positive broilers (92, 93), recent investigations have revealed that *C. coli* can also be common in these birds (94, 95).

Campylobacter is primarily a surface contaminant and can be retained with water on the poultry skin, eventually entering openings and crevices in the skin (96). Campylobacters that enter skin crevices and feather follicles may be difficult to remove because of capillary action or irreversible attachment to the skin tissue (97). These sites can provide a suitable microenvironment for the survival of *Campylobacter* in chicken skin. Moreover, some components within the surface structure of chicken skin, such as proteins, fatty acids, and oils, can enhance the survival of campylobacters by hindering the formation of ice crystals in frozen poultry meat (98, 99). The reported *Campylobacter* counts on fresh poultry carcasses and products (e.g., fillets) can vary

from none or less than 1 to 6 $\log_{10}$ CFU/g, depending on the study settings and testing methods (2, 38, 100–103). Hence, once poultry contaminated with *Campylobacter* is introduced into the kitchen, it can serve as a focal point for cross-contamination (104). In addition, irrespective of the transfer route, *Campylobacter* cells initially present on chicken breast fillets can be transferred efficiently to prepared foods (2, 104, 105). This efficient transfer potential emphasizes the importance of taking measures to prevent cross-contamination during food handling as long as the incidence of *Campylobacter* on chicken products remains high.

CLINICAL ASPECTS OF HUMAN ILLNESSES

High rates of campylobacteriosis translate into substantial social and economic costs. Gellynck et al. (106) estimated that the cost for 2004 of *Campylobacter* enteritis and sequelae in Belgium was €27.3 million. In The Netherlands, the incidence of *Campylobacter* enteritis for 2000 was estimated to be 500 cases per 100,000 people, resulting in a total social cost of €21 million (107). In the United States, the economic burden from health losses due to this pathogen was estimated at $1.56 billion (108). In the United Kingdom, estimated costs to patients and the health care system were £50 million for *Campylobacter* enteritis, while the cost of hospitalization for *Campylobacter*-related Guillain-Barré syndrome was £1.26 million (109). A careful estimation of the *Campylobacter* enteritis disease burden should consider the impact of both intestinal illness and extraintestinal illness and its complications.

Intestinal Illness

More than 90% of human cases of campylobacteriosis cases can be attributed to *C. jejuni* and, to a lesser extent, *C. coli* (11, 81). However, enteric illnesses due to *C. jejuni* and *C. coli* are clinically indistinguishable. Gastroenteritis is the most common clinical presentation seen in humans infected with *C. jejuni*. Following an incubation period typically on the order of 24 to 72 hours, an acute diarrheal illness develops and is commonly followed by a nonspecific syndrome of fever, chills, myalgia, and headache, in addition to abdominal cramping. Patients typically have 8 to 10 bowel movements a day at the peak of illness. The diarrhea can range from loose and watery to bloody, and leukocytes and erythrocytes are present in most cases, whether or not blood is voided in the stool (110–112). A few reports are available on the infective dose of *C. jejuni*, which is believed to be as low as a few hundred bacteria. In two studies of experimental infections in humans, *C. jejuni* caused illness with oral doses of 500 CFU (113) and 800 CFU (114). The enteric illness was self-limiting and resolved within a week in most individuals. However, extended illness can occur, particularly in individuals with underlying illness (111, 112).

In many areas of the world, human campylobacteriosis cases are reported throughout the year but peak during the summer. The mechanisms behind this phenomenon are poorly understood; however, ambient temperature is hypothesized to play a role in this seasonal trend. A recent investigation in Japan (115) showed effects of climatic elements on *Campylobacter* colonization in broiler flocks. There was a positive

correlation between *Campylobacter* colonization in chickens and increasing temperature, which can be associated with the effect on the *Campylobacter* environmental sources and/or vectors. Additionally, humidity also exhibited a positive correlation with *Campylobacter* colonization. It was shown that during the period of decreasing temperature, high humidity can be a fundamental factor for *Campylobacter* infection. Furthermore, similar to humidity, solar radiation, like other climatic elements, showed a negative correlation with temperature, which can promote *Campylobacter* colonization during the period of reducing temperature (115).

A study in England revealed a linear relationship between mean weekly temperature and reported *Campylobacter* enteritis cases, with a 1°C increase corresponding to a 5% increase in the number of reports up to a threshold of 14°C (116). In addition, some studies attribute the seasonality of *Campylobacter* enteritis cases to variation in human behavior during the summer months, such as increased outdoor activities (e.g., barbecuing and swimming). Seasonal variation in the occurrence of *Campylobacter* in poultry flocks is also suggested to play a role in the seasonality of human cases (116). The numbers of *Campylobacter* in the small intestines and ceca of broilers have a seasonal pattern, with a distinct peak in the summer (117, 118). Also, it is hypothesized that temporal distribution of human cases of campylobacteriosis could be a function of the growth kinetics of one or more fly species that become more active in the summer months (119, 120).

The development of protective immunity has been documented in volunteer infection studies in which individuals challenged with a particular *C. jejuni* strain were protected from disease (but not reinfection) when rechallenged with the same strain (114). Studies of poultry abattoir workers have revealed that they develop antibody responses during their employment. Long-term workers may asymptomatically shed *C. jejuni* in their feces, unlike new workers, who develop clinical signs of *C. jejuni*-associated gastroenteritis (121). Recently, Tam et al. (122) determined in a case-control study that the risk for illness associated with recent chicken consumption was much lower for persons who regularly ate chicken than for those who did not, suggesting that partial immunological protection against enteric illness may follow regular chicken preparation or consumption. Hence, it may be necessary to assess the relative importance of immunity and behavioral factors when one is determining the risk of acquiring a *Campylobacter* infection (123).

Extraintestinal Illness

Occasionally, individuals infected with *C. jejuni* present with a pseudoappendicitis syndrome and do not have diarrhea. Furthermore, *Campylobacter* enteritis may play a role in the induction of irritable bowel syndrome and inflammatory bowel disease (124). Several reports indicated the positive relation between *Campylobacter* spp. and inflammatory bowel diseases such as Crohn's disease and ulcerative colitis (125). Other organ systems can also be affected following *C. jejuni* infection; however, the incidence of extraintestinal manifestations associated with *C. jejuni* infection is very low compared to the incidence of the enteric disease (111, 126). Furthermore, HIV/AIDS patients have exhibited symptoms including persistent diarrhea and severe bacteremia

when infected by *Campylobacter* spp. (127). This can be one of the main reasons of increasing morbidity and mortality caused by *Campylobacter* among HIV-positive individuals, particularly in the developing world (128).

To date, Guillain-Barré syndrome (GBS) is the most extensively studied extraintestinal manifestation associated with *C. jejuni* infection. GBS is the most common form of acute neuromuscular paralysis since the near-worldwide eradication of poliomyelitis, with an annual incidence of 1 to 2 per 100,000 population in many parts of the world (129). Symptoms generally begin with motor and sensory deficits of the lower extremities, which can subsequently spread to upper extremities and the trunk; this can lead to the need for ventilatory support. Most GBS patients recover completely, but others can be left with severe neurological impairment (130, 131). It is now known that in most cases in which a specific pathogen is identified, *C. jejuni* is the most frequently reported etiologic agent associated with GBS cases (Table 10.4).

Table 10.4 Prevalence of production of antibodies to *Campylobacter jejuni* in patients with GBS

Study	No. positive/no. tested(%)	Detection procedure
Islam et al. (234)	54/97 (56)	Serology testing
Barzegar et al. (235)	23/48 (48)	Serology testing
Nachamkin et al. (236)	32/78 (41)	Serology testing
Takahashi et al. (237)	113/1,049 (11)	Stool culture testing
Sinha et al. (26)	19/80 (26)	Serology testing
Hadden et al. (238)	53/229 (23)	Serology testing

It has been hypothesized that patients who suffer from GBS following *C. jejuni* infection develop antibodies against certain classes of the bacterial LOS that cross-react with peripheral nerve cell surface gangliosides (110, 132).

ANTIMICROBIAL-RESISTANT *CAMPYLOBACTER*

Antimicrobial intervention is recommended only in campylobacteriosis cases with severe and/or prolonged enteritis, septicemia, or extraintestinal complications (133). Ternhag et al. (134) determined through a meta-analysis of clinical trials that antimicrobial therapy shortened the carrier state of *Campylobacter* species in the human intestinal flora. In cases where *Campylobacter* infections need to be treated, macrolide antibiotics such as erythromycin are the first choice of treatment. Fluoroquinolones such as ciprofloxacin are also recommended, but the treatment is challenged by a higher prevalence of resistance against this antibiotic than against erythromycin (Table 10.5). Moreover, the rate of resistance to erythromycin and to an lesser extent to ciprofloxacin is higher within the species *C. coli* than *C. jejuni*. Also, the country or region has a clear correlation with the prevalence of resistance to both antibiotics (Table 10.5).

Development of resistance to macrolides in *C. jejuni* and *C. coli* may be due to different events, such as target mutations in 23S rRNA genes and in ribosomal proteins encoded by *rpID* and *rpIV*, ribosomal methylation encoded by *erm*(B), and multidrug efflux pumps, which can confer on *Campylobacter* strains high-level resistance (>512 μg/ml) to erythromycin. More details about those events can be found in the review by Bolinger and Kathariou (135). The effects of macrolide-resistant *Campylobacter* on human health have been determined in only a small number of studies. For instance, a Danish cohort study estimated an increase in the risk of invasive illness and death following infection with macrolide-resistant *Campylobacter* strains compared to susceptible strains (136). Development of resistance to macrolides in *Campylobacter* during therapy has not been documented in humans, and the origin of erythromycin-resistant strains has been linked to veterinary use of the macrolide-lincosamide group (137, 138).

Ciprofloxacin is widely regarded as a valuable antimicrobial therapy in severe cases of community-acquired bacterial diarrhea (133). Mutations in the gyrase gene (*gyrA*), most commonly at position 86 (threonine to isoleucine; ACT → ATT), are the principal mechanism conferring resistance in *Campylobacter*. Luo et al. (139) determined that *C. jejuni* strains gain increased fitness after acquiring this resistance-conferring mutation. The CmeABC multidrug efflux pump works in synergy with GyrA mutations. As a consequence, changes in the activation of this pump also have an effect on the fluoroquinolone resistance level (140).

Table 10.5 Prevalence[a] of erythromycin-and ciprofloxacin-resistant *Campylobacter* isolated from humans and broilers

Source of isolates	Country	Prevalence[a] of strains resistant to:	Erythromycin	Ciprofloxacin		
		C. *jejuni*	C. *coli*	C. *jejuni*	C. *coli*	Reference
Humans	EU countries[b]	1.5 (0-8.7)	14.4 (0-53.5)	60.8 (42.1-96.6)	70.6 (36.5-100)	239

Broiler meat	Belgium	0.7		53.1		244
	EU countries[b]	0.9 (0-3.7)	10.9 (0-72.7)	53.0 (20.0-75.0)	76.2 (36.4-100)	239

[a] Prevalence is reported as number of antibiotic-resistant *Campylobacter* strains/number of *Campylobacter* strains tested.

[b] Numbers in parentheses are the ranges found in European Union countries.

There is growing concern regarding the increase in resistance of *C. jejuni* to ciprofloxacin and other fluoroquinolones (141–143). Several studies have revealed that infections with fluoroquinolone-resistant *Campylobacter* in humans are associated with prolonged diarrhea (144–146). Hence, in areas of high incidence of quinolone-resistant organisms, fluoroquinolones are not recommended for treating community-acquired bacterial diarrhea, because campylobacters are often among the predominant causes (147). The use of fluoroquinolones (mainly enrofloxacin) in veterinary medicine is correlated with an increase in quinolone resistance in food animals, especially in poultry, and most importantly in human *Campylobacter* infections (142). A temporal association between the emergence of quinolone resistance and its increase in animals and humans following the introduction of enrofloxacin in animal production has been determined by several investigators (148, 149). These findings, along with risk assessment modeling, prompted the U.S. Food and Drug Administration to propose the withdrawal of fluoroquinolone use in poultry in 2000; a lengthy legal hearing

concluded with an order to withdraw enrofloxacin from use in poultry (effective in September 2005). However, it is important to note that the veterinary use of fluoroquinolones is not the only selective pressure that acts on *C. jejuni* to select for quinolone resistance. A number of studies have revealed that fluoroquinolone use in humans can lead to the emergence of quinolone-resistant campylobacters (24, 144, 145). In addition, some studies revealed significantly higher rates of quinolone resistance in travel-related *Campylobacter* infections than in domestically acquired infections (144).

Additionally, it has been revealed that the *tet*(O) gene is responsible for tetracycline resistance in *Campylobacter* isolates (150). The result of an investigation in Baltic countries indicated that resistance to tetracycline in *Campylobacter* isolates of human-origin was significantly higher than that in animal-origin isolates (151).

DETECTION OF *CAMPYLOBACTER* IN FOODS

Since it became clear that *Campylobacter* is a foodborne pathogen, methods to detect the occurrence of this bacterium in different types of samples were developed and used. Based on the fact that the risk for human infections is related to the number of ingested *Campylobacter* cells (and the number in food products), more and more attention is being given to the determination of the numbers of *Campylobacter* in samples, and direct enumeration (quantitative) methods are increasingly being used in monitoring and surveillance instead of presence/absence (qualitative) testing after enrichment.

To grow *Campylobacter* in the laboratory, preventive measures have to be taken to avoid the inhibitory effect of oxygen and its reactive derivatives. Therefore, most of the selective media used today include ingredients that quench the toxic effect of oxygen derivatives on campylobacters, such as lysed blood, charcoal, hemin, or hematin and a combination of ferrous sulfate, sodium metabisulfite, and sodium pyruvate; the generation of a microaerobic atmosphere, containing 5 to 10% carbon dioxide and 3 to 5% oxygen, for culturing is also required (85).

Enumeration Methods

For enumeration of campylobacters, direct plating on modified charcoal cefoperazone deoxycholate agar (mCCDA) is a reliable alternative to the most-probable-number method (152). In addition, Rosenquist et al. (153) determined through a collaborative study that direct plating on mCCDA is an acceptable protocol for enumeration of thermotolerant *Campylobacter* on chicken meat. Oyarzabal et al. (154) determined that mCCDA and modified Campy-Cefex agar yielded comparable results for enumerating *Campylobacter* spp. from poultry carcass rinses. mCCDA is currently the medium recommended by the International Organization for Standardization (ISO) for enumeration of *Campylobacter* spp. in the food chain (155). A disadvantage of mCCDA is the partial or total swarming of bacteria, including *Campylobacter*, making counting impossible or difficult (156, 157).

As for other pathogens, chromogenic selective agar media are available on the market, such as CampyFood agar (bioMérieux, Marcy l'Étoile, France), RAPID 'Campylobacter agar (Bio-Rad, Marnes-la-Coquette, France), Brilliance CampyCount Agar (Oxoid, Basingstoke, United Kingdom), and CHROMagar *Campylobacter* (CHROMagar, Paris, France). For broiler meat, counts obtained using CampyFood Agar and RAPID 'Campylobacter agar were similar to those obtained with mCCDA (156, 157), whereas Ahmed et al. (158) found significantly lower *Campylobacter* counts on CampyFood agar than on mCCDA for artificially contaminated samples, and they also found that the recovery rate on different media differed with *Campylobacter* species. Only RAPID'Campylobacter agar totally inhibited the growth of background microflora (157). Swarming on those two media could be prevented through a long drying period (more than 30 min) before inoculation.

Detection Methods

Detection after enrichment is required for recovery of a low number of *Campylobacter* organisms. The formulation of enrichment broth media has been modified to avoid inhibitory effects on *Campylobacter* by components in the broth formula. Corry et al. (85) reviewed the historical developments in culture-based procedures for detection of campylobacters.

The new ISO 10272-1:2017 standard (155) describes methods for the detection of *Campylobacter* not only in food and feed samples but also in the primary production stage (Fig. 10.1). This ISO method encompasses three procedures: procedure A is enrichment in Bolton broth; procedure B is enrichment in Preston broth, and procedure C is plating on mCCDA without a previous enrichment step. Enrichment in Bolton broth is the standard isolation procedure. When problems with background flora resistant to third-generation beta-lactam antibiotics are suspected, procedure B can be included. After enrichment, plating on selective agar media is carried out, followed by identification of presumptive colonies. Bolton broth is also recommended by the U.S. Food and Drug Administration for the isolation of *Campylobacter* species from food and water (159).

It is likely that no single method is ideal for the entire range of types of samples to be tested. Various studies focused on the effect of enrichment media or selective agar media on the detection efficiency of *Campylobacter* in samples collected from broiler production chain. Baylis et al. (160) compared Bolton broth, Preston broth, and *Campylobacter* enrichment broth. This study revealed that Bolton broth was the best compromise between recovery of *Campylobacter* from naturally contaminated food samples and inhibition of competitors. However, the same study also revealed that *Escherichia coli* and *Pseudomonas* spp. were frequently isolated from Bolton broth. The efficiency of detection methods is clearly influenced by the combination of enrichment broths and selective agar media used for the detection of *Campylobacter* in broiler meat samples (161). In this study, the number of positive samples increased considerably through the replacement of mCCDA by CampyFood agar as selective agar medium after enrichment in Bolton broth, while after enrichment in Preston broth, the type of selective medium had no influence on the detection rate. Moreover, this study

demonstrated that for samples containing fewer than 10 CFU/g, the use of CampyFood agar instead of mCCDA after enrichment in Bolton broth made it possible to double the number of positive samples.

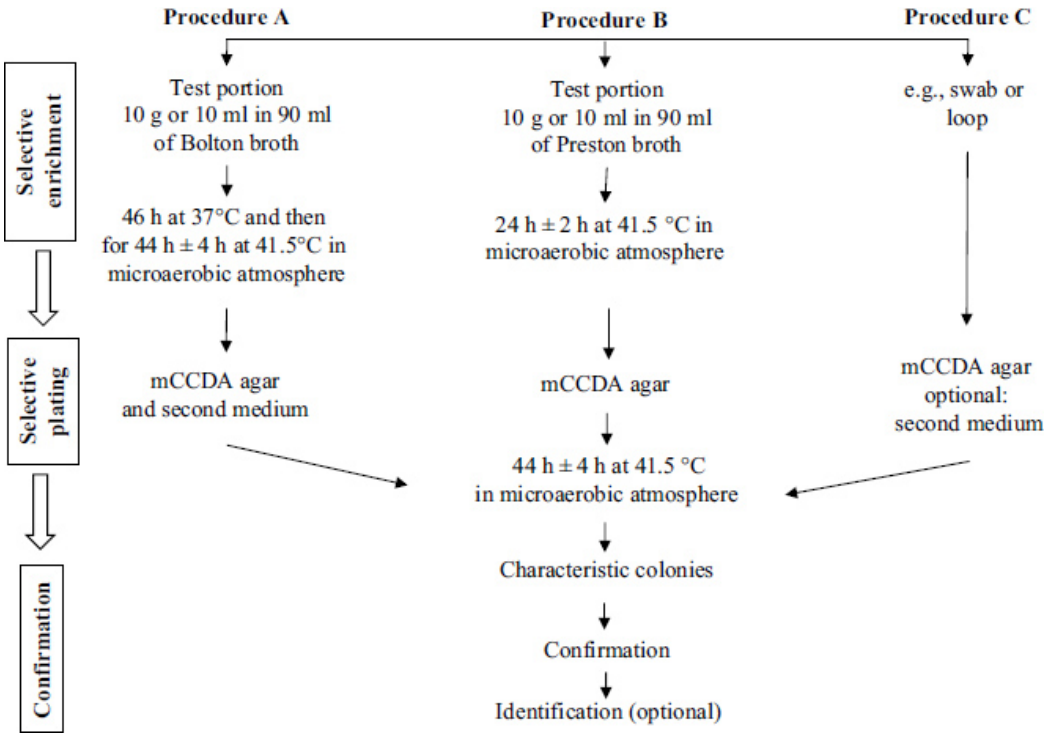

Figure 10.1 ISO 10272-2:2017 method for the detection of *Campylobacter* spp. in the food chain.

Jasson et al. (162) demonstrated that extended-spectrum-beta-lactamase-producing *E. coli* was able to grow in Bolton broth. Since the same antibiotic (sodium cefoperazone) is used in mCCDA as in Bolton broth, such *E. coli* strains may be able to crowd the mCCDA plates, resulting in the inability to discover suspected *Campylobacter* colonies on medium. Therefore, replacement of mCCDA by a selective agar medium containing other inhibitory substances is recommended. It has also been suggested to adapt the Bolton supplement so that the growth of extended-spectrum-beta-lactamase-producing *E. coli* can be prevented (163, 164). Assessment of the effect of Bolton broth supplemented with potassium clavulanate, triclosan, or polymyxin on the isolation of *Campylobacter* from poultry meat indicated that higher numbers of positive samples were obtained when the enrichment broth was supplemented with potassium clavulanate or triclosan, whereas addition of polymyxin led to an extensive reduction of the number of positive samples (165). Smith et al. (166) restored the selectivity of mCCDA successfully by the addition of tazobactam to the medium in an experimental setup.

PCR-Based Methods

In recent years, alternative methods have been developed for detection of *Campylobacter* spp. in foods. Conventional PCR is now routinely used for the detection

and identification of *Campylobacter*, and numerous methods with various levels of accuracy and sensitivity, depending on the specificity of the targeted regions of the genome, have been published (14, 16). For detection of the genus *Campylobacter*, a highly conserved region of the 16S rRNA is the target for the PCR, whereas more specific loci are used for the detection of particular *Campylobacter* species (167–169).

Real-time PCR (RT-PCR) has been developed for qualitative and quantitative detection of campylobacters in food samples, and some of these methods have been commercialized. The quantitative dimension of RT-PCR is based on correlating the number of cycles required to reach the threshold value with the initial number of campylobacters in the sample. However, the threshold limit of quantification of these RT-PCR methods ranges from 2 to 3 log CFU/g, which could result in false-negative results (170). Another drawback of PCR-based detection methods is that many research groups have developed specific protocols that work well in their own laboratories but do not allow comparison of results between laboratories using different protocols. Hence, interlaboratory proficiency tests, collaborative trials, and standardized protocols are urgently needed for these alternative methods.

In contrast to classical culture methods that detect living bacteria that can grow, genome-based methods detect DNA from live and dead bacteria. This feature might present interpretation difficulties when the method is used for analysis of food and environmental samples. It has been proposed that treating samples with propidium monoazide (PMA) prior to quantitative PCR (qPCR) could ensure the quantification of only viable cells with intact membranes. PMA can intercalate into the double-helical DNA available from dead cells with compromised membranes, and upon extensive visible light exposure, cross-linking of the two strands of DNA occurs, leaving it unavailable for PCR amplification (171). However, it has been demonstrated that the PMA-qPCR does not fully reduce the signal from dead cells, although if the remaining PMA-qPCR signal was associated with viable cells, this related to unacceptably high numbers of campylobacters being present in the initial sample (172, 173).

Optimization of molecular methods to the level at which they would enable reliable *Campylobacter* quantification reduces both the time and cost requirements, as well as facilitating *Campylobacter* surveillance throughout all stages in the food production chain (174).

CAMPYLOBACTER CONTROL IN THE FOOD CHAIN

Control of *Campylobacter* at the Farm Level

As described previously, direct and indirect epidemiologic data indicate that poultry meat is the most important source of human cases of *Campylobacter* enteritis (175). This evidence provides the justification for focusing control measures primarily along the poultry meat processing chain. Poultry-related interventions at the primary production stage have been proposed. Two types of interventions at the farm level can be identified, namely, interventions intended to avoid the entry of *Campylobacter* into

poultry houses, leading to colonization of birds, and interventions meant to decrease the number of *Campylobacter* organisms in the intestines of colonized birds (176).

A wide range of risk factors contributing to the status of flocks have been identified (177, 178). Therefore, biosecurity (e.g., hand washing, fly screens, pest-proof buildings, and foot dipping) plays an important role. However, applying biosecurity interventions at poultry production sites has resulted in variable levels of success in different countries (179, 180). Such variation may be attributed to differences in the *Campylobacter* loads in the poultry chain and environment. Hence, the effectiveness of biosecurity-related interventions in primary production should be based on a good understanding of the regional risk factors at the farm level (181).

The use of antimicrobials to eliminate *Campylobacter* infection in flocks is not acceptable, since this may stimulate the development of resistant microflora, including *Campylobacter*, in the treated birds, with possible consequences for the treatment of patients. A wide range of approaches to reduce *Campylobacter* counts in colonized birds have been screened in recent decades. A first group of approaches consists of using products known to have an antimicrobial effect against *Campylobacter in vitro*, such as organic acids, medium-chain fatty acids, herb extracts, essential oils, and probiotics (182). A large number of these studies found significant reductions compared to the control groups, but in most of those cases, the reduction was limited to a 1-log-CFU reduction of the numbers in the ceca (183–186).

The effect of bacteriophages is still variable (no reduction of more than 2 log CFU). Moreover, the development of phage resistance in *Campylobacter* can reduce the effect of the treatment (187). Passive immunization by the addition of hyperimmune egg yolk to feed could reduce the *Campylobacter* counts in ceca by about 4 log CFU/g (188). Also, vaccination experiments are still not very successful, since only a 1-to 2-log-CFU reduction is obtained in the ceca. Recently preliminary tests with vaccine candidates demonstrated a reduction between 2 and 4 log CFU (77). Additional studies are needed to find treatments which result in a significant reduction of *Campylobacter* in the ceca not only under experimental conditions but also under field conditions. It has been estimated that a 3-log-CFU reduction of *Campylobacter* in the ceca would result in a more than 90% reduction of human infections related to poultry meat consumption (189).

Control of *Campylobacter* at the Slaughterhouse Level

In most cases, carcasses from *Campylobacter*-colonized flocks become contaminated during slaughter. Colonized birds carry *Campylobacter* not only in the intestines but also on feathers and skin, sometimes in high numbers (up to 6 log CFU/g and 5 log CFU/g, respectively) (190), when entering the slaughter process. Plucking and evisceration are steps potentially leading to an increase of the contamination level of carcasses, whereas final washing and air chilling can reduce the contamination (76, 190). Skin contamination after air chilling has been linked to the numbers present in the ceca, the transport and holding time before slaughter, and the frequency of rupture of the intestines (191). Slaughtering of positive flocks leads to contamination of the slaughter equipment. When a negative flock is slaughtered after a positive one,

carcasses of the former flock become contaminated, especially at the start of slaughter, and contamination decreases over time (192).

A European Union study performed in 2008 found that 53% of the tested broiler carcasses contained at least 10 CFU/g of neck skin, and 5.8% of the carcasses contained more than 10,000 CFU/g (86). Highly contaminated samples have been associated with a higher probability of causing human illness (105, 193). In the EU risk assessment, based on the collected baseline data of 2008, it was estimated that microbiological criteria with critical limits of 1,000 and 500 CFU/g of skin would lead to reductions of 50% and 90% of the health risk caused by poultry meat (176).

Therefore, in addition to primary interventions at the farm level, there is a need to apply interventions at the processing level in order to reduce the contamination of poultry meat meant for human consumption.

Freezing of contaminated poultry carcasses is a reliable intervention to achieve a 1-to 2-log-CFU reduction of *Campylobacter* counts. Compulsory freezing of processed broilers from *Campylobacter*-positive broiler flocks in Iceland resulted in substantial reductions in the number of human cases of *Campylobacter* enteritis and is currently being used on a voluntary basis in Norway, Sweden, and Denmark (153, 194, 195). However, worldwide, many consumers prefer to buy fresh poultry meat with no change in product quality. In addition, freezing meat from all *Campylobacter*-positive broiler flocks might not be a feasible option in many countries, as it would limit the marketing of domestically produced chilled meat and increase dependence on imported product. This dilemma highlights the need to apply multiple hurdles during postharvest processing in order to achieve low counts of *Campylobacter* on chicken meat (30, 31).

Some alternative physical decontamination technologies may also achieve a reduction in *Campylobacter* numbers. For example, Corry et al. (196) determined that crust freezing of chicken carcasses (based on rapid ice crystallization on the “meat surface” that results in a thin frozen crust, followed by temperature equalization) could reduce *Campylobacter* numbers by 2 log CFU. However, Boysen and Rosenquist (197) reported that crust freezing of broiler carcasses provided only a 0.42-log-CFU reduction in *Campylobacter* counts. Hence, the application of crust freezing needs to be optimized before it is widely adopted as a *Campylobacter* intervention. Another temperature-related intervention is the application of a steamultrasound treatment. A study in Denmark revealed that this technology could reduce *Campylobacter* counts by 2.5 log CFU on broiler carcasses (197). However, Musavian et al. (198) attained a reduction of only about 1 log CFU when treating naturally contaminated broiler skin. Irradiation allows a high reduction of bacteria, including *Campylobacter*, in food. However, this treatment is not accepted by consumers all over the world. Therefore, treatment of poultry meat with this method is not an option.

Chemical decontamination can also be an effective intervention for reducing the microbial load on carcasses. However, in the European Union, decontamination of poultry carcasses and meat using chemicals is not allowed. Chlorine, chlorine dioxide, acidified sodium chlorite, trisodium phosphate, and peroxyacid are typically used in poultry processing in the United States, either as sprays or washes for online

reprocessing or as additions to the chill water tank to reduce microbial contamination and to limit the potential for microbial cross-contamination. Trisodium phosphate solutions of 8 to 12% can reduce *Campylobacter* counts on chicken carcasses by 1.0 to 2.0 log CFU (199, 200). Treatment of chicken carcasses with chlorine compounds has also been extensively studied, but with varying results, depending on the compound and treatment regimen used in the processing plant. The use of electrolyzed water, of which hypochlorous acid is the principal active antimicrobial agent, has shown some potential under experimental conditions for reducing numbers of *Campylobacter* on broiler carcasses but needs additional evaluation under processing facility conditions (106, 201).

Application of lactic acid (2.5%) was highlighted as a cost-effective intervention strategy in a Dutch risk assessment study (193). However, lower concentrations are required, as the use of 2.5% lactic acid causes a yellow discoloration of the skin of chicken carcasses. Detailed research on appropriate treatment time and temperature and the effects of the food matrix on the antimicrobial activity of chemicals is still needed. In addition, more research may be needed on the toxicological, environmental, and food-sensory effects of chemical applications to carcasses.

Results of current risk assessment models are in agreement in showing that reducing the numbers of *Campylobacter* on broiler meat is highly effective in reducing the burden of illness (193). Because *Campylobacter* enteritis is a leading foodborne bacterial infection in many parts of the world, there is a need for setting targets (e.g., process hygiene criteria) for *Campylobacter* in the broiler meat chain. In 2017, the European Commission issued a regulation fixing process hygiene criteria for *Campylobacter* on broiler carcasses after chilling, which went into effect 1 January 2018 (202). The limit is set at 1,000 CFU/g of neck skin; in a first implementation step, 20 of 50 tested samples may contain more than the stated limit, but over time, the number of samples permitted to exceed the limit will be reduced to reach 10 samples in 2025. This legislation will force the poultry production industry to take actions. Therefore, more scientific research is needed so that appropriate and feasible interventions can be applied in the field.

CONCLUSIONS

Campylobacter species, and notably *C. jejuni*, are among the most common causes of human bacterial enteric illnesses worldwide. In the past decade, and after completion of the genome-sequencing project for multiple *Campylobacter* strains, more fundamental information became available regarding the diversity and pathogenesis of these intriguing bacteria. In addition, the application of discriminatory molecular subtyping tools (e.g., MLST and PFGE) was useful in clarifying some aspects of host association and source attribution. Evidence from epidemiological studies and molecular subtyping investigations has identified poultry meat as a major vehicle for foodborne transmission of *Campylobacter* enteritis. Future research and scientific collaborations among the medical, food, and veterinary professions are needed to substantially reduce *Campylobacter* contamination in the poultry meat chain.

Research directions should focus on practical control options that would be appealing to stakeholders in the farm, slaughterhouse, and processing sectors. In addition, there are opportunities for the development of enhanced *Campylobacter* detection and quantification methods. Methods for identifying highly contaminated samples through online detection would be very useful, as this could help in identifying and excluding highly contaminated samples from the human food supply chain.

We express our appreciation to HamidReza Sodagari (Ph.D. student at Murdoch University) and Dan Li (Ghent University), supported by a postdoctoral grant from the Research Foundation–Flanders (Fonds voor Wetenschappelijk Onderzoek–Vlaanderen), for their help with editing and layout of the text, tables, and references of this chapter.

Shiga Toxin-Producing *Escherichia coli*

Escherichia coli is a facultatively anaerobic, Gram-negative bacterium that is primarily present in the gastrointestinal tract of humans and warm-blooded animals. Although most commensal *E. coli* strains are harmless, many are pathogenic and cause a variety of diseases in humans and animals (1). Specific virulence attributes that have been acquired by such strains enable them to cause three principal types of infections in humans: intestinal gastroenteritis, urinary tract infections, and neonatal sepsis/meningitis.

E. coli isolates can be serologically or genetically differentiated based on three major surface antigens or their encoding genes, which enable serotyping: the O (somatic), H (flagellar), and K (capsule) antigens (2, 3). At present, more than 700 serotypes of *E. coli* have been identified based on O, H, and K antigens (4). It is considered necessary to determine only the O and the H antigens, not the K antigens, to serotype strains of *E. coli* associated with diarrheal disease. The O antigen identifies the serogroup of a strain, and the H antigen identifies its serotype. The application of serotyping to isolates associated with diarrheal disease has revealed that particular serogroups often fall into one category of pathogenic *E. coli*. However, some serogroups, such as O55, O111, O126, and O128, are in more than one category.

Pathogenic *E. coli* strains are categorized into specific groups (pathotypes) based on their virulence determinants. These virulence determinants include those controlling adhesions (CFAI/CFAII, type 1 fimbriae, P fimbriae, S fimbriae, and intimin), invasions (hemolysins, siderophores, siderophore uptake systems, and *Shigella*-like invasins), motility (flagella), toxins (heat-stable enterotoxin [ST] and heat-labile enterotoxin [LT], Shiga toxins [Stxs], cytotoxins, and endotoxins), antiphagocytic surface structures (capsules, K antigens, lipopolysaccharides), and genetic characteristics (genetic exchange through transduction or conjugation, transmissible plasmids, R factors, and drug resistance and virulence plasmids). The five categories of gastrointestinal pathogenic *E. coli* include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), enteroinvasive *E. coli* (EIEC), enteroaggregative *E. coli* (EAEC), and Shiga toxinproducing *E. coli* (STEC). This chapter focuses largely on the STEC group, which among the *E. coli* strains that cause foodborne illness is the most significant group based on the frequency of foodborne illness in the United States and the severity of illness. More information on other types of diarrheagenic *E. coli* is available in several review articles (5, 6).

EPEC

EPEC was the first pathotype of *E. coli* described and can cause watery diarrhea like ETEC, but these organisms do not possess the same colonization factors as ETEC and do not produce LT or ST. The major O serogroups associated with illness include O55, O86, O111ab, O119, O125ac, O126, O127, O128ab, and O142. Humans are an important reservoir. The original definition of EPEC is “diarrheagenic *E. coli* belonging to serogroups epidemiologically incriminated as pathogens but whose pathogenic mechanisms have not been proven to be

related to either enterotoxins, or *Shigella*-like invasiveness" (6). However, EPEC strains have been determined to induce attaching-and-effacing (A/E) lesions in cells to which they adhere and can invade epithelial cells. Some types of EPEC are referred to as enteroadherent *E. coli*, based on specific patterns of adherence. EPEC is an important cause of traveler's diarrhea in Mexico and in North Africa.

ETEC

ETEC is a major cause of infantile diarrhea in developing countries and regions with poor sanitation (5, 6). It is also the agent most frequently responsible for traveler's diarrhea but does not cause disease in the local adults because of developed immunity. ETEC colonizes the proximal small intestine by fimbrial colonization factors (e.g., CFAI and CFAII) and produces LT or ST, which elicits fluid accumulation and a diarrheal response. LT is similar to cholera toxin in both structure and mode of action, and ST is a peptide that causes an increase in cyclic GMP in host cell cytoplasm, leading to the same effects as those that occur with an increase in cyclic AMP. The most frequently isolated ETEC serogroups include O6, O8, O15, O20, O25, O27, O63, O78, O85, O115, O128ac, O148, O159, and O167. Humans are the principal reservoir of ETEC strains that cause human illness.

EIEC

EIEC causes nonbloody diarrhea and dysentery similar to that caused by *Shigella* spp. by invading and multiplying within colonic epithelial cells (5, 6). As with *Shigella*, the invasive capacity of EIEC is associated with the presence of a large plasmid (ca. 140 MDa) that encodes Several outer membrane proteins involved in invasiveness. The antigenicity of these outer membrane proteins and that of the O antigens of EIEC are closely related. EIEC strains do not produce LT, ST, or Stx. The principal site of bacterial localization is the colon, where EIEC invades and proliferates in epithelial cells, causing widespread cell death. Humans are a major reservoir, and the serogroups most frequently associated with illness include O28ac, O29, O112, O124, O136, O143, O144, O152, O164, and O167. Among these serogroups, O124 is the most commonly encountered.

EAEC

EAEC has recently been associated with persistent diarrhea in infants and children in several countries worldwide (5, 6). These *E. coli* strains are uniquely different from the other types of pathogenic *E. coli* because of their ability to produce a characteristic pattern of aggregative adherence on HEp-2 cells. EAEC organisms adhere to the surface of HEp-2 cells in a formation with the appearance of stacked bricks. Serogroups associated with EAEC include O3, O15, O44, O77, O86, O92, O111, and O127. A distinctive heat-stable, plasmid-encoded toxin has been isolated from these strains, called the EAST (enteroaggregative ST). EAEC also produces a hemolysin related to that produced by uropathogenic strains of *E. coli*. However, the roles of the toxin and the hemolysin in virulence have not been proven. More epidemiologic information is needed to elucidate the significance of EAEC as an agent of diarrheal disease.

Although EAEC has seldom been implicated in major foodborne disease incidents, there was a large outbreak in 2011 that was centered in Germany but affected various other countries in the European Union (7). This outbreak, suspected to have been caused by contaminated

sprouts, infected over 4,000 people, had a high hemolytic-uremic syndrome (HUS) rate (~23%), and resulted in 50 fatalities (8). The causative agent was identified as *E. coli* O104:H4 belonging to sequence type 678 (ST678), which produced Stx2a and therefore was considered a STEC strain (8–10). However, wholegenome sequencing (WGS) of the pathogen revealed that it shared 93% genomic homology with EAEC strain 55589 and also carried the *aggR* gene, which is a transcriptional activator essential for the expression of the aggregative adherence fimbriae (AAF) I and is found on an EAEC virulence plasmid. Hence, genetic analyses revealed that the causative pathogen was a multiantibioticresistant EAEC strain that had acquired the ability to produce Stx via phage conversion.

STEC

STEC was first recognized as a human pathogen in 1982, when *E. coli* O157:H7 was identified as the cause of two outbreaks of hemorrhagic colitis. Since then, many other serogroups of *E. coli*, such as O26, O111, O145, O45, O113, O121 (also known as the "big six") (11–13) and sorbitol-fermenting O157:NM, also have been associated with cases of hemorrhagic colitis and have been classified as STEC. However, serotype O157:H7 is the predominant cause of STEC-associated disease in the United States and many other countries. All STEC strains produce factors cytotoxic to African green monkey kidney (Vero) cells, factors which are hence named verotoxins or Stxs because of their similarity to the Shiga toxin produced by *Shigella dysenteriae* type 1 (14). Production of Stxs by *E. coli* O157:H7 was first reported in 1983 (15) and was subsequently associated with a severe and sometimes fatal condition, HUS (16). *E. coli* organisms of many different serotypes are capable of producing Stxs and hence are named Shiga toxin-producing *E. coli* (STEC). More than 600 serotypes of STEC have been identified, including approximately 160 O serogroups and 50 H types, and the list is still increasing (17). However, only strains that cause hemorrhagic colitis are considered enterohemorrhagic *E. coli* (EHEC), and at least 130 EHEC serotypes have been recovered from human patients.

Major non-O157 EHEC serogroups identified in the United States include O26, O45, O103, O111, O121, and O145 (18). In 2011, the U.S. Department of Agriculture Food Safety and Inspection Service (USDA FSIS) declared O26 and these five non-O157 STEC serogroups adulterants in ground beef and nonintact beef products, beginning testing for these pathogens in June 2012 in domestic and imported beef trimmings (19). From 2010 to 2012, the incidence rate of human STECs in the United States, as reported by the CDC, showed an increasing trend, with fewer O157 and more non-O157 STEC strains (https://www.cdc.gov/nationalsurveillance/pdfs/STEC-2014-REPORT_508c.pdf). Even though the total incidence of human STEC infections in the United States from 2012 to 2014 has decreased, with O157 cases trending down, cases caused by non-O157 strains are increasing, reinforcing the importance of these pathogens. The annual report of human STEC infections published by CDC for 2014 identifies the 10 most frequently culture-confirmed human STEC serogroups causing infections in the United States as O157 (43.2%), O26 (16.3%), O103 (14.2%), O121 (3.7%), O45 (2.6%), O145 (2.5%), O186 (0.9%), and O69 (0.4%) (https://www.cdc.gov/nationalsurveillance/pdfs/STEC-2014-REPORT_508c.pdf).

CHARACTERISTICS OF *E. COLI* O157:H7 AND NON-O157 STEC

E. coli O157:H7 was first identified as a foodborne pathogen in 1982. There had been prior isolation of the organism, which was identified retrospectively among isolates at the CDC; the

isolate was obtained from a California woman with bloody diarrhea in 1975 (20). In addition to production of Stxs, most strains of *E. coli* O157:H7 also possess several characteristics uncommon to most other *E. coli* strains: inability to grow well at temperatures of ≥44.5°C in *E. coli* broth, inability to ferment sorbitol within 24 hours, inability to produce β-glucuronidase (i.e., inability to hydrolyze 4-methylumbelliferyl-D-glucuronide [MUG]), possession of a pathogenicity island known as the locus of enterocyte effacement (LEE), and carriage of a 60-MDa (92-kbp) plasmid. Non-O157 STEC strains do not share the growth and metabolic characteristics described above, although they allproduce Stxs and many contain LEE and the large plasmid. EHEC can produce pediatric diarrhea, copious bloody discharge, i.e., hemorrhagic colitis, and intense inflammatory response, and the illness may be complicated by HUS.

There is tremendous genetic diversity among STEC isolates. O157 STEC infections are more likely than non-O157 STEC infections to result in bloody diarrhea (80% versus 45%), hospitalization (34% versus 8%), and HUS (6% versus <2%) (21). Of the cases of non-O157 STEC illness reported by the CDC in 2014 in the United States, 96% were represented by just six serotypes, including O26 (31%), O103 (27%), O111 (21%), O121 (7%), O145 (5%), and O45 (5%) (https://www.cdc.gov/nationalsurveillance/pdfs/STEC-2014-REPORT_508c.pdf). At present, *E. coli* O157:H7 is the dominant STEC isolate in the United States (43% of reported human STEC infections), Canada, the United Kingdom, and Japan, and non-O157 STEC strains are dominant among isolates in Europe, Argentina, Australia, Chile, and South Africa.

Acid Resistance

Foodborne pathogens must pass through an acidic gastric barrier with pH values as low as 1.5 to 2.5 to cause infections in humans. Some enteric pathogens, such as *Vibrio cholerae*, use an "assault tactic" that involves large numbers of infecting cells, in the hope that a few will survive and gain entrance into the intestine. *E. coli* O157:H7, however, has effective mechanisms for tolerating extreme acid stress. Three systems in STEC are involved in acid resistance, including an acid-induced oxidative system, an acid-induced arginine-dependent system, and a glutamate-dependent system (22). The oxidative system is less effective in protecting the organism from acid stress than the arginine-dependent and glutamate-dependent systems. The alternate sigma factor RpoS is required for oxidative acid tolerance but is only partially involved with the other two systems. Once induced, the acid resistance state can persist for a prolonged time (ca. 28 days) at refrigeration temperature. More detailed information on acid resistance can be found in a review article by Foster (23).

The minimum pH for *E. coli* O157:H7 growth is 4.0 to 4.5, but growth is dependent upon the interaction of pH with other factors. Studies on inactivation of *E. coli* O157:H7 with organic acid sprays on beef using acetic, citric, or lactic acid at concentrations of up to 1.5% revealed that *E. coli* O157:H7 populations were not appreciably affected by any of the treatments (24). *E. coli* O157:H7, when inoculated at high populations, survived fermentation, drying, and storage in fermented sausage (pH 4.5) for up to 2 months at 4°C (25), in mayonnaise (pH 3.6 to 3.9) for 5 to 7 weeks at 5°C and for 1 to 3 weeks at 20°C (26), and in apple cider (pH 3.6 to 4.0) for 10 to 31 days or 2 to 3 days at 8 or 25°C (27). Induction of acid resistance in *E. coli* O157:H7 also can increase tolerance to other environmental stresses, such as heat, radiation, and some antimicrobials.

Studies (28) have compared the survival characteristics of *E. coli* O157:H7 and other STEC types (O26:H11 and O111:NM) in chocolate and confectionery products during storage at different temperatures. Results revealed that all three serotypes survived storage at 38°C for

up to 43 days, but after 90 days, only *E. coli* O26:H11 and O111 were recovered. However, *E. coli* O157:H7 was recovered after O26 and O111 were no longer detected when a similar study was conducted with biscuit cream and mallow. The determination of the desiccation tolerance with 15 strains of *E. coli* O157:H7, 15 strains of *E. coli* O26:H11, and 5 strains of *E. coli* O111:NM revealed that all of them survived on paper disks after 24 h of drying at 35°C, showing no difference among serotypes (29).

Antimicrobial Resistance

Initially, when *E. coli* O157:H7 was first associated with human illness, the pathogen was susceptible to most antimicrobials affecting Gram-negative bacteria (30). Several studies revealed a trend toward increasing resistance to antimicrobials among *E. coli* O157:H7 isolates (31, 32). Overall, antimicrobial resistance among *E. coli* O157:H7 clinical isolates is low compared to that of other enteric pathogens and had no significant change from 2005 to 2014 (https://www.cdc.gov/narms/pdf/2014-Annual-Report-narms-508c.pdf). However, resistance to clinically important antimicrobials has been reported; in 2014, 5.1% (9/155) of *E. coli* O157 clinical isolates were resistant to streptomycin, 1.9% (3/155) were resistant to ampicillin, 5.81% (9/155) were resistant to nalidixic acid, 7.1% (11/155) were resistant to sulfisoxazole, 7.1% (11/155) were resistant to tetracycline, and two (1.3%) were resistant to trimethoprim-sulfamethoxazole. Some *E. coli* O157:H7 strains isolated from humans, animals, and food have developed resistance to multiple antimicrobials, with streptomycin-sulfisoxazole-tetracycline being the most common resistance profile. Approximately 6% (9/155) of the *E. coli* O157 clinical isolates in 2014 were resistant to three or more classes. Non-O157 STEC strains isolated from humans and animals also have acquired antimicrobial resistance, and some are resistant to multiple antimicrobials commonly used in human and veterinary medicine (33). However, antimicrobial resistance among STEC strains was low compared to that of non-STEC *E. coli* strains (34). The recent emergence of the *mcr-1* gene—a plasmid-borne gene that can make a bacterium resistant to colistin (a last-resort antimicrobial against multidrug-resistant bacteria)—has raised concerns about the ability of such genes to easily spread to other bacteria that are already multidrug resistant, which is a persistent threat to public health worldwide. Fortunately, the *mcr-1* gene has not yet been detected in STEC strains, although it has been found in many non-STEC strains (35–37).

Inactivation by Heat and Irradiation

Studies on the thermal sensitivity of *E. coli* O157:H7 in ground beef revealed that the pathogen has no unusual resistance to heat, with *D* values at 57.2, 60, 62.8, and 64.3°C of 270, 45, 24, and 9.6 seconds, respectively (38). Heating ground beef sufficiently to kill typical strains of *Salmonella* will also kill *E. coli* O157:H7 (Table 11.1). The presence of fat protects *E. coli* O157: H7 in ground beef, with *D* values for lean (2.0% fat) and fatty (30.5% fat) ground beef of 4.1 and 5.3 min, respectively, at 57.2°C and 0.3 and 0.5 min, respectively, at 62.8°C (39). Pasteurization of milk (at 72°C for 16.2 s) is an effective treatment that kills more than 10^4 *E. coli* O157:H7 cells per ml (40). Proper heating of foods of animal origin, e.g., heating foods to an internal temperature of at least 68.3°C for several seconds, is an important critical control point to ensure inactivation of *E. coli* O157:H7.

The use of irradiation to eliminate foodborne pathogens in food has been approved by many countries. Unlike many other processing technologies, irradiation at dosages that kill enteric foodborne pathogens still maintains the raw character of foods. In the United States, an irradiation dose of 4.5 kGy is approved for refrigerated and 7.5 kGy for frozen, raw ground

beef. D_{10} values for *E. coli* O157:H7 in raw ground beef patties range from 0.241 to 0.307 kGy, depending on temperature, with D_{10} values being significantly higher for patties irradiated at −16°C than at 4°C (41). Hence, an irradiation dose of 1.5 kGy should be sufficient to eliminate *E. coli* O157:H7 at the cell numbers likely to occur in ground beef. At present, there is no reason to believe that current interventions used in foods for mitigating *Salmonella* and *E. coli* O157:H7 contamination would not be effective against non-O157 STEC.

Table 11.1 Comparison of *D* values for *E. coli* O157:H7 and *Salmonella* spp. in ground beef and *Salmonella* spp. in ground beef

		D value (min)	
	E. coli O157:H7		
Temp (°C)	30.5% fat	17–20% fat	*Salmonella* spp.
51.7	115.5	ND[a]	54.3
57.2	5.3	4.5	5.43
62.8	0.47	0.40	0.54

WGS OF STEC

Thanks to the recent decrease in the cost of sequencing, the instigation of numerous sequencing initiatives (GenomeTrakr at CFSAN FDA [https://www.fda.gov/food/foodscienceresearch/wholegenomesequencingprogramwgs/ucm363134.htm], global microbial identifier consortium-Global Effort [http://www.globalmicrobialidentifier.org/]; 100K genomes at UC Davis [42]), and the availability of quicker and benchtop sequencing platforms, such as Ion Torrent (Thermo Scientific) and MiSeq (Illumina), the number of sequenced STEC genomes has increased substantially. Overall, more than 59,000 genomes of *E. coli* and *Shigella* have been sequenced as of November 2017. There are two freely available databases that accumulate all *E. coli* genome data that are being released to the public: Pathogen Detection (https://www.ncbi.nlm.nih.gov/pathogens/) and EnteroBase (http://enterobase.warwick.ac.uk/species/index/ecoli) (Fig. 11.1A and B). These databases provide different tools for analysis of the genomes. The EnteroBase website also contains historical data for >77,000 *E. coli* and *Shigella* strains and hosts the most-used multilocus sequence typing (MLST) scheme database for *E. coli*. The number of STEC genomes available in the NCBI and EnteroBase databases will continue to increase, and these resources can be used for source tracking, detection of antimicrobial resistance genes, epidemiology, and determining evolution of different groups of strains or phylogroups. The availability of this wealth of data had resulted in a more comprehensive approach to comparative and functional genomics of STECs. Evidence of the use of these data is that researchers have built a data repository for the genes that cause pathogenicity in *E. coli* (http://www.mgc.ac.cn/cgi-bin/VFs/compvfs.cgi?Genus=Escherichia), and it has been used by open-source genomic web tools to perform *in silico* searches for the presence of virulence genes, serotype, antimicrobial resistance genes, and sequence type from *E. coli* draft genomes (https://cge.cbs.dtu.dk/services) (Fig. 11.1C). The combination of all these results can be used for predicting the virulence potential of *E. coli* strains and for fast genotyping of their genomes. When this tool was used together with phylogenetic analysis, it was shown that an

EPEC O26:H11 strain was also able to acquire an *stx*-carrying phage and that certain strains believed to be STEC O26:H11 were indeed EPEC strains (43).

Comparative Genomics of EHEC

Comparative analysis showed that the chromosome of *E. coli* O157:H7 consists of 4.1-Mb backbone sequences shared by *E. coli* K-12 (commensal strain) and 1.4-Mb O157-specific sequences encoding many virulence determinants, such as Stx genes (*stx*) and the LEE (44, 45). This comparative analysis revealed considerable genomic plasticity, since *E. coli* O157:H7 EDL933 contained 1,000 more genes than *E. coli* K-12. Besides differences in the sizes of their chromosomes, O157 EHEC strains carry other plasmids, with the most important being the EHEC virulence plasmid pO157 (46). This EHEC plasmid is described in more detail below. Genomic comparison between EHEC strains of serotypes O26, O111, and O103 reveals that, similar to O157:H7, EHECs have even larger genomes (5.37 Mb for O111:H$^-$ strain 11128 and 5.69 Mb for O26:H11 strain 11368) than *E. coli* K-12 (4.6 Mb) and contain a large number of mobile elements, such as prophages and integrative elements. However, the chromosomal backbone regions are highly conserved as well among non-O157 EHEC strains of O26, O111, and O103 (44). EHECs are divided into two main lineages: EHEC lineage 1 contains O157:H7/– (e.g., Sakai and EDL933) and O145:H28 (e.g., RM13514 and RM13516), whereas EHEC lineage 2 contains O26 (e.g., 11368), O111 (e.g., 11128), and O103 (e.g., 12009) (46, 47). The EHEC-like virulence plasmids in the EHEC lineage 2 strains are very different from pO157, with variation in gene content and organization, indicative of a different and independent evolutionary history for each individual plasmid. The availability of genomic information from many of these strains has enabled the construction of phylogenies, which showed that that some strains unrelated to either EHEC lineage carry *stx* genes and have the potential to become EHEC strains, revealing the plasticity of the *E. coli* genome (Fig. 11.2).

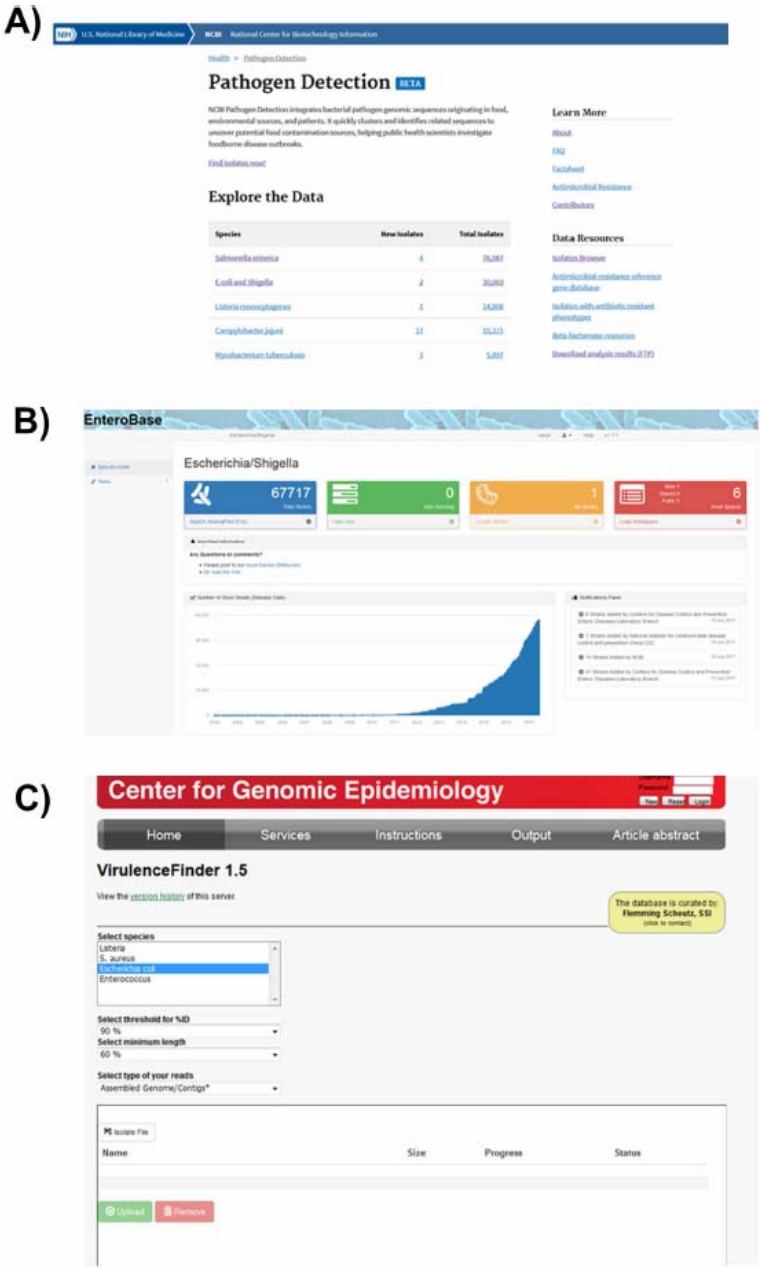

Figure 11.1 Snapshot of the two freely available databases containing all genomes as well as historical metadata (MLST) available for *E. coli* and *Shigella* and the web tool for *in silico* determination of virulence genes, serotyping, and MLST for *E. coli*. (A) NCBI pathogen detection; (B) EnteroBase; (C) DTU web tool.

Virulence genes, especially those for non-LEE effectors and nonfimbrial adhesins, are well conserved in non-O157 EHEC, in addition to the *stx* genes and LEE island. They have great similarity to their whole gene repertoire and share many genes that are specific to EHEC or rarely present in other pathotypes (45). These genes are directly or indirectly related to virulence, thus conferring a similar virulence potential among EHEC strains.

It is noteworthy that, despite carrying the same or similar virulence genes, mobile elements that are commonly present in EHEC (multiple lambdoid prophages, several types of

integrative elements, and virulence plasmids) have remarkably divergent genomic structures. This property suggests that EHEC strains have complex and independent evolutionary pathways and that mobile elements are the primary driving force for the parallel evolution of EHEC (45). However, the availability of thousands of genomic sequences has enabled better comparisons and the ability to determine the true phylogenetic history of strains that were considered to be atypical EHEC strains, such as O26:H11 (43) and O157:H7 (48). In both cases, it was revealed that these atypical strains either had lost their *stx* phage or had not yet acquired the phage. Comparative genomics have also revealed recently that an O111:H strain that caused an HUS outbreak in Australia in 1995 contained two copies of the stx_2 phage, explaining why the infections caused by these strains were more severe than those caused by an earlier clone of the same strain that contained only one copy of the stx_2 phage (21). A more detailed summary of the use of genomic information available for STEC analysis, determination of evolution, and control in global production systems can be found in a review article by Franz et al. (49).

RESERVOIRS OF *E. COLI* O157:H7 AND NON-O157 STECS

Cattle

Initially, foods of bovine origin (notably, undercooked ground beef, and, less often, unpasteurized milk) were the vehicles most frequently associated with outbreaks of *E. coli* O157:H7 infection (20). Subsequently, cattle were identified as important sources, or reservoirs, of this pathogen. Since that time, many studies have focused on their role as a reservoir of *E. coli* O157:H7. A number of other vehicles have since been implicated in *E. coli* O157 infections, including fresh produce, contaminated water, and direct contact with animals or their environment at livestock exhibitions and by petting (50, 51). The sources and reservoirs of non-O157 STEC infections are not as clearly defined. Unlike *E. coli* O157 illness, most major outbreaks of illness caused by non-O157 STEC have not been directly associated with beef products. Instead, outbreaks have been traced to a wider variety of sources, including vegetables, water, and unpasteurized milk (52). Given that non-O157 STEC also colonizes live cattle, it is probable that cattle play an important role in the epidemiology of human non-O157 STEC infection as well. However, epidemiologic data to pinpoint the primary routes of human exposure are lacking. Recently, meat or meat products have been implicated in human outbreaks (53–55). As isolation and detection methods for non-O157 STEC are improved, the understanding of the vehicles and routes of transmission of non-O157 STEC should also improve.

Detection of *E. coli* O157:H7 and STEC on Farms

The first reported isolation of *E. coli* O157:H7 from cattle was from a <3-week-old calf with colibacillosis in Argentina in 1977 (56). However, this presentation was atypical, as the clonal genotypic group of *E. coli* O157 most frequently associated with human disease rarely causes bovine illness. Instead, most cattle harbor these bacteria without outward signs of illness or loss of productivity (57). The prevalence of fecal excretion of *E. coli* O157:H7 varies by age, with higher prevalence values being reported for younger animals (2 to 24 months of age) than adults in field studies. The reasons for agerelated differences are unclear, but they may be due to ruminal development differences, differences in microbial flora in the gastrointestinal tract, or management differences, such as dietary factors (58). Nevertheless, older animals, including those at the time of harvest and during lactation, may also shed these

bacteria in their feces asymptomatically. The presence of more than one strain of *E. coli* O157:H7 on a single farm on a single sample date has been described (59).

Shedding of *E. coli* O157 at the individual-animal level typically lasts for a few days to several weeks following exposure (60). However, there is an association with the excretion of larger numbers of bacteria and for longer periods of time if the bacteria are intimately attached to the intestinal mucosa, a phenomenon that occurs predominantly, if not exclusively, at the rectoanal junction in cattle (61). Cattle may excrete *E. coli* O157 in the feces at cell numbers that are so low as to be detectable only through sensitive enrichment culture methods or are as high as 10^6 CFU/g. Cattle shedding high numbers of *E. coli* O157 (>10^3 CFU/g) can contribute substantially to contamination of carcasses at harvest, contamination of the environment, and cattle-to-cattle transmission and are considered to be "supershedding" (62, 63). The factors that govern bovine supershedding of *E. coli* O157 (and whether the phenomenon occurs for non-O157 STEC) are currently poorly understood and are under investigation.

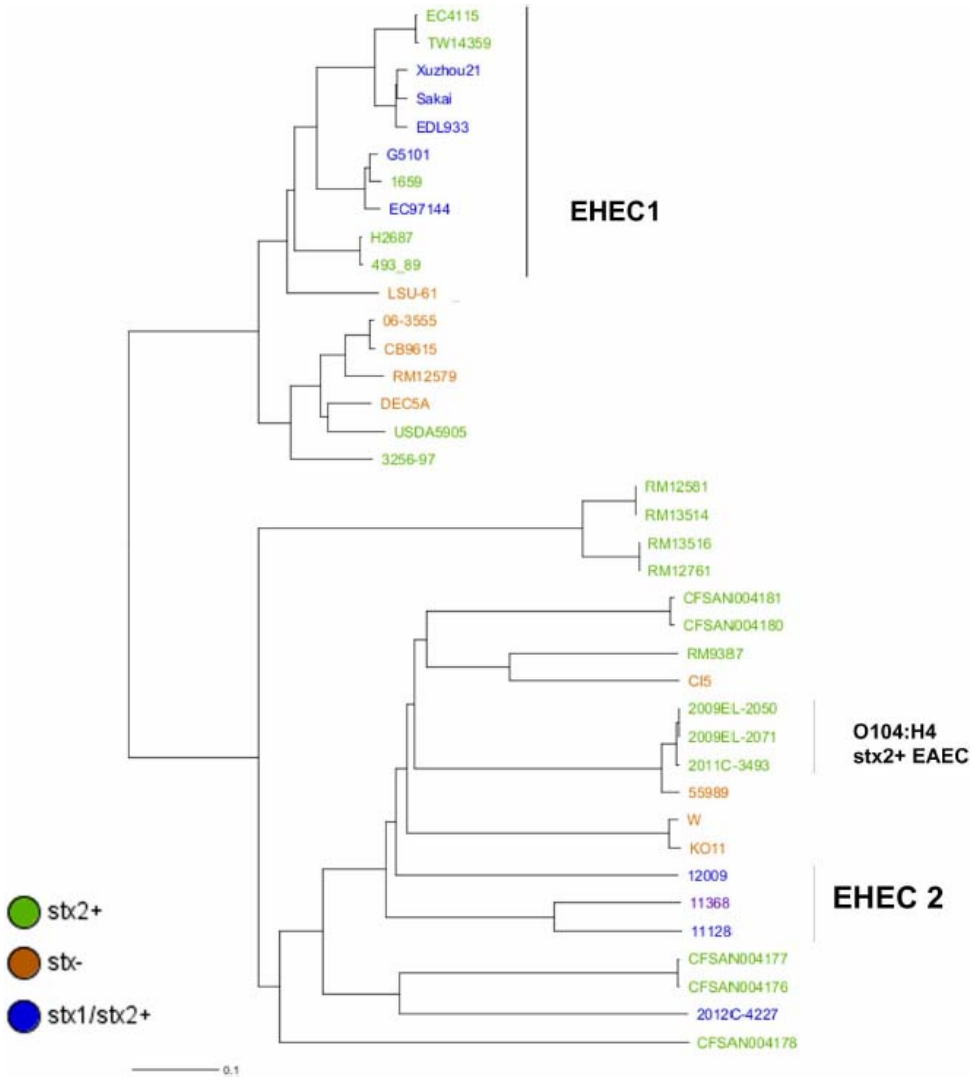

Figure 11.2 Neighbor-joining phylogenetic tree of 59 *E. coli* genomes available at NCBI using a custom-made core genome MLST analysis showing *stx* distribution on those genomes. The species-based phylogeny was inferred using 820 conserved core genome loci. The two EHEC lineages are shown as well as strains belonging to the German outbreak of *E. coli* O104:H4 in 2011 (stx_2 EAEC). The colors represent the presence and type of *stx* gene.

At the herd level, most bovine populations are positive for *E. coli* O157 and non-O157 STEC at some time or another (64). Prevalence, however, is variable, and peaks in prevalence are sporadic and currently unpredictable. Fecal excretion of *E. coli* O157:H7 by cattle occurs in a seasonal pattern, with higher prevalence occurring in the summer or early fall, which coincides with the seasonal variation in disease incidence seen in humans, where higher rates are also observed during the summer months. In nine herds sampled for approximately 1 year, the prevalence of *E. coli* O157:H7 during June through October was several times that observed in December through March. Observed seasonal effects of *E. coli* O157:H7 excretion in cattle could be due to confounding factors, such as differences in the microbial flora of the gastrointestinal tract in cattle during the summer and during the winter months, changes in diet, or the presence of conditions conducive to multiplication of the bacteria in

environmental niches. Non-O157 STEC strains are suspected to follow a similar seasonal pattern of colonization in cattle, but this has not been extensively documented (65).

Herd prevalence rates of STEC fluctuate between 0 and 100% (66). Although total STEC prevalence in a herd may average 60 to 70%, the fraction of these strains that actually pose a threat to public health is undetermined. Many STEC isolates from cattle carry only the *stx* gene and no ancillary virulence genes typically found in cases of human disease (67, 68). A study on STEC carriage by dairy cattle on farms in Canada revealed that 36% of cows and 57% of calves were STEC positive in all of the 80 herds tested (69). Of these, only seven animals (0.45%) on four farms (5%) were positive for *E. coli* O157:H7. A 2002 USDA national study revealed that 38.5% of dairy farms had at least one *E. coli* O157:H7-positive cow and that 4.3% of individual cows were *E. coli* O157 positive.

Factors Associated with Bovine Carriage of *E. coli* O157:H7

E. coli O157:H7 has been isolated from cattle feces from most regions of the world in which studies have been conducted (64). There are, however, some regions, such as Scandinavia, Africa, and Norway, which report lower prevalence rates than others. This may be due to climate factors or farm management practices that are less conducive to cattle's being colonized with *E. coli* O157:H7.

Domestic Animals and Wildlife

Although cattle contribute significantly to STEC contamination of the food chain, either directly through meat or milk or indirectly through contamination of water and the food production environment, STEC is also frequently isolated from many other domestic and wild ruminants, such as sheep, goats, deer, and water buffalo (57, 70). In addition, *E. coli* O157 and other non-O157 STEC types can colonize a number of other animals, including dogs, horses, swine, wild birds, and rodents (71), albeit less commonly than occurs in ruminants. Outbreaks of foodborne STEC infections have been associated with food products derived from sheep, goats, and deer. Moreover, nonruminant species may play a role in transmission of STEC between cattle farms and contamination of the environment (and crops) and may constitute a source of direct transmission. For a list of animal hosts of STECs, see the review article by Persad and LeJeune (72).

Possibility of Control of STEC in Food Animals

Despite 25 years of research on the topic and their potential for enhancing food safety, very few effective control measures for STEC in live animals have been identified. Several tentative associations between fecal shedding of *E. coli* O157:H7 and feed or environmental factors have been made from epidemiologic studies of dairy herds. For example, some calf starter feed regimens or environmental factors and feed components, such as whole cottonseed, were associated with reduced prevalence of *E. coli* O157:H7. Feeding of distillers' grains or barley can increase *E. coli* O157 shedding compared to that observed with corn-fed cattle, but the mechanisms driving these differences are unknown (73, 74).

Likewise, grouping calves before weaning is associated with increased carriage of *E. coli* O157:H7 (75). Given that *E. coli* O157 can survive for several months to years in environmental niches on the farm, food and water hygiene and manure handling have been researched (76). Several studies have revealed that *E. coli* O157:H7 can survive for weeks and months in bovine feces and water (66). The pathogen was frequently isolated from water troughs on farms. Commercial feeds often contained detectable *E. coli*, indicating widespread

fecal contamination, although *E. coli* O157:H7 was only infrequently detected (77, 78). Despite the gaps in understanding the factors influencing *E. coli* O157 carriage in cattle, preharvest interventions have been applied to live cattle with mixed results (79). Feeding of specific probiotic bacteria has repeatedly resulted in decreased prevalence of *E. coli* O157 in feedlot cattle (80, 81). Likewise, the administration of sodium chlorate in the feed or water may provide a control method immediately prior to harvest (80). Vaccination of cattle to reduce *E. coli* O157 colonization has also been studied (81, 82), with some promising results, but sufficient data demonstrating the efficacy of current vaccines are lacking. Other possible control measures include bacteriophage therapy and washing the hides of cattle. Achieving a better understanding of the factors influencing the exposure and colonization of cattle with *E. coli* O157 and other STEC will enhance the development of novel control strategies.

Many interventions have also been applied at the time of harvest to mitigate the potential negative impacts of cattle entering beef-processing facilities carrying STEC. These include strict attention to slaughter and processing hygiene, as well as postharvest interventions, such as surface steam pasteurization and application of acid rinses on carcasses (79). Although preliminary studies clearly identified a direct correlation between the prevalence of *E. coli* O157:H7 in the live animal and rates of contamination of carcasses, modern processing techniques can reduce and mitigate the impacts of carriage of *E. coli* O157 and other STEC types among animals presented for harvest (83). Presently, it is thought that most animals can be processed safely, and it is only when the prevalence is extremely high or the magnitude of shedding is large (supershedding cattle) that these factors overwhelm the current system and contamination persists on carcasses or in products.

Humans

Fecal shedding of *E. coli* O157:H7 by patients with hemorrhagic colitis or HUS usually lasts for no more than 21 days following the onset of symptoms (84). However, in some instances, the pathogen can be excreted in feces for many weeks. A child infected during a day care center-associated outbreak continued to excrete the pathogen for 62 days after the onset of diarrhea (85). In the 2011 outbreak of *E. coli* O104:H4, adults shed the microorganism for up to 90 days (86). Studies of persons living on dairy farms in Canada, aiming to determine carriage of *E. coli* O157:H7 by farm families, revealed elevated titers of antibody against the surface antigens of *E. coli* O157, and *stx*-positive strains were isolated from feces from 6.3% of the persons tested on 80 farms (87). Some of the *stx*-positive strains were O157:H7, whereas the rest belonged to eight other serotypes (87). The prevalence of STECs in employees working in slaughterhouses or dairy farms appears to be influenced by country and seasons (88–90). An asymptomatic long-term carrier state has not been identified. The significance of fecal carriage of *E. coli* O157:H7 by humans is the potential for person-to-person dissemination of the pathogen, a situation which has been observed repeatedly in outbreak settings. A factor contributing to person-to-person transmission of the pathogen is its extraordinarily low infectious dose; it is estimated at <100 cells, and it is possible that as few as 10 cells can produce illness in highly susceptible populations (91). Inadequate attention to personal hygiene, especially after using the restroom, can result in transfer of the pathogen to other persons through contaminated hands, resulting in secondary transmission.

CHARACTERISTICS OF DISEASE

The spectrum of human illness of STEC infection includes mild nonbloody diarrhea and life-threatening conditions, such as hemorrhagic colitis and HUS. The occurrence of these

conditions is relatively low in the United States (92); however, they are medically and epidemiologically actionable (93). Some persons may be infected but asymptomatic, but typically for a short time (<3 weeks). Ingestion of the bacteria is followed typically by a 3-to 4-day incubation period (range, 2 to 8 days), during which colonization of the large bowel occurs. Illness typically begins with severe abdominal cramps and nonbloody diarrhea for 1 to 2 days, which then progresses in the second or third day of illness to bloody diarrhea that lasts for 4 to 10 days (94, 95). Many outbreak investigations revealed that more than 80% of patients with microbiologically confirmed cases of diarrhea caused by *E. coli* O157:H7 had frank blood in the stools, but in some outbreaks, there have been reports of 30% of cases having nonbloody diarrhea. Symptoms usually resolve after a week, but about 6% of patients progress to HUS, one-half of whom require dialysis and 75% of whom require transfusions of erythrocytes and/or platelets. The case fatality rate from *E. coli* O157:H7 infection is about 1%. Similar but less severe symptoms have been observed in infections with non-O157 STEC: only 45% of patients develop bloody diarrhea, and fewer than 2% progress to HUS.

HUS largely affects children, among whom it is the leading cause of acute renal failure (96). The risk that a child younger than 10 years of age with a diagnosed *E. coli* O157:H7 infection will develop HUS is about 15% (95). The syndrome is characterized by a triad of features: acute renal insufficiency, microangiopathic hemolytic anemia, and thrombocytopenia. Significant pathological changes include swelling of endothelial cells, widened subendothelial regions, and hypertrophied mesangial cells between glomerular capillaries. These changes combine to narrow the lumina of the glomerular capillaries and afferent arterioles and result in thrombosis of the arteriolar and glomerular microcirculation. Complete obstruction of renal microvessels can produce glomerular and tubular necrosis, with an increased probability of subsequent hypertension or renal failure.

INFECTIOUS DOSE

Retrospective analyses of foods associated with outbreaks of EHEC infection revealed that the infectious dose is very low. For example, analyses of frozen ground beef patties associated with a 1993 multistate outbreak caused by *E. coli* O157:H7 in the western United States suggested that the infectious dose was below 700 organisms (97). Another study in 1994 revealed that 2 to 45 bacteria was the probable infectious dose for persons who consumed dry fermented salami contaminated with *E. coli* O157:H7 (98). These data suggest that the infectious dose of *E. coli* O157:H7 may be fewer than 100 cells. Additional evidence for a low infectious dose is the capability for person-to-person and waterborne transmission of EHEC infection.

DISEASE OUTBREAKS

Geographic Distribution

E. coli O157:H7 has been the cause of many major outbreaks of severe illness worldwide. At least 30 countries on six continents have reported *E. coli* O157:H7 infection in humans. In the United States, 107 outbreaks of *E. coli* O157:H7 infection associated with food were documented between 2011 and 2015 (Table 11.2). These outbreaks contributed to 1,460 illnesses during this time. More importantly, most cases of STEC infections occur as sporadic cases. Over the last 5 years, the number of actual cases reported each year in the United States

averaged about 4,000 (Fig. 11.3) (https://www.cdc.gov/foodsafety/outbreaks/multistate-outbreaks/outbreaks-list.html).

The precise incidence of foodborne *E. coli* O157:H7 illness in the United States is not known, because infected persons experiencing mild or no symptoms and persons with nonbloody diarrhea are less likely to seek medical attention than patients with bloody diarrhea; hence, such cases would not be reported. The CDC reports that the annual average numbers of laboratory-confirmed cases of *E. coli* O157:H7 and non-O157 infections are 3,704 and 1,579, respectively (99). It also estimates that *E. coli* O157:H7 causes 63,153 illnesses each year in the United States, and non-O157 STEC accounts for an additional 112,752 cases. Sixty-eight percent of O157 cases and 82% of non-O157 cases are attributed to foodborne transmission.

Large outbreaks of *E. coli* O157:H7 infections involving hundreds of cases also have been reported in Canada, Japan, and the United Kingdom. The largest outbreak occurred in May to December 1996 in Japan, involving more than 9,000 reported cases (100). In the same year, 21 elderly people died in a large outbreak involving 501 cases in central Scotland (101). Although *E. coli* O157:H7 is still the predominant serotype of STEC in the United States, Canada, the United Kingdom, and Japan, an increasing number of outbreaks and sporadic cases related to STEC of serotypes other than O157:H7 have been reported. In continental Europe, Australia, and Latin America, non-O157 STEC infections are more common than *E. coli* O157:H7 infections. Details of many reported foodborne and waterborne outbreaks of STEC infections are provided in Table 11.3. There are no distinguishing biochemical phenotypes for non-O157 STEC, making screening for these bacteria problematic and laborintensive, and for this reason, only a limited number of clinical laboratories test for it. Therefore, the prevalence of non-O157 STEC infections may be underestimated.

Table 11.2 Vehicles of foodborne outbreaks and associated cases of *E. coli* O157 infections in the United States between 2011 and 2015[a]

Transmission route	No. of outbreaks	% of total outbreaks	No. of cases associated with outbreaks	% of total cases
Ground beef	14	13.08	121	8.29
Unknown food vehicle	33	30.84	322	22.05
Produce	26	24.30	560	38.36
Other beef	2	1.87	6	0.41
Chicken	4	3.74	134	9.18
Dairy product	11	10.28	105	7.19
Other food vehicles: pizza, pork, apple cider, deli meat, etc.	17	15.89	212	14.52
Total	107	100	1,460	

[a] Data from the CDC (https://wwwn.cdc.gov/foodborneoutbreaks/). For data from 2000 to 2010, see previous versions of this chapter.

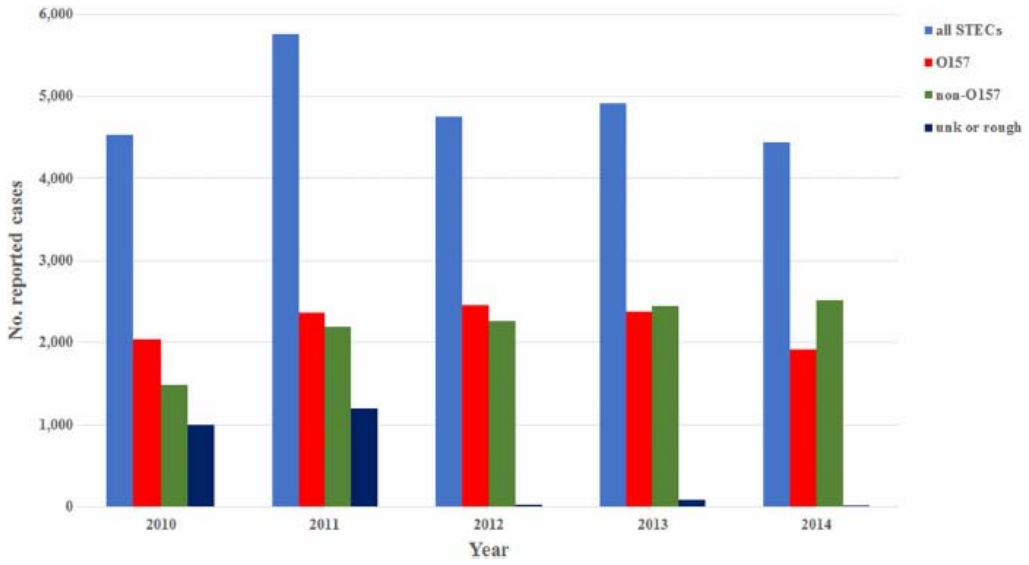

Figure 11.3 Number of cases of STEC disease in the United States by year, 2010 to 2014 (https://www.cdc.gov/ecoli/surveillance.html). Unk, unknown.

Seasonality of *E. coli* O157:H7

Outbreaks and clusters of *E. coli* O157:H7 infections peak during the warmest months of the year. Approximately 89% of the outbreaks reported in the United States occurred from May to November (102). FoodNet data indicate the same trend. The reasons for this seasonal pattern are unknown but may include (i) an increased prevalence of contaminated product on the market (due to increased prevalence in cattle), (ii) increased exposure to *E. coli* O157 from nonbeef sources during the summer (103), and (iii) increased exposure from consumption of vegetables or from recreational contact with the environment.

Age of Patients

All age groups can be infected by *E. coli* O157:H7, but the very young and the elderly most frequently experience severe illness with complications (104). HUS usually occurs in children. Population-based studies have suggested that the highest age-specific incidence of *E. coli* O157:H7 infection occurs in children 2 to 10 years of age. In addition to naïve or incompletely developed immune responses, the high rate of infection in this age group may be attributable to more frequent exposure to contaminated environments and infected animals and more opportunities for person-to-person spread between infected children with relatively undeveloped hygiene skills.

Transmission of *E. coli* O157:H7

Food remains the predominant transmission route, accounting for 52% of 350 outbreaks and 61% of 8,598 outbreak-related cases from 1982 to 2002 (102). A variety of foods have been identified as vehicles of *E. coli* O157:H7 infections, although ground beef is one of the most frequent food vehicles. Examples of other foods that have been implicated in outbreaks include roast beef, cooked meats, venison meat and jerky, salami, raw milk, pasteurized milk, yogurt, cheese, ice cream bars, lettuce, prepackaged spinach, unpasteurized apple cider/juice, cantaloupe, potatoes, radish sprouts, alfalfa sprouts, fruit and vegetable salads, cookie dough, flour, pepperoni pizzas, and cake (105).

The route of *E. coli* O157:H7 transmission for many outbreaks is unknown. Outbreaks attributed to transmission by person-to-person contact, water, animal contact, manure exposure, and laboratory exposure have also been reported. An outbreak investigation of a petting zoo-associated *E. coli* O157:H7 infection in 2003 in British Columbia, Canada, revealed that the main contributors to the propagation of illnesses among class-room and families were secondary transmission (of the 45 cases reported, 26 were reported as primary and 19 as secondary), asymptomatic infection (one infected individual was asymptomatic but transmitted the infection to his parents and siblings, and his stool sample was positive for *E. coli* O157:H7), and prolonged shedding (50). In contrast to *E. coli* O157:H7 outbreaks, in which a food is most often identified as a vehicle, the modes of transmission of most outbreaks caused by non-O157 STEC are unknown (18, 52). Only a few outbreaks of non-O157 STEC have been clearly associated with foods/water (Table 11.3).

Table 11.3 Representative foodborne and waterborne outbreaks of *E. coli* O157:H7 and other STEC infections[a]

Yr	Month	Location[b]	No. of cases/no. of deaths	Setting	Vehicle or transmission mode
1982	2; 5	Oregon; Michigan	26; 21	Community	Ground beef
1985		Canada	73/17	Nursing home	Sandwiches
1987	6	Utah	51	Custodial institution	Ground beef, person-to-person contact

Examples of Foodborne and Waterborne Outbreaks

Original Outbreaks

The first documented outbreak of *E. coli* O157:H7 infection occurred in the state of Oregon in 1982, with 26 cases and 19 persons hospitalized (106). All patients had bloody diarrhea and severe abdominal pain. The median age was 28 years, with a range of 8 to 76 years. The duration of illness ranged from 2 to 9 days, with a median of 4 days. This outbreak was associated with eating undercooked hamburgers from fast-food restaurants of a specific chain. *E. coli* O157:H7 was recovered from stools of patients. A second outbreak followed 3 months later and was associated with the same fast-food restaurant chain in Michigan, with 21 cases and 14 persons hospitalized. The median age was 17 years, with a range of 4 to 58 years. Contaminated hamburgers again were implicated as the vehicle, and *E. coli* O157:H7 was isolated both from patients and from a frozen ground beef patty. That *E. coli* O157:H7, a heretofore-unknown human pathogen, was the causative agent was established by its association with the food and recovery of the bacterium with identical microbiologic characteristics from both the patients and the meat from the implicated supplier.

1993 Multistate Outbreak

A large multistate outbreak of *E. coli* O157:H7 infection in the United States occurred in Washington, Idaho, California, and Nevada in early 1993 (107). Approximately 90% of primary cases were associated with eating at a single fast-food restaurant chain (chain A), from which *E. coli* O157:H7 was isolated from hamburger patties. Transmission was amplified by secondary spread (48 patients in Washington alone) via person-to-person transmission. In total, 731 cases were identified, with 629 in Washington, 13 in Idaho, 57 in Las Vegas, NV, and 34 in southern California. The median age of patients was 11 years, with a range of 4 months to 88 years. One hundred seventy-eight persons were hospitalized, 56 developed HUS, and 4 children died. Because neither specific laboratory testing nor surveillance for *E. coli* O157:H7 was carried out for earlier cases in Nevada, Idaho, and California, the outbreak went unrecognized until a sharp increase in cases of HUS was identified and investigated in the state of Washington.

The outbreak resulted from insufficient cooking of hamburgers by chain A restaurants. Epidemiologic investigation revealed that 10 of 16 hamburgers cooked according to chain A's cooking procedures in Washington State had internal temperatures less than 60°C, which was substantially less than the minimum internal temperature of 68.3°C required by the state. Cooking patties to an internal temperature of 68.3°C would have been sufficient to kill the low populations of *E. coli* O157:H7 detected in the contaminated ground beef.

Outbreaks Associated with Produce

Produce-associated outbreaks of *E. coli* O157:H7 infection were first reported in 1991, and produce has since remained a prominent food vehicle of STEC infections. Raw vegetables, particularly lettuce and alfalfa and vegetable sprouts, have been implicated in several outbreaks of *E. coli* O157:H7 infection in North America, Europe, and Japan. In May 1996, a mesclun mix of organic lettuce was associated with a multistate outbreak in which 47 cases were identified in Illinois and Connecticut. A large multistate (26 states) outbreak of *E. coli* O157:H7 infection occurred in the summer of 2006 (108). A total of 199 persons were infected, with 102 (51%) patients hospitalized, 31 (16%) cases of HUS, and three deaths. *E. coli* O157 was isolated from 13 packages of spinach supplied by patients living in 10 states.

Between May and December 1996, multiple outbreaks of *E. coli* O157:H7 infection occurred in Japan, involving 9,451 cases and 12 deaths (100). The largest outbreak affected 7,470

schoolchildren, teachers, and staff in Osaka in July 1996. Epidemiologic investigations revealed that white radish sprouts were the vehicle of transmission.

Apple Cider and Juice Outbreaks

The first confirmed outbreak of *E. coli* O157:H7 infection associated with apple cider occurred in Massachusetts in 1991, involving 23 cases (109). In 1996, three outbreaks of *E. coli* O157:H7 infection associated with unpasteurized apple juice and/or cider were reported in the United States. The largest of the three occurred in three western states (California, Colorado, and Washington) and in British Columbia, Canada, with 71 confirmed cases and one death. *E. coli* O157:H7 was isolated from the implicated apple juice. An outbreak also occurred in Connecticut, with 14 confirmed cases. Manure contamination of apples was the suspected source of *E. coli* O157:H7 in several of the outbreaks. Using apple drops (i.e., apples picked up from the ground) for making apple cider is a common practice, and apples can become contaminated by resting on soil contaminated with manure. Apples can also become contaminated if they are transported or stored in areas that contain manure or are treated with contaminated water. Investigation of the 1991 outbreak in Massachusetts revealed that the implicated cider press processor also raised cattle that grazed in a field adjacent to the cider mill. Fecal droppings from deer also were found in the orchard where apples used to make the cider were harvested.

Waterborne Outbreaks

Reported waterborne outbreaks of *E. coli* O157:H7 infection have increased substantially in recent years, being associated with swimming water, drinking water, well water, and ice. Investigations of lake-associated outbreaks revealed that in some instances, the water was likely contaminated with *E. coli* O157:H7 by toddlers defecating while swimming, and swallowing lake water was subsequently identified as the risk factor. A 1995 outbreak in Illinois involved 12 children ranging in age from 2 to 12 years (110). Although *E. coli* O157:H7 was not recovered from water samples, high levels of *E. coli* were detected, indicating likely fecal contamination. A large waterborne outbreak of *E. coli* O157:H7 among attendees of a county fair in New York occurred in August 1999 (51, 111). More than 900 persons were infected, of which 65 were hospitalized. *Campylobacter jejuni* also was identified in some patients. Two persons died from HUS, including a 3-year-old girl and a 79-year-old man. Unchlorinated well water used to make beverages and ice was the vehicle. Recreational water exposure is responsible for many cases of *E. coli* O157:H7 infections (112).

Waterborne outbreaks of *E. coli* O157 infections have also been reported in other locations of the world. Drinking water, which was probably contaminated with bovine feces, was implicated in outbreaks in Scotland (51) and southern Africa (113). *E. coli* O157:NM was isolated from water associated with the latter outbreak. Walkerton, Ontario, Canada, was the site of one of the largest waterborne disease outbreaks associated with *E. coli* O157:H7 (114). In this community, 2,300 people were infected and 7 of them died.

Outbreaks of Non-O157 STEC Infections

Several outbreaks of non-O157 STEC infections have been reported worldwide. An outbreak in early 1995 in South Australia was associated with *E. coli* O111:NM and involved 23 cases of HUS after consumption of an uncooked, semidry fermented sausage product. In June 1999, an outbreak of *E. coli* O111:H8 infection occurred, involving 58 cases at a teenage cheerleading camp in Texas. Contaminated ice was the implicated vehicle. More recently, a restaurant-associated *E. coli* O111:NM outbreak occurred in Oklahoma during late August and early

September 2008 (115, 116). The outbreak caused 341 cases, 70 hospitalizations, and one death. The exact source of the contamination was undetermined, but contamination by a food handler was suspected.

Several other outbreaks caused by non-O157 STEC have also been reported. STEC O103:H25 was the cause of an outbreak associated with fermented sausage in Norway in 2006 (32). STEC O123:H$^-$ was identified as the causative agent in a family outbreak associated with eating undercooked ground beef in France in 2009 (104), whereas STEC O26 sickened several individuals in Maine and New York in 2010, leading to a large recall of ground beef. A multistate outbreak of STEC O145 infections occurred in May 2010 in the United States, with more than 30 cases reported from five states (http://www.cdc.gov/ecoli/2010/ecoli_o145/index.html). Shredded romaine lettuce from one processing facility was identified as a source of infection in this outbreak. An outbreak associated with multiple STEC serotypes (O26, O84, and O121) occurred in a Colorado prison in 2007, involving 135 cases and 10 hospitalizations. Pasteurized cheese and margarine were the food vehicles of the outbreak. More recently, an outbreak of STEC O121:H19 that began in December 2015 and ended in September 2016 in the United States was linked to flour (https://www.cdc.gov/ecoli/2016/o121-06-16/index.html). The outbreak caused 63 confirmed cases and 17 hospitalizations and resulted in the product's being recalled. The outbreak affected 24 states. WGS analyses revealed that the strains belonged to ST655 and carried stx_{2a} and *eae* genes, as well as other virulence genes described for EHECs. A similar O121 *E. coli* outbreak, also linked to flour, occurred in Canada from November 2016 to April 2017, with 30 confirmed cases occurring in six provinces.

A foodborne outbreak in Germany in May and June 2011 sickened more than 4,000 people and caused more than 50 deaths (7, 9, 10, 117). The causative agent was identified as an *E. coli* O104:H4 that produced Stx2a. Approximately 23% of the patients developed HUS, which was a much higher rate than those previously reported for patients infected with EHEC. The outbreak spread quickly over northern Germany, with some cases in other European countries, the United States, and Canada, and is one of the largest outbreaks of *E. coli* infection reported to date. Six confirmed cases of O104:H4 infections were identified in the United States. An Arizona resident who traveled to Germany before becoming ill died. Results of WGS analysis revealed the outbreak strain was genetically more related to EAEC, which is associated with cases of acute or persistent diarrhea worldwide in children and adults (see "EAEC" above), than with EHEC.

MECHANISMS OF PATHOGENICITY

Significant virulence factors associated with the pathogenicity of EHEC have been identified based on histopathology of tissues of HUS and hemorrhagic colitis patients, studies with tissue culture and animal models, and studies using cell biology and molecular genetics approaches. A general body of knowledge of the pathogenicity of EHEC has been developed and indicates that the bacteria cause disease by their ability to adhere to the host cell membrane, colonize the large intestine, and then produce one or more Stxs (118–120).

Attaching and Effacing

Numerous studies on the pathogenesis of EHEC have focused on elucidating the mechanisms of adherence and colonization. By adhering to intestinal epithelial cells, EHEC subverts cytoskeletal processes to produce a histopathological feature known as an A/E lesion (Fig.

11.4). *E. coli* O157:H7 produces an A/E lesion in the large intestine similar to that induced by EPEC, which in contrast occurs predominantly in the small intestine. The A/E lesion is characterized by intimate attachment of the bacteria to the plasma membranes of the host epithelial cells, localized destruction of the brush border microvilli, and assembly of highly organized pedestal-like actin structures (121). Most EHEC strains contain a ca. 43-kb pathogenicity island called the LEE and other phage genes encoding effector proteins (Fig. 11.5). The LEE is organized into five major operons, *LEE1* to *LEE5*, encoding a type III secretion system (T3SS), secreted proteins, chaperones, and regulators (5). The secreted proteins consist of effectors that are translocated into the host cell by the T3SS and translocators required for delivering the effectors.

Type III Secretion System

T3SS is associated with the virulence of many Gramnegative bacterial pathogens. The T3SS apparatus (see Fig. 11.6) is a complex "needle and syringe" structure that is assembled from the products of approximately 20 genes in the LEE (121, 122). The system is used by EHEC to directly translocate virulence factors from the bacteria into the targeted host cells in a single step.

The genes encoding structural proteins of the T3SS are largely conserved, whereas genes encoding effector proteins display substantial variability (123). The conserved T3SS gene cluster in the LEE is likely acquired by horizontal gene transfer, whereas genes encoding secreted proteins are more diverse and may have been obtained by distinct events.

Intimin

Intimin is a 94-kDa outer membrane protein encoded by *eae* (*E. coli* attaching and effacing). The *eae* genes of pathogenic *E. coli* present considerable heterogeneity in their 3′ ends, which encode the C-terminal 280 amino acids (Int280) involved in binding to the enterocytes and transmembrane intimin receptor (Tir) (see below), and the corresponding changes in the amino acid sequence also represent antigenic variations. Based on the sequence and antigenic differences, more than 10 distinct intimin types have been identified and classified, with α, β, ε, and γ being the main intimin types (124). Intimin α is typically found in EPEC, whereas ε and γ are closely associated with EHEC, and β is present in both EPEC and EHEC. *E. coli* O157:H7 produces intimin γ.

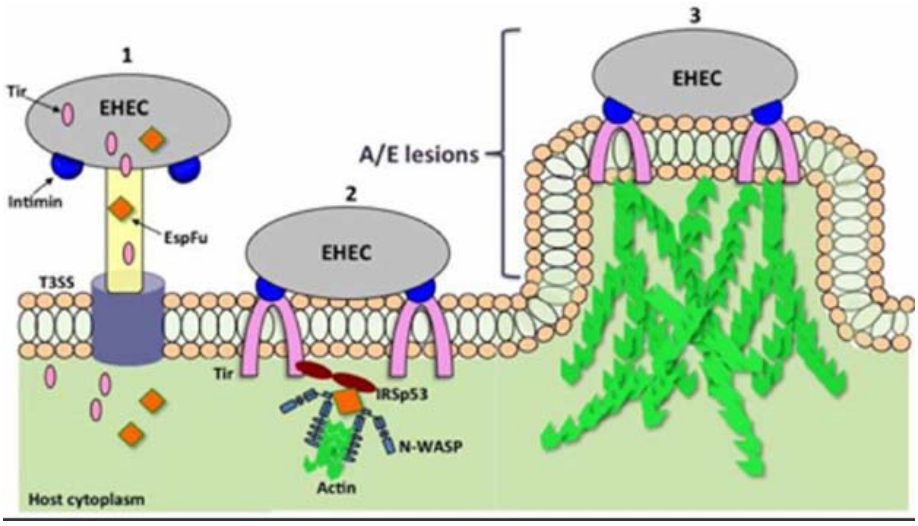

Figure 11.4 Electron microscopy image of an A/E lesion and schematic illustration of A/E lesion formation in EHEC. Effector proteins undergo A/E translocation through the T3SS, which forms a pore through the membranes of EHEC. EHEC translocates a number of proteins: EspB and EspD, which form a translocon in the plasma membrane; the cytoplasmic proteins EspF, EspG, and Map; the translocated intimin receptor Tir, which inserts into the plasma membrane; and other unidentified effectors. Formation of the EHEC pedestal is also shown. EHEC intimately attaches to the host cell through intimin-Tir binding. The binding triggers the formation of actin-rich pedestals beneath adherent bacteria after Wiskott-Aldrich syndrome protein and the heptameric actin-related protein Arp2/3 are recruited to the pedestal tip. Reproduced from reference 117 with permission.

Intimin is exported via the general secretory pathway to the periplasm, where it is inserted into the outer membrane. Intimin has two functional regions: the highly conserved N-terminal region is inserted into the bacterial outer membrane, forming a β-barrel-like structure, and mediates dimerization; the variable Int280 extends from the bacterium and interacts with Tir receptors in the host cell membrane, which were previously translocated into the host cell membrane. Interaction of intimin with host cells stimulates production of microvillus-like processes.

Autoagglutinating Adhesin (*saa*)

Most STECs causing diseases are LEE positive, but some STEC strains that cause diseases or HUS are LEE negative. Besides *eae*, there are other described adhesin genes in LEE-positive STEC strains, such as *iha*, *lpfA*, and *efa-1*, which influence bacterial adhesion and intestinal colonization (125). Paton et al. in 2001 described an autoagglutinating adhesin protein designated Saa (STEC autoagglutinating adhesin) that increased the adhesion of LEE-negative STEC O113:H21 to epithelial cells (125).

Effector Proteins

Numerous effector proteins have been identified in EHEC and are translocated into the host cell via the LEE-encoded T3SS (121), including Tir, Map (mitochondrionassociated protein), EspF, EspG, EspH, SepZ, and EspB, which are encoded by the LEE, whereas others, such as Cif (cycle inhibiting factor), EspI, EspJ, and TccP (Tir-cytoskeleton coupling protein) are encoded by prophages (Fig. 11.5). A more extensive analysis and description of these factors

can be found in a review article by Stevens and Frankel (126). Tir localizes to the host cell plasma membrane. It contains two membrane-spanning transmembrane domains and forms a hairpin-like structure, with both its C and N termini being located within the host cell and the region between the two transmembrane domains forming an extracellular loop, exposed on the surface of the cell, which interacts with intimin. Like intimin in the bacterial outer membrane, plasma membrane-bound Tir is a dimer. The intracellular amino and carboxy termini of Tir interact with a number of focal adhesion and cytoskeletal proteins, linking the extracellular bacterium to the host cell cytoskeleton. These interactions lead to the formation of actin-rich pedestals beneath adherent bacteria after Wiskott-Aldrich syndrome protein and the heptameric actin-related protein Arp2/3 are recruited to the pedestal tip (Fig. 11.4).

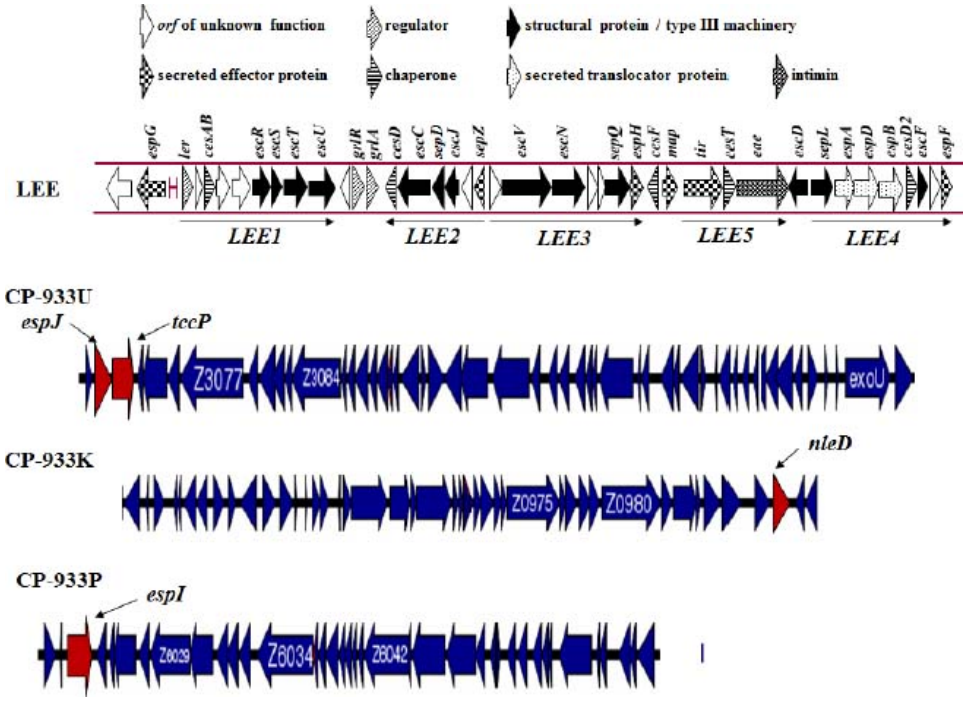

Figure 11.5 Genetic organization of the EHEC LEE and EHEC prophages CP-933U, CP-933K, and CP-933P. Reproduced from reference 121.

Effector proteins are delivered to the host cell cytoplasm from the extremity of the EspA filament through a translocation pore formed in the plasma membrane of the host cell by the translocator proteins EspB and EspD (Fig. 11.6) (121). Additional proteins, SepL ("Sep" is an acronym for "secretion of EPEC protein") and SepD, also play a role in the formation of the translocation apparatus. SepL is a soluble cytoplasmic protein that interacts with SepD. These proteins could be involved in the switch from secretion of translocator proteins to secretion of effector proteins through the type III machinery.

Virulence Plasmids

The primary virulence determinants of EHEC strains are chromosomally encoded. However, plasmids may play an important role in EHEC pathogenesis as well. An F-like 92-kb plasmid, pO157, found in most clinical isolates of *E. coli* O157:H7, shares sequence similarities with plasmids present in other EHEC serotypes. Based on DNA sequence analysis, pO157 contains 100 open reading frames (127). Genes coding for putative virulence factors in pO157 include those coding for enterohemolysin (*ehxA*), the general secretory pathway (*etpC* to *etpO*), serine

protease (*espP*), catalase-peroxidase (*katP*), a potential adhesin (*toxB*), a Cl esterase inhibitor (*stcE*), and A/E gene-positive conserved fragments (*ecf*). Nonetheless, the role of pO157 in bacterial virulence and survival is largely unknown. Toxicity results from the insertion of EhxA into the cytoplasmic membranes of target mammalian cells, thereby disrupting permeability. The EHEC catalase-peroxidase, a bifunctional periplasmic enzyme, protects the bacterium against oxidative stress, a possible defense strategy of mammalian cells during bacterial infection.

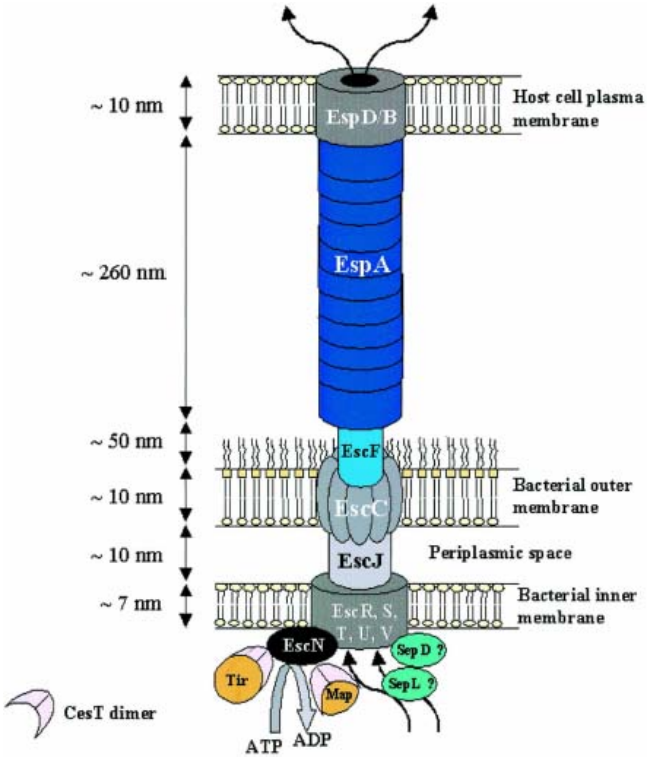

Figure 11.6 T3SS apparatus of EHEC. The basal body of the T3SS is composed of the secretin EscC, the inner membrane proteins EscR, EscS, EscT, EscU, and EscV, and the EscJ lipoprotein, which connects the inner and outer membrane ring structures. EscF constitutes the needle structure, whereas EspA subunits polymerize to form the EspA filament. EspB and EspD form the translocation pore in the host cell plasma membrane, connecting the bacteria with the eukaryotic cell via EspA filaments. The cytoplasmic ATPase EscN provides the energy to the system by hydrolyzing ATP molecules into ADP. SepD and SepL are represented as cytoplasmic components of the T3SS. Reproduced from reference 121.

Large hemolysin-encoding plasmids are also present in most non-O157 EHEC strains (128). A large plasmid of *E. coli* O113 (pO113) shares *ehx*, *espP*, and *iha* genes present in pO157. It also contains genes sharing similarity with the IncI1 transfer region and several genes for adhesins and toxins but lacks the *toxB* region found in pO157. Among those are Sab and SubA proteins. Sab is a 1,431-amino acid outer membrane autotransporter protein that enhances biofilm formation (129), whereas SubA (encoded by the *subA* gene) is a potent toxin that causes cytotoxicity in eukaryotic cells (130). These three genes (*saa*, *subA*, and *sab*) were all identified in pO113 from an *E. coli* O113:H21 strain that caused HUS (125). Analysis of *ehxA* and *repA* (a replication gene) of the RepFIB replicon revealed the evolutionary divergence of plasmids pO157 and pO113 from a common ancestor. Phylogenetic analyses of *ehxA* and *repA* were incongruent. These findings reveal differences in selective pressures between virulence

genes and constitutive genes and point to the difficulties in examining the phylogeny of plasmid genomes due to their high degree of plasticity and mobility.

Shiga Toxins

STEC strains produce one or two Stxs. The nomenclature of the Stx family and their important characteristics are listed in Table 11.4. Molecular studies on Stx1 from different *E. coli* strains revealed that Stx1a either is completely identical to the Stx of *S. dysenteriae* type 1 or differs by only one amino acid. However, during the last decade, several variants of Stx1 have been described. Some minor variants have 99% nucleotide sequence homology with stx_1 of phage 933J. A more substantial deviation from Stx1 was observed in an Stx variant from an ovine strain, *E. coli* OX3:H8 131/3, and subsequently among human isolates (131). It differs from Stx1a of phage 933J by 9 amino acids within the A subunit and 3 amino acids within the B subunit and is designated Stx1c. Another Stx1 variant, Stx1d, was identified in STEC ONT:H19, of bovine origin, with a difference from Stx1a of 20 amino acids in the A subunit and 7 amino acids in the B subunit (132).

Table 11.4 Nomenclature and biological characteristics of Stxs[a]

				Biological characteristics				
		% Nucleotide sequence homology to *stx*		% Nucleotide sequence homology to stx_2				
Nomenclature	Genetic loci	A subunit	B subunit	A subunit	B subunit	Receptor	Activation by intestinal mucus	Disease
Stx	Chromosome	NA	NA			Gb3	No	Human diarrhea, HC, HUS
Stx1a	Phage	99	100			Gb3	No	Human diarrhea, HC, HUS
Stx1c	Chromosome	97	96			Unknown	Unknown	Human and sheep?
Stx1d	Unknown	93	92			Unknown	Unknown	Cattle?
Stx2a	Phage			NA	NA	Gb3	No	Human diarrhea, HC, HUS
Stx2b	Phage			95	87	Gb3	No	Human diarrhea, HC, HUS
Stx2c	Phage			100	97	Gb3	No	Human diarrhea, HC, HUS
Stx2d	Phage			99	97	Gb3	Yes	Human diarrhea, HC, HUS
Stx2e	Chromosome			93	84	Gb4	No	Pig edema disease
Stx2f	Unknown			63	57	Unknown	Unknown	Pigeon
Stx2g	Unknown			94	91	Unknown	Unknown	Bovine

[a] From references 14, 113 and 143. Abbreviations: HC, hemorrhagic colitis; HUS, hemolytic-uremic syndrome; NA, not applicable.

Unlike Stx1, toxins of the Stx2 group are not neutralized by antiserum raised against Stx and do not cross-hybridize with Stx1-specific DNA probes. There is sequence and antigenic variation within toxins of the Stx2 family produced by *E. coli* O157:H7 and other STEC. At least seven variants of Stx2 have been identified, including Stx2a, Stx2b, Stx2c (Stx2vh-a and Stx2vh-b), Stx2d (Stx2d-OX3a and Stx2d-Ount), Stx2e, Stx2f, and Stx2g (133–135). The Stx2c subgroup is approximately 97% related to the amino acid sequence of the B subunits of Stx2a, whereas the A subunit of Stx2c shares 98 to 100% amino acid sequence homology with Stx2a. Stx2e is associated with edema disease, which occurs principally in piglets, and shares 93% and 84% amino acid sequence homology with the A and B subunits, respectively, of Stx2a. Hence, the Stx2-related toxins have only partial serological reactivity with anti-Stx2 serum. Stx2f and Stx2g of STEC strains isolated from feral pigeons and cattle wastewater have also been described (135, 136).

Structure of the Stx Family

Stxs are holotoxins composed of a single enzymatic A subunit of approximately 32 kDa in association with a pentamer of receptor-binding B subunits of 7.7 kDa (14). The Stx A subunit can be split by trypsin into an enzymatic A1 fragment (approximately 27 kDa) and a carboxyl-terminal A2 fragment (approximately 4 kDa) that links A1 to the B subunits. The A1 and A2 subunits remain linked by a single disulfide bond until the enzymatic fragment is released and enters the cytosol of a susceptible mammalian cell. Each B subunit is composed of six antiparallel strands forming a closed barrel capped by a single helix between strands 3 and 4. The A subunit lies on the side of the B subunit pentamer, nearest to the C-terminal end of the B-subunit helices. The A subunit interacts with the B-subunit pentamer through a hydrophobic helix that extends to half of the 2.0-nm length of the pore in the B pentamer. This pore is lined by the hydrophobic side chains of the B-subunit helices. The A subunit also interacts with the B subunit via a four-stranded mixed sheet composed of residues of both the A2 and A1 fragments.

Genetics

Whereas most stx_1 operons share a great deal of homology, there is considerable heterogeneity in the stx_2 family. Unlike the genes of other Stx2 proteins, which are located on bacteriophage that integrate into the chromosome, the Stxs of *S. dysenteriae* type 1, Stx1c and Stx2e, are encoded by chromosomal genes (131, 137). A sequence comparison of the growing stx_2 family reveals that genetic recombination among the B-subunit genes, rather than base substitutions, has given rise to the variants of Stx2 present in human and animal strains of *E. coli* (138). However, the operons for every member of the Stx subgroups are organized identically; the A and B subunit genes are arranged in tandem and separated by a 12-to 15-nucleotide gap. The operons are transcribed from a promoter that is located 5′ to the A-subunit gene, and each gene is preceded by a putative ribosome-binding site. The existence of an independent promoter for the B-subunit genes has been suggested. The holotoxin stoichiometry suggests that expression of the A-and B-subunit genes is differentially regulated, permitting overproduction of the B polypeptides.

Receptors

All members of the Stx family bind to globoseries glycolipids on the eukaryotic cell surface; Stx, Stx1a, Stx2a, Stx2b, Stx2c, and Stx2d bind to glycolipid globotriaosylceramide (Gb_3), whereas Stx2e primarily binds to glycolipid globotetraosylceramide (Gb_4) (139). The alteration of binding specificity between Stx2e and the rest of the Stx family is related to carbohydrate specificity of receptors (140). The amino acid composition of B subunits of Stx2a and Stx2e differs at only 11 positions, yet Stx2e binds primarily to Gb_4, whereas Stx2a binds only to Gb_3. High-affinity binding also depends on multivalent presentation of the carbohydrate, as would be provided by glycolipids in a membrane. The affinity of Stx1 for Gb_3 isoforms is influenced by the length of the fatty acyl chain and by its level of saturation. Stx1 binds preferentially to Gb_3 containing $C_{20:1}$ fatty acid, whereas Stx2c prefers Gb_3 containing $C_{18:1}$ fatty acid. The basis for these findings may be related to the ability of different Gb_3 isoforms to present multivalent sugar-binding sites in the optimal orientation and position at the membrane surface. It is also possible that different fatty acyl groups affect the conformation of individual receptor epitopes on the sugar. Bovine cells do not express high numbers of the Gb_3 receptors on their surface, and hence, cattle are not adversely affected by the toxin.

Mode of Action

Stxs act by inhibiting protein synthesis. Each of the B subunits is capable of binding with high affinity to an unusual disaccharide linkage (galactose-1,4-galactose) in the terminal trisaccharide sequence of Gb_3 (or Gb_4) (141). Following binding to the glycolipid receptor, the toxin is endocytosed from clathrin-coated pits and transferred first to the *trans*-Golgi network and subsequently to the endoplasmic reticulum and nuclear envelope. While it appears that transfer of the toxin to the Golgi apparatus is essential for intoxication, the mechanism of entry of the A subunit from the endosome to the cytosol and particularly the role of the B subunit in the process remain unclear. In the cytosol, the A subunit undergoes partial proteolysis and splits into a 27-kDa active intracellular enzyme (A1) and a 4-kDa fragment (A2) bridged by a disulfide bond. Although the entire toxin is necessary for its toxic effect on whole cells, the A1 subunit is capable of cleaving the *N*-glycoside bond in one adenosine position of the 28S rRNA that comprises 60S ribosomal subunits (142). This elimination of a single adenine nucleotide inhibits the elongation factor-dependent binding to ribosomes of aminoacyl-bound tRNA molecules. Peptide chain elongation is truncated, and overall protein synthesis is suppressed, resulting in cell death.

Role in Disease

The role of Stxs in mediating colonic disease, HUS, and neurological disorders has been investigated in numerous studies (14, 141, 143). However, there is no satisfactory animal model for studying hemorrhagic colitis or HUS, and the severity of disease precludes study of experimental infections in humans. Therefore, the present understanding of the role of Stxs in causing disease is obtained from a combination of studies, including histopathology of diseased human tissues, animal models, and endothelial tissue culture cells. Results of recent studies support the concept that Stxs contribute to pathogenesis by directly damaging vascular endothelial cells in certain organs, thereby disrupting the homeostatic properties of these cells.

The involvement of Stx in enterocolitis is demonstrated when fluid accumulation and histological damage occur after purified Stx is injected into ligated rabbit intestinal loops. The

fluid secretion may be due to the selective killing of absorptive villus tip intestinal epithelial cells by Stx. However, intravenous administration of Stx to rabbits can produce nonbloody diarrhea, suggesting that other mechanisms for triggering diarrhea are possible. Studies with genetically mutated STEC strains also reveal that Stx has a role in intestinal disease, but the significance of Stx in provoking a diarrheal response differs depending upon the animal model used.

Epidemiologic studies have revealed a correlation between enteric infection with *E. coli* O157:H7 and development of HUS in humans. Histopathologic examination of kidney tissue from HUS patients revealed profound structural alterations in the glomeruli, the basic filtration unit of the kidney (143). The damage caused by Stxs is often not limited to the glomeruli. Arteriolar damage, involving internal cell proliferation, fibrin thrombus deposition, and perivascular inflammation, occurs (144). Cortical necrosis also occurs in a small number of HUS cases. In addition, human glomerular endothelial cells are sensitive to the direct cytotoxic action of bacterial endotoxin. Endotoxin in the presence of Stxs can also activate macrophage and polymorphonuclear neutrophils to synthesize and release cytokines, superoxide radicals, or proteinases and amplify endothelial cell damage.

Neurological symptoms in patients and experimental animals infected with *E. coli* O157:H7 have also been described and may be caused by secondary neuron disturbances that result from endothelial cell damage by Stxs. Studies involving mice perorally administered an *E. coli* O157:H strain revealed that Stx2 impaired the blood-brain barrier and damaged neuron fibers, resulting in death. The presence of the toxin in neurons was verified by immunoelectron microscopy (145).

Epidemiologic and laboratory studies have revealed that *stx* genotype and host factors such as age, preexisting immunity, and the use of antibiotics are important in the development of HUS (134, 146, 147). Stx2a and Stx2c are associated with high virulence and the ability to cause HUS, whereas Stx2b, Stx2d, Stx2e, Stx1a, and Stx1c occur in milder or asymptomatic infections (134, 147). Cell culture studies revealed that Stx2a, Stx2d, and elastase-cleaved Stx2d were at least 25 times more potent than Stx2b and Stx2c. *In vivo* studies in mice revealed that the potency of Stx2b and Stx2c was similar to that of Stx1, whereas Stx2a, Stx2d, and elastase-cleaved Stx2d were 40 to 400 times more potent than Stx1 (7).

CONCLUDING REMARKS

The serious nature of the symptoms of hemorrhagic colitis and HUS caused by *E. coli* O157:H7 and EHEC places this group of pathogens in a category apart from other foodborne pathogens, which typically cause only mild symptoms. The severity of the illness it causes combined with its apparent low infectious dose (<100 cells) qualifies *E. coli* O157:H7 to be among the most serious of known foodborne pathogens. *E. coli* O157:H7 causes disease by its ability to adhere to the host cell membrane and colonize the large intestine, after which it produces one or more Stxs. Although the pathogen has been isolated from a variety of domestic animals and wildlife, cattle are a major reservoir of *E. coli* O157:H7, with undercooked ground beef being among the most frequently implicated vehicles of transmission. Very few highly effective control measures for *E. coli* O157:H7 and other STEC types in live animals have been identified. The number of cases associated with fresh produce, such as lettuce, sprouts, and spinach, has increased substantially in recent years. An important feature of this pathogen is its acid tolerance. Outbreaks have been associated with consumption of contaminated high-acid foods, including apple juice and fermented dry

salami. Recreational and drinking waters also have been identified as vehicles of transmission of *E. coli* O157:H7 infections. GenomeTrakr and other web tools will help us identify other uncommon causes and vehicles and track down sources of contamination in the future.

Stx-producing *E. coli* strains other than O157:H7 have been increasingly associated with cases of HUS. More than 130 non-O157 STEC serotypes have been isolated from humans, but not all of these serotypes have been shown to cause illness. Although genomic analyses reveal that virulence genes are well conserved in many non-O157 STEC, in addition to the *stx* genes and the LEE island, some STEC strains may have a low potential to cause HUS; other non-O157 STEC isolates, including many found in healthy individuals, may not be pathogens. *E. coli* O157:H7 is still by far the most important serotype of STEC in North America. Isolation of non-O157 STEC requires techniques not generally used in clinical laboratories; hence, these bacteria are less frequently sought or detected in routine practice. Recognition of non-O157 STEC in foodborne illness necessitates identification of serotypes other than O157:H7 in persons with bloody diarrhea and/or HUS and preferably in implicated food. The increased availability in clinical laboratories of techniques such as testing for Stxs or their genes and identification of other virulence markers using WGS analysis will continue to enhance the detection of disease attributable to non-O157 STEC.

Shigella

Foodborne infections caused by *Shigella* species remain an important source of diarrheal illness worldwide in both economically developed and developing countries. A considerable amount of research has been conducted on *Shigella* since shigellosis (bacillary dysentery) was first differentiated from amoebic dysentery in 1887 and the etiologic agent was isolated and described by Shiga during an outbreak in Japan 10 years later (1). Historically, the primary route of transmission of *Shigella* spp. was relegated to water, but as indicated by Smith (2), contaminated foods have emerged as a more important vehicle. However, the foodborne aspects of shigellosis are often a neglected area of study across the international food safety community.

Shigella spp. are endemic worldwide because of their ease of transmission. Fecally contaminated food and water can lead to rapid onset of large-scale epidemics of shigellosis with a high mortality rate in underdeveloped countries. Compounding the extent of this pathogen's effects on global health are the current lack of a protective vaccine and the extraordinary ease with which these bacteria acquire antibiotic resistance. The globalization and importation of food supply present additional risks that are being measured through the international cooperation among the World Health Organization (WHO) and public regulatory agencies (3).

This chapter presents important features of *Shigella* spp., the disease they cause, and the impact that these pathogens have with respect to food safety. Diagnosis, epidemiology, ecology, modes of transmission, and examples of recent foodborne outbreaks are discussed, along with current understanding of the genetics of

Shigella pathogenesis, the genes involved in causing disease, and how they are regulated. No single review can be completely comprehensive, so the reader is encouraged to refer to several excellent recent reviews for additional information (4–12).

CHARACTERISTICS OF THE ORGANISM

Classification and Biochemical Characteristics

Shigella organisms are Gram-negative, nonsporulating, nonmotile, facultative anaerobic rod-shaped bacteria. Adopted as a genus in 1950, *Shigella* is subgrouped into four species based on biochemical, serological, and clinical phenotypic differences: *Shigella dysenteriae* (group A; 15 serotypes), *S. flexneri* (group B; 14 classical serotypes and subserotypes), *S. boydii* (group C; 19 serotypes), and *S. sonnei* (group D; 1 serotype). *S. boydii* 13 was removed from the genus *Shigella* in 2005 (13), but a new serotype, *S. boydii* 20 serovar nov., was added in the same year (14). Serologic typing is based only on differences in the O (lipopolysaccharide [LPS]) antigen, since *Shigella* lacks the H (flagellar) and K (capsular) antigens. Consequently, *Shigella* serotyping is affected by the bacterial transition from the smooth form to the rough form, a phenotype frequently seen with *S. sonnei*, which harbors the LPS-encoding genes on a plasmid that is relatively unstable during bacterial culture. Plasmidencoded genes are also necessary for synthesis of the LPS O side chain in *S. dysenteriae* 1 (15). *S. sonnei*, *S. flexneri* 2a, and *S. dysenteriae* type 1 are the most common species isolated from cases of shigellosis, the latter being responsible for most of the deadly cases due to the unique expression of the cytotoxic Shiga toxin (Stx) common to Shiga toxin-producing pathogenic *Escherichia coli* isolates, including the enterohemorrhagic *E. coli* O157:H7 strain. Although historically *S. dysenteriae* type 1 was the only member of the genus *Shigella* to harbor the *stx* genes, recently other *Shigella* spp. were also found to carry the *stx* genes but on a lambdoid phage (16–19).

As members of the family *Enterobacteriaceae*, *Shigella* spp. are nearly genetically identical to the genus *Escherichia* and closely related to the salmonellae (20). Nevertheless, they are biochemically distinguished from other enteric bacteria by their inability to ferment acetate, mucate, and lactose (although some strains of *S. sonnei* may ferment mucate or lactose upon prolonged incubation); lack of citric acid, inositol, salicin, or adonitol utilization as a sole carbon source; and inability to synthesize lysine decarboxylase (21). The four species require nicotinic acid for growth in a minimal synthetic medium, are oxidase negative, do not produce H_2S, and do not produce gas from glucose except for *S. flexneri* 6 and *S. boydii* 14. *S. dysenteriae* strains have the additional property of not being able to ferment mannitol. *S. dysenteriae* type 1 expresses an active β-galactosidase but does not produce catalase, an extremely rare feature among the *Enterobacteriaceae*. Although *S. sonnei* strains have only one serotype, they can be subdivided into biovars on the basis of their ability to hydrolyze *o*-nitrophenyl-β-D-galactopyranoside (ONPG), xylose, and rhamnose.

The traditional classification of shigellae has been challenged by the advent of comparative genomic techniques. Niche adaptation of *Shigella* was influenced by two major genetic events: acquisition of the large virulence plasmid pINV, encoding a type III secretion system (T3SS) and effectors, and concomitant inactivation or loss of chromosomal factors, including loci referred to as antivirulence genes. Furthermore, nucleotide sequencing of multiple conserved genes has indicated that *Shigella* emerged from *E. coli*. It has been postulated that *Shigella* spp. evolved directly from commensal *E. coli* lineages and that these evolutionary steps likely occurred multiple times, with each branch-off corresponding to the independent acquisition of a large (230-kb) pINV virulence plasmid (20, 22). Additional comparative genomic analyses indicate that most *Shigella* strains can be separated into three main clusters that originated from multiple *E. coli* ancestors, with clusters 1 and 2 containing strains which branched from *E. coli* 50,000 to 270,000

years ago and cluster 3 emerging between 35,000 and 170,000 years ago (23).

The three clusters can be further subdivided into five subclusters that contain strains from mainly one serogroup, indicating that modern genotyping and traditional serogrouping are correlated (24). Furthermore, a recent genomic analysis of 336 available *E. coli* and *Shigella* genomes found that using whole-genome-based alignments resulted in phylogenetic placement of *Shigella* within a diverse set of *E. coli* genomes and formed three separate clades. When sequenced *Shigella* isolates were assessed separately, five clearly defined monophyletic clades were formed. The comparison of *Shigella*-only genomes enabled subclade designations for improved discrimination based solely on genomic content (25). Nevertheless, pathogenic *S. flexneri* and nonpathogenic *E. coli* K-12 genomes still share a common chromosomal backbone. These genomes have undergone a number of large (>5-kb) rearrangements, including inversions and translocations (26). Most *Shigella* virulence determinants are plasmid-borne; novel chromosomal open reading frames (ORFs) (i.e., chromosomal genes unique to *Shigella* which are not present in the *E. coli* genome) are scarce. As an example, *S. flexneri* 2a strain 2457T has 175 ORFs that are unique, whereas the remaining 3,030 ORFs are shared with *E. coli* K-12 strain MG1655 (26).

S. sonnei and *S. dysenteriae* type 1 appear to share an ancestor with *E. coli* O157:H7, and *S. dysenteriae* types 8 and 10 are isolated clones within *E. coli*. Modern taxonomy also revealed that enteroinvasive *E. coli* (EIEC) strains were more closely related to *Shigella* than to commensal *E. coli* strains. EIEC causes dysentery like *Shigella* and may share identical O antigens with *Shigella*, but traditional classification places them as a subgroup of *E. coli* because many are motile, are lactose, mucate, and/or acetate fermenters, and require a higher infectious dose to cause infection. It is now commonly accepted that the EIEC phenotype arose several times independently from different *E. coli* ancestors and represents

an intermediate stage in the convergent evolution leading towards the more contagious and virulent *Shigella* (23) (Fig. 12.1).

Diagnosis

Shigella spp. are not particularly fastidious in their growth requirements, and in most cases, the organisms are routinely cultivated in the laboratory on artificial media. Cultures of *Shigella* are easily isolated and grown from analytical samples, including water and clinical samples. In the latter case, *Shigella* organisms are present in the feces of patients in concentrations ranging from 10^3 to 10^{10} viable bacteria per g of stool during the acute phase of infection. Identification is readily accomplished using culture media, biochemical analysis, and serological typing. *Shigella* spp. are shed in the feces and continue to be isolated from convalescent patients (10^2 to 10^3 per g of stool) for weeks or longer after the initial infection. They have the reputation of being more fastidious and difficult to cultivate than other enteric bacteria, particularly during later stages of the illness. However, this relates more to the lack of a selective enrichment broth for *Shigella*, leading to its being outgrown by the resident bacterial fecal population. Use of the semiselective agar media Hektoen, salmonella-shigella (inhibitory for *S. dysenteriae* type 1), and xylose-lysine-deoxycholate or the recently developed chromogenic agars can increase the chance of isolating of *Shigella* (27).

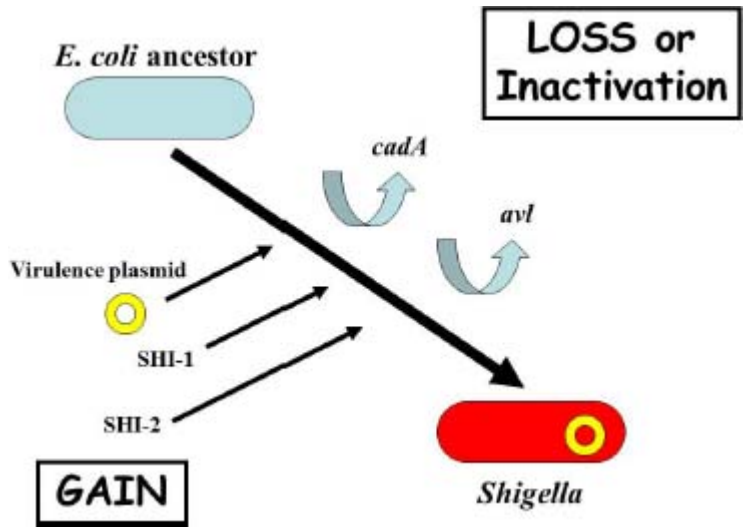

Figure 12.1 Overview of the genetic steps that contributed to the formation of pathogenic *Shigella* species from an *E. coli* ancestor. These include the acquisition of the virulence plasmid, several pathogenicity islands (SHI-1 and SHI-2 are shown), and the loss of ancestral traits (i.e., "black holes") incompatible with virulence (e.g., *cadA* and *avl*), often referred to as antivirulence genes (57).

Because the time from the initial clinical diagnosis indicating a potential outbreak to the start of an investigation to determine the cause of that outbreak can be considerable, identifying the causative agent in a timely manner can be challenging. This time lag can be exacerbated when the etiological agent has as narrow an environmental niche and survivability band as *Shigella*. Despite being saprophytic, *Shigella* spp. have a very specific host range, essentially residing only in the intestines of humans and certain other higher primates.

Shigella spp. are shed in patients with shigellosis at 10^6 to 10^8 CFU/g of stool. Although these numbers are high, the pathogens do not survive well after secretion under various environmental conditions, including temperature, exposure to sunlight, and water availability (28). Isolation of *Shigella* from foods is therefore a challenge. Many additional characteristics of the food, including its composition, physical parameters (such as pH and salt content), and the natural resident microbial flora that compete for nutrients, may

affect the successful recovery of shigellae. Considering that *Shigella* may be present in low numbers or in a poor physiological state in the suspected food samples, special enrichment procedures are often required for successful detection of foodborne *Shigella* (29).

Although molecular detection does not generally prove that an organism is alive and competent to cause disease, PCR techniques may be considered more sensitive and specific than conventional culture techniques. Several single, nested, and multiplex PCR assays have been designed to routinely amplify one or more markers present in single or multiple copies (e.g., *ipaH*) in *Shigella* and EIEC bacterial genomes (30). However, they generally do not differentiate between the four *Shigella* spp., EIEC, and/or specific serotypes. Targeting the O-serotype-specific gene(s) using PCR (31) or microarrays (32) can bring more discriminatory power to the tests. Farfán et al. (33) identified two markers that specifically differentiate between *S. flexneri*, *S. sonnei*, and diarrheagenic *E. coli* strains, while the study by Sahl et al. describing the *Shigella* monophyletic clades utilized a combination of *ipaH3* and clade-specific primers to correctly identify all *Shigella* species tested, without any false-positive results for *E. coli* strains tested (25).

Conventional analysis of isolated *Shigella* species entails the application of serological means with serotype-specific antisera. Other means to serotype isolates use PCR assays that target genes for the synthesis of O antigens. For the majority of cases, these two methods accurately determine the serotype of the *Shigella* spp. However, there have been reported situations in which discrepancies between the phenotype and genotype data have emerged. These discrepancies can arise from point mutations, cross-reactivity of the antisera used, insertions or deletions in genes responsible for O-antigen synthesis, or the emergence of novel genotypes (34). Wholegenome sequencing (WGS) has been applied to determine the serotype of *Shigella* isolates as well as to provide data to build phylogenetic relationships (35). WGS has been an extremely useful tool to identify outbreak patterns as well as the

spread of the pathogen from one geographical area to other parts of the world (global dissemination) (36).

Last, WGS is poised to become an integral part of tracking microbial pathogens that are the etiological agents of foodborne outbreaks. PulseNet, based at the Centers for Disease Control and Prevention (CDC), currently uses pulsed-field gel electrophoresis (PFGE) to match clinical and food isolates to ascertain outbreak relationships, but future surveillance tracking will be based on WGS (https://www.cdc.gov/pulsenet/pathogens/wgs.html). PulseNet International and other regional surveillance networks, e.g., PulseNet Latin America and Caribbean (37), intend to transition from PFGE to WGS analysis.

Epidemiology

Approximately 51 million *Shigella* diarrheal episodes and 15,000 deaths occur each year throughout the world (38). Although most cases of shigellosis are due to person-to-person transmission, outbreaks commonly result from food and/or water contamination. Episodes of shigellosis seem to follow seasonal variations in certain countries. In arid countries such as Egypt, transmission peaks in the hot dry season, mainly due to the consumption of contaminated water and decreased personal hygiene in times of water shortage (21). Conversely, the peak is in the rainy season in China and Thailand (39) as a result of water-washing-related transmission during heavy rains. These situations reflect the association of shigellosis with unsanitary conditions that foster fecal transmission. In developed countries, the highest incidence of shigellosis generally occurs during the warmer months of the year, when consumption of raw foods, such as fresh fruits and vegetables, and use of recreational facilities are the highest.

The distribution of *Shigella* spp. varies in different parts of the world. Fifteen years ago, the proportions of *S. flexneri*, *S. sonnei*, *S. boydii*, and *S. dysenteriae* were estimated to be, respectively, 60% (predominantly serotype 2a followed by 1b, 3a, 4a, and 6), 15%, 6%,

and 6% (30% of *S. dysenteriae* cases were type 1) in developing countries and 16% (predominantly serotype 3a followed by 1b, 1c, 2a, and Y variant [40]), 77%, 2%, and 1% in industrialized countries, with nearly half of the cases being reported among travelers (41). In some cases, specific geographical regions host one *Shigella* species, such as *S. boydii*, which is not frequently encountered outside the Indian subcontinent. Interestingly, travelers returning from India and neighboring countries and eastern, western, or northern Africa were at a higher risk for shigellosis (42).

Importantly, the distribution of *Shigella* spp. also seems to evolve with time and, of note, with the economy of a region (43). *S. dysenteriae* dominated in early parts of the 20th century but was replaced by *S. flexneri* in the 1930s and 1940s in the absence of epidemics in developing countries and in more recent times by *S. sonnei* in developed countries. With economic improvement within a developing country, a transition from *S. flexneri* to *S. sonnei* is observed, and the latter becomes responsible for the majority of shigellosis outbreaks, as seen since 2000 in Thailand (39) and Iran (44). While studying diarrheal disease caused by *Shigella* in six Asian countries, Warren et al. (11) found a link between socioeconomic factors and particular *Shigella* spp.; for example, in less resource-rich countries, the predominant species was *S. flexneri*. In addition, they observed that the variation of serotype differed temporally and with regard to geographic location, implying that the change in distribution may affect the effectiveness of any potential vaccine in areas of the world that have such shifts in serotypes.

Shigella spp. are capable of causing disease in otherwise healthy individuals. Certain populations, however, may be more predisposed to infection and disease due to the nature of transmission of the organism. Shigellae are transmitted by the fecal-oral route, direct person-to-person contact (fingers), food, water, and inanimate objects. More than two-thirds of all episodes of shigellosis are seen in children between 1 and 5 years old, who tend to explore their environment with their mouths (41, 45, 46). Sustained endemic

transmission and epidemics of bacillary dysentery are facilitated when crowding and poor sanitation conditions create an environment for direct fecal-oral contamination; examples include day care centers, custodial institutions, mental hospitals, and nursing homes, as well as refugee camps in time of war or political turmoil, where mass displacement and gathering occur. In the past 3 decades, major outbreaks have occurred in Africa, southern Asia, and Central America, causing up to 20,000 deaths in only a month (47). Oral-anal and digital-anal sexual practices favor the transmission of *Shigella* and contribute to outbreaks of shigellosis among the homosexual community (48). Additionally, human immunodeficiency virus (49)-positive individuals may present more severe and persistent forms of shigellosis.

The disease is communicable as long as an infected person excretes the organism in the stool. Secondary attack rates following exposure to the primary case can be as high as 40% among household contacts (46). The ease with which bacillary dysentery is transmitted from person to person is likely due to the very low infectious inoculum required.

Ecology

Shigella and EIEC have an extremely narrow host range. Only humans and other higher primates can develop shigellosis, but there is no evidence that the disease occurs naturally in the wild in nonhuman primates without prior contact with humans (50). While *Shigella* organisms are usually excreted for a few weeks after the illness, more than 10% of infected individuals, notably children, excrete shigellae for longer than 10 weeks (51). In areas where the organism is highly prevalent, up to 50% of all *Shigella* infections may be asymptomatic, and asymptomatic carriers of *Shigella* may exacerbate the maintenance and spread of this pathogen in developing countries. Two studies, one in Bangladesh (52) and the other in Mexico (53), showed that *Shigella* was isolated from stool samples collected from asymptomatic children under the age of 5 years.

The presence and persistence of *Shigella* in the environment is not well documented compared to those of other members of the *Enterobacteriaceae*. While the *E. coli-Shigella* ancestors gained genes that allowed them to access a new niche, i.e., the intracellular host milieu, positive selection subsequently fashioned the genome to allow virulence factors to be maintained (54) (Fig. 12.1). Accordingly, the evolution of *Shigella* was shaped by a massive loss of genes: 543 in *S. dysenteriae* Sd197, 347 to 371 in *S. flexneri*, 366 in *S. boydii* Sb227, and 255 in *S. sonnei* Ss046 (55). The majority of the lost phenotypes include surface appendages, cell motility, transport, and bacterial metabolism, reflecting the organism specialization to the intracellular pathogenic lifestyle (56–58). Because *Shigella* lacks flagella, fimbriae, and curli appendages and does not produce poly-β-1,6-*N*-acetylglucosamine or colonic acid polysaccharides, the organisms are not expected to form biofilms to protect them from damaging environmental factors (59). Nevertheless, a recent publication found that *Shigella* forms a biofilm in response to bile salts found in the small intestine (60). Current work is directed toward identifying the bacterial factors required for biofilm formation. In addition, *Shigella* incorporation into pre-established mixed-species biofilm communities has been suggested (61).

Ingestion of contaminated water is a recognized mode of transmission for shigellosis. Nevertheless, *S. dysenteriae* does not survive in water for more than 2 to 3 days. *S. flexneri* and *S. sonnei* can survive from 6 to 47 days and from 35 to 39 days, respectively (9). The community of organisms within fertile soil is biologically diverse and includes many bacterivorous organisms, including amoebae and nematodes. Over the last few years, these environmental predators have gained increasing attention as their roles as hosts for pathogenic bacteria, including *Legionella* and *Chlamydia*, are being uncovered (62). *S. sonnei* and *S. dysenteriae* can also survive phagocytosis by *Acanthamoeba* and grow in this group of ubiquitous free-living amoebae (63, 64). Considering that EIEC can paralyze and kill the nematode *Caenorhabditis elegans*

(65), agents of bacillary dysentery may well use amoebae and worms as environmental reservoirs.

SHIGELLA IN FOODS

Food Contamination

Shigella can be transmitted by consumption of raw or processed food. Generally, poor personal hygiene practices by food workers at the point of final preparation and food service are the major factor for food contamination (66). It has been recommended that infected personnel be monitored until stool samples are negative for *Shigella* (46). An extensive epidemiological investigation, for example, traced the source of a 2000 *S. sonnei* outbreak involving 406 diarrheal patients across 10 states in the United States to an employee participating in the preparation of the contaminated commercial five-layer dip (67). On at least one occasion, food (muffins and doughnuts) deliberately contaminated with *S. dysenteriae* type 2 was used as a biological weapon, leading to a dozen cases of shigellosis in Texas in 1996 (68).

Shigellae from infected individuals can spread by several routes, including food, fingers, feces, flies, and fomites. *S. sonnei* can survive for over 3 h on fingers, and *S. dysenteriae* type 1 can be recovered for up to 1 h (69, 70). *S. flexneri* can survive in feces for 12 days at 25°C (71). Flies can transmit the bacteria from fecal matter to foods. Utensils used in food preparation can also act as a vehicle for food contamination. For example, an early study by Nakamura (72) showed that *S. sonnei* could survive on metal utensils for more than 28 days at 15°C and up to 13 days at 37°C. Improper storage of contaminated foods is the second most common factor that accounted for foodborne outbreaks due to *Shigella*. Other contributing factors are inadequate cooking, contaminated equipment, and food obtained from unsafe sources. Consumption of raw vegetables harvested in fields where sewage is used as fertilizer or wastewater is used for irrigation can cause infection (73).

Survival and Growth in Foods

A number of raw or undercooked foods have been linked to shigellosis outbreaks, including lettuce, parsley, bean dip, cold sandwiches, potato salad, tofu salad, egg salad, hamburgers, tomatoes, and oysters (74). Establishments or events where these foods were served include homes, restaurants, camps, picnics, schools, airlines, sorority houses, and military mess halls. In many cases, the food source was not determined (75). Because *Shigella* spp. are not generally associated with specific foods, routine microbiological examination of foods to identify these pathogens is not usually performed. Many outbreaks are attributed to foods that require extensive manipulation during preparation and service, and investigation of food handling practices is generally more productive than microbiological examination of foods.

As discussed previously, the phylosphere (the total above-ground surfaces of plants) is not the natural habitat for *Shigella*. However, rapid growth of *S. sonnei* has been documented in shredded lettuce held at room temperature (76). Similarly, viable *S. flexneri* 2a survived for at least 72 h on damaged tomatoes (77), while *S. sonnei* did not survive desiccation on intact tomato surfaces (78). Islam et al. (79) showed that *S. flexneri* could grow on the surface of cucumbers for up to 24 h at 25°C and 37°C and survived for more than 72 h at 5°C. Cucumber skin is more textured than the waxy tomato skin and may provide sites where the bacteria are more protected from desiccation (73).

S. flexneri grew extremely well at 25°C and 37°C in sterilized milk, cooked rice, lentil soups, cooked beef, and fish and can persist for at least 3 days in all these foods except fish when stored at 5°C (79). Additionally, survival of *S. sonnei* in potato salad and raw ground beef at cold temperatures has been observed for at least 28 days and 9 days, respectively (78). *Shigella* can survive a temperature range of −20°C to room temperature; however, it survives for a longer time in foods stored frozen or at refrigeration temperatures than at room temperature. For example, two strains of *S. boydii* 18 were

inoculated into bean salad and stored at 4 or 23°C (80). No growth was observed at the lower temperatures, but both strains survived. At 23°C, a 2-order-of-magnitude increase was noted over 2 days, after which the number of viable cells declined.

Shigella tolerance to the low pH of the stomach contributes to its low infectious dose and its ability to survive in moderately acidic foods, such as fruits and vegetables. *S. flexneri* and *S. sonnei* can grow in the laboratory in rich media acidified to pH 4.75 and 4.5, respectively, and can survive in media with a pH range of 2 to 3 for a few hours. *S. sonnei* and *S. flexneri* could be recovered from tomato juice (pH 3.9 to 4.1) and apple juice (pH 3.3 to 3.4) after a few days at room temperature (81). Lowering the temperature increases the survival rate of *Shigella* in response to low pH and high salt stress. *S. flexneri* can grow at 37°C at pH 6 in the presence of 6% NaCl or at pH 5 with only up to 2% salt (82). The tolerance of *S. flexneri* to salt suggests that it may survive in salty foods, such as pickled vegetables, caviar, pickled herring, cured ham, and certain cheeses, over a long period of time. Whether *S. sonnei* survives better than *S. flexneri* in foods is still a matter of debate (83).

Foodborne Outbreaks

Foodborne outbreaks are not always easily recognizable when symptoms are mild and cases go unreported (74). As an example, a shigellosis outbreak caused by *S. sonnei* in Spain led to the infection of 60 preschool pupils and 28 family members over a 2-month period because it was undetected during the first month of occurrence (84). Even when epidemiological methods strongly imply a common food source, rapid turnover of produce may impair the ability to trace it back for analysis. Moreover, as discussed earlier, *Shigella* spp. are often not recovered and identified from foods when standard bacteriological methods are used.

The estimated number of total cases of foodborne illness in the United States each year is approximately 9.4 million annually from 31 known pathogens (85), but foodborne illness may be

significantly underreported because smaller and geographically dispersed outbreaks may not reach the attention of public health officials. Furthermore, an additional 38.4 million cases are caused by unspecified agents, bringing the total number of yearly cases to 48 million, thereby representing approximately one case for every six Americans (86). Based on the results reported by the CDC (85, 87), there are over 450,000 cases of shigellosis in the United States annually, approximately one-third of which are linked to a foodborne outbreak.

The Foodborne Diseases Active Surveillance Network (FoodNet) (88) is utilized as part of the CDC's continuing surveillance of reportable diseases caused by foodborne pathogens, including *Shigella*. From 1998 to 2004, 90 foodborne outbreaks of shigellosis were responsible for 5,324 illnesses reported to the CDC by state and local health departments (74). Compared to previous years, the incidence of foodborne shigellosis has been decreasing in the United States since 2000. Of the 17,468 laboratory-confirmed cases of foodborne infection in the United States in 2009, *Shigella* was identified in 1,849 cases, a 22% decrease compared to 2006 to 2008. A 2011 CDC publication on foodborne illnesses caused by 25 pathogens in the United States (85), which updated data from the report by Mead et al. (87), was based on laboratory-confirmed cases from five surveillance programs, some of which are indicated above. For illnesses caused by *Shigella*, most of the information cited in this new report used data from the surveillance programs covering the years 2005 to 2008. The estimated number of episodes attributed to this pathogen was given as 14,864 per year, of which nearly a third were foodborne related. This report also indicated that the numbers of hospitalizations and deaths due to illnesses acquired via foods were 1,456 and 10, respectively.

One of the striking features about foodborne outbreaks caused by shigellae is that contamination of foods usually is not at the processing plant; rather, the source is often traced to workers during final preparation of the food. As is evident from the examples below, these incidents can occur by improper food

handling in homes, small town gatherings and picnics, and largescale food service operations, such as those on cruise ships and in institutional facilities. Disease caused by the ingestion of these contaminated foods can subsequently lead to rapid person-to-person dissemination, particularly in crowded environments. *S. sonnei* has caused the majority of food-borne shigellosis in developed countries; however, *S. flexneri* and *S. dysenteriae* have also been implicated in some cases, generally via the import of contaminated produce.

Examples of Foodborne Outbreaks Caused by *Shigella* spp.

1989 and 1994—Shigellosis aboard Cruise Ships

In October 1989, 14% of the passengers and 3% of the crew members aboard a cruise ship reported having gastrointestinal symptoms (89). A multiple-antibioticresistant strain of *S. flexneri* 4a was isolated from several ill passengers and crew. The source of this outbreak was identified as German potato salad. Contamination was introduced by infected food handlers, first in the country where the food was originally prepared and second by a member of the galley crew on the cruise ship. Another outbreak of shigellosis occurred in August 1994 on the cruise ship SS *Viking Serenade* (90). A total of 586 passengers (37%) and 30 (4%) crew members reported having diarrhea, and one death occurred. In this outbreak, *S. flexneri* 2a was isolated from patients. The suspected source of contamination was spring onions.

1990—Operation Desert Shield

Diarrheal diseases during a military operation can be a major factor in reducing troop readiness. In Operation Desert Shield, enteric pathogens were isolated from 214 U.S. soldiers, and of those, 113 were diagnosed with *Shigella* infections, with *S. sonnei* being the most prevalent species isolated (91). Shigellosis accounted for more time lost from military duties and was responsible for more severe

morbidity than enterotoxigenic *E. coli*, the most common enteric pathogen isolated from U.S. troops in Saudi Arabia (91). The suspected source was contaminated fresh vegetables, notably, lettuce.

2000—Five-Layer Bean Dip

An outbreak of shigellosis caused by the ingestion of contaminated five-layer (beans, salsa, guacamole, nacho cheese, and sour cream) party dip occurred in three West Coast states (92). The causative agent was *S. sonnei*, which was isolated from at least 30 patients. The pathogen was found in just one layer (cheese) of the dip and was initially detected by a PCR assay targeting shigellae. Eventually, the pathogen was isolated by enrichment followed by plating on selective agar (67).

2001—Tomato-Linked Outbreak

Several restaurants in the New York area purchased tomatoes that were overripe and bruised from one distributor. These "special" tomatoes were identified as the source based on epidemiological data, including the fact that only restaurants that received these tomatoes were linked to the illnesses. Over 880 people reported being ill. *S. flexneri* 2a was isolated from several patrons of the restaurant as well as ill and asymptomatic employees from these restaurants. None of the workers from the restaurants reported being ill before the tomatoes arrived. PFGE of all the isolated *S. flexneri* strains linked all the restaurant patrons to this one outbreak (77).

2004—Unpasteurized Milk Curds

In October 2004, 41 persons in Vilnius, Lithuania, became sick after consuming unpasteurized milk curd produced in a local dairy. In addition to being isolated from the patients, *S. sonnei* was isolated from the dairy owner and two of her household members (93).

2004—Airline Food

In August 2004, inflight meals, likely raw carrot salad, contaminated with *S. sonnei* were served on 12 different flights departing from Honolulu International airport in Hawaii and led to 116 cases of shigellosis in two foreign countries, a U.S. territory, and nearly half of U.S. states. Between 300 and 1,500 passengers were potentially affected. The source of the outbreak was not identified with certainty (94).

2007—Raw Baby Corn

In August 2007, two shigellosis outbreaks in Denmark and Australia involving 215 and 20 cases, respectively, had a similar multidrug-resistant (MDR) *S. sonnei* isolate (95, 96). Epidemiological investigations linked the outbreaks to the consumption of raw baby corn imported from a common supply chain in Thailand. Inspection of a Thai collecting house revealed that the baby corn was placed directly on the ground and processed manually by locals without strict hygiene measures. Importantly, the water used to wash the corn contained only half of the recommended chlorine dose for disinfection (97).

2009—Sugar Peas

In April to June 2009, 37 persons became infected with *S. sonnei* in Denmark (98) and Norway (99) after consuming sugar peas imported from Kenya. *S. sonnei* was detected on the contaminated vegetable by PCR but could not be culture confirmed (99). During the same period, 35 to 47 persons became infected with *S. dysenteriae* type 2, presumably after consuming sugar peas imported from Kenya (100). However, the pathogen could not be identified from the vegetables recovered at a patient's house.

2014 and 2015—Two Outbreaks in California

Two independent foodborne outbreak clusters caused by *S. sonnei* occurred in San Jose, California, and in the San Diego, California, area. The former affected 182 people and originated in a local seafood restaurant. Notably, the *S. sonnei* isolates from patients in

this outbreak carried the lambdoid bacteriophage harboring the *stx* genes. The *S. sonnei* strain responsible for the outbreak in the San Jose area did not contain the *stx* genes but did have plasmid-borne antibiotic resistance genes, notably those encoding resistance to the fluoroquinolone class of antibiotics (101, 102).

CHARACTERISTICS OF DISEASE

Clinical Presentation

Disease caused by *Shigella* spp. is distinguished from disease caused by most of the other foodborne pathogens described in this volume in at least two important respects: the production of bloody diarrhea or dysentery and the low infectious dose required to cause clinical symptoms. Bloody diarrhea refers to diarrhea in which the stools contain visible red blood. Dysentery has the same meaning, but the passage of bloody mucoid stools is accompanied by severe abdominal and rectal pain, cramps, and fever. While abdominal pain and diarrhea are experienced by nearly all patients with shigellosis, fever occurs only in about one-third and frank blood in the stools in about 40% of the cases (103).

The clinical picture of shigellosis ranges from a mild watery diarrhea to severe dysentery. All *Shigella* spp. can cause acute bloody diarrhea. The dysentery stage of the disease caused by *Shigella* spp. may or may not be preceded by watery diarrhea. This stage reflects the transient multiplication of bacteria as they pass through the small bowel. Jejunal secretions probably are not effectively reabsorbed in the colon due to transport abnormalities caused by bacterial invasion and destruction of the colonic mucosa. The dysentery stage of disease correlates with extensive bacterial colonization of the colonic mucosa. The bacteria invade the epithelial cells of the colon and spread from cell to cell but penetrate only as far as the lamina propria. Foci of individually infected cells produce microabscesses that coalesce, forming large abscesses and mucosal ulcerations. As the infection progresses,

dead cells of the mucosal surface slough off, thus leading to the presence of blood, pus, and mucus in the stools.

The incubation period for shigellosis is 1 to 7 days, but the illness usually begins within 3 days. Strains of *S. dysenteriae* type 1 cause the most severe disease, whereas *S. sonnei* produces the mildest. *S. flexneri* and *S. boydii* infections can be either mild or severe. Despite the severity of the disease, shigellosis is generally self-limiting. If left untreated, clinical illness usually persists for 1 to 2 weeks (although it may be as long as a month), and the patient recovers. In some cases, there can be protracted asymptomatic shedding of the pathogen.

Infectious Dose

As mentioned above, an important aspect of *Shigella* pathogenesis is the extremely low 50% infective dose (ID_{50}), i.e., the oral dose required to cause disease in 50% of healthy adult volunteers challenged with a virulent strain of the pathogen. The ID_{50} for *S. flexneri*, *S. sonnei*, and *S. dysenteriae* varies, ranging from 10 CFU for virulent strains of *S. dysenteriae* to 140 CFU for *S. flexneri* and to less than 500 CFU for *S. sonnei* (see reference 104 for a review of infective doses of pathogens). Volunteers became ill when doses as low as 200 cells were given (42), and this number is generally considered an average infectious dose for *Shigella* spp. One of the host's innate defense factors is the low pH of the stomach, in which the gastric fluids can effectively kill microbial pathogens in 15 minutes (105). However, the influence of the food matrix which harbors bacterial pathogens, such as *Shigella*, may be significant with regard to surviving this harsh environment and indirectly affect the infectious dose. An example of this is when 180 CFU of wild-type *S. flexneri* 2a strain were administered with bicarbonate buffer instead of milk, which increased the shigellosis rate to 43%, indicating that resistance to gastric juice partially accounts for the high bacterial infectivity (106). The low infectious dose of *Shigella* underscores the high communicability of bacillary dysentery and

gives the disease great explosive potential for person-to-person spread as well as foodborne and waterborne outbreaks.

Complications

Shigellosis can be a very painful, incapacitating disease and is more likely to require hospitalization than many other forms of bacterial diarrhea. It is not usually life-threatening, and mortality is rare, except in malnourished children, immunocompromised individuals, and the elderly. However, complications arising from the disease include severe dehydration, intestinal perforation, toxic megacolon, septicemia, seizures, hemolytic uremic syndrome (HUS), and reactive arthritis (107). HUS is a rare but potentially fatal complication associated with infection by *S. dysenteriae* 1 (108). The syndrome is characterized by hemolytic anemia, thrombocytopenia, and acute renal failure. Epidemiologic studies suggest that Shiga toxin produced by *S. dysenteriae* 1 is the cause of HUS. This hypothesis is supported by the fact that HUS is also caused by strains of enterohemorrhagic *E. coli*, which produce high levels of Shiga toxin (see chapter 11). Shiga toxins cause HUS by entering the bloodstream and damaging vascular endothelial cells, particularly those in the kidney. The syndrome comprises three symptoms, urethritis, uveitis, and reactive arthritis, with the latter being the most dominant symptom. Reactive arthritis is a postinfection sequela to shigellosis that is strongly associated with individuals of the HLAB27 histocompatibility group (109). Infections caused by several other Gram-negative enteric pathogens also can lead to this type of sterile inflammatory polyarthropathy (110).

Treatment and Prevention

Although stool fluid losses are not as massive as with other bacterial diarrheas (e.g., cholera), the diarrhea associated with shigellosis combined with water loss from fever and the decreased water intake due to anorexia may result in severe dehydration (107). Oral intake of liquids can generally replace fluid losses, although

intravenous rehydration may be required in very young and elderly patients. Antidiarrheal drugs are not recommended because they decrease intestinal mobility and may worsen shigellosis. On the other hand, antibiotics shorten the duration of dysentery and bacterial excretion in feces. However, there is some controversy regarding the use of antibiotics in treating shigellosis. Since the infection is self-limited in normally healthy patients and full recovery occurs without the use of antibiotics, drug therapy is usually not indicated. Additionally, treatment of shigellosis has been confounded by a widespread increase in MDR *Shigella* strains, a critical health concern for treatment of infected individuals, particularly in the absence of an effective vaccine. Although the majority of outbreaks of illness caused by MDR *Shigella* in the last few years have occurred in southern Asia (India, Bangladesh, and China), there have been reports of outbreaks caused by MDR *Shigella* in South America (Chile) and the Middle East (Iran) (111–118). MDR outbreaks have been documented recently in the United States and other industrialized nations (119–122). For example, importation and domestic transmission of *S. sonnei* strains resistant to ciprofloxacin in the San Francisco area have been documented (119), as well as travel-acquired and domestically acquired MDR *S. sonnei* infections in Pennsylvania (123).

Although clonal expansion of particular resistant strains may participate in the increase of treatment failure, horizontal transfer has been proposed as the main mechanism of dissemination of antibiotic resistance determinants among *Shigella* spp. via mobile genetic elements, such as plasmids and transposons. Additionally, these genetic elements may carry integrons than can assimilate and exchange exogenous DNA cassettes, usually antibiotic resistance genes, by site-specific recombination and therefore can easily accumulate antibiotic resistance traits. Class 1 integrons have been detected in *S. flexneri* and *S. dysenteriae* (124, 125) but are less frequent in other *Shigella* spp. than class 2 integrons, which have been isolated from developed countries (e.g., Japan, South Korea,

and Ireland) (126–128) and developing countries (e.g., Brazil), especially among *S. sonnei* isolates.

The underlying explanation for the rapid worldwide distribution of MDR *Shigella* strains could be a substantial flux in the epidemiological landscape of this pathogen over the last century. International travelers are an underappreciated and significant factor for dissemination of *Shigella* spp. around the world (129, 130). These travelers, upon return to their homeland, may introduce novel MDR strains to naïve populations. These strains may then become endemic to a region, particularly if they are more resistant to elimination by antibiotics than native circulating strains. Another possible route of emergence of MDR strains is asymptomatic carriage of *Shigella* isolates, which may also account for persistence of these MDR strains, since an environmental reservoir for the bacteria has not yet been identified (131). Asymptomatic carriers of *Shigella* strains, therefore, may be exposed to broad-spectrum antibiotic drug treatment meant to target other infections. The inadvertent consequence would be ample selective pressure on *Shigella* MDR strains to perhaps circulate in the population. It is interesting that *Shigella* and other enteric pathogens utilize common drug resistance mechanisms to resist bile exposure, particularly the AcrAB efflux pump (60, 132). Therefore, exposure to bile during host infection may contribute to MDR development by inducing drug resistance mechanisms prior to antibiotic exposure. Finally, in developing nations, which account for the largest burden of *Shigella* infections, antibiotic use is often unregulated. This can easily lead to circumstances that lend themselves to the misuse and overuse of antibiotics (133).

The choice of antimicrobial drugs has changed over the years as resistance to antibiotics has occurred, with different patterns of resistance being reported around the world. Ampicillin and the combination trimethoprim-sulfamethoxazole (SXT), once the treatments of choice against shigellosis, long ago lost their efficacy in most of the world due to the development of drug resistance (134) and are no longer recommended for therapy due to this

widespread resistance pattern. In Belgium, resistance to SXT increased from 38% to 67% of *S. sonnei* isolates between 1990 and 2007 (128). In the United States, among the 552 *Shigella* isolates received by the National Antimicrobial Resistance Monitoring System at the CDC in 2008 (89.9% *S. sonnei* and 8.7% *S. flexneri*), 62.5% were resistant to ampicillin, 41.1% to SXT, and 22.8% to both treatments (135). In sub-Saharan Africa, among the 109 *Shigella* isolates isolated in Mozambique from 2001 to 2003 (86% *S. flexneri* and 14% *S. sonnei*), 56% were resistant to ampicillin, 84% to SXT, and 25% to both treatments (136).

Subsequently, first-generation quinolones have been used as a solution for the last 2 decades, but resistance to nalidixic acid is now common in Asian countries (137) and frequently found in Africa. For example, the majority of the *S. dysenteriae* type I isolates that were responsible for the devastating epidemics between 1993 and 1995 in refugee camps in Rwanda, Tanzania, and Democratic Republic of the Congo were resistant to all the commonly used antibiotics, including nalidixic acid (138). Nalidixic acid has therefore been replaced by fluoroquinolones, but ciprofloxacin resistance is now increasingly common in Asian countries (134), in particular in India, where a 48% increase has been reported between 2002 and 2007 (139). Quinolone resistance remains rare in the United States compared to Asian countries, but fluoroquinolone resistance has been reported in New York City, with half of the cases occurring in travelers from Asia or people that may have come into contact with travelers from the Indian subcontinent (140).

Ciprofloxacin has become the antibiotic of choice for MDR strains, but the emergence of ciprofloxacin resistance in *Shigella* has shifted the attention to third-generation cephalosporins, such as ceftriaxone; however, their cost is often prohibitive for patients in developing countries. The discovery of extended-spectrum β-lactamases that confer resistance to third-generation cephalosporins in *S. flexneri* and *S. sonnei* isolates in the United States (141), Vietnam (51), France (142), Lebanon (143), and India (51) compromises treatment options for shigellosis and is extremely

concerning, particularly for isolates displaying additional resistance to nalidixic acid (137). The macrolide azithromycin is recommended by the American Academy of Pediatrics for treatment of shigellosis in children and by the WHO as a second-line treatment in adults. A macrolide-resistant clinical variant of *S. sonnei* was isolated in France in 2007 (144).

Extensive use of antibiotics selects for drug-resistant organisms, and therefore, many believe that antimicrobial therapy for shigellosis should be reserved only for the most severely ill patients. On the other hand, there are persuasive public health arguments for the antibiotic management of shigellosis. Antibiotic treatment limits the duration of disease and shortens the period of fecal excretion of this pathogen (145). Since an infected person or asymptomatic carrier can be an index case for person-to-person, foodborne, and waterborne spread, antibiotic treatment of these individuals can be a significant public health tool to contain the spread of shigellosis. However, antibiotics are not a substitute for improved hygienic conditions to contain secondary spread of shigellosis. The most effective means of preventing secondary transmission are hand-washing with soap and chlorination of water. This point is highlighted by the recent *Shigella* outbreak in Flint, Michigan. Due to the lead contamination issues in the water system, residents were afraid to use and further expose their children to the water, thereby triggering an outbreak of shigellosis. It has been documented through news reports that residents were using baby wipes as alternatives to handwashing, not realizing that antimicrobial compounds are absent in the wipes (146). Food handling and preparation are important processes that also deserve attention, and persons with diarrhea should be excluded from handling food. Bardhan et al. (147) proposed that the 80% reduction in shigellosis-associated deaths observed in Asia in the past 10 years was due to measles vaccination, vitamin A supplementation, and improved nutrition in that part of the world. Breastfeeding has also been shown to provide protection during the first 3 years of life, especially in malnourished children.

Despite many years of intensive effort, an effective vaccine against shigellosis has not been developed yet. Natural infections result in about 72% protection against a second episode of shigellosis due to the homologous serotype but provide less than 30% protection against a heterogeneous serotype, suggesting that the *Shigella* O antigen is the key antigen for protection (47). A vaccine active against *S. sonnei*, *S. dysenteriae* 1, *S. flexneri* 2a, *S. flexneri* 3, and *S. flexneri* 6 would cover more than 80% of the strains currently causing morbidity and mortality in both developed and developing countries. Two main approaches were undertaken initially: (i) attenuated strains of *Shigella* were used as live oral vaccines, and (ii) O polysaccharides of *Shigella* covalently linked to carrier proteins were used as a parenteral conjugate vaccine (5). Whereas the first approach generated some degree of protection, administration of the live attenuated *Shigella* variants, for example, *S. flexneri* 2a SC602, *S. sonnei* WRSS1, or *S. dysenteriae* 1 strain WRSd1, was followed by fever and mild diarrhea. The second approach was relatively successful and safe when tested in adults and young children, but the *S. sonnei* conjugate had no efficacy in children less than 2 years old (148) and did not achieve protection in a population where the pathogen is endemic (149). New vaccine candidates include the use of new-generation conjugate vaccines that use synthetic oligosaccharides or a combination of invasion proteins and LPS named Invaplex (5).

VIRULENCE FACTORS

Hallmarks of Virulence

Shigella spp. and EIEC are the principal agents of bacillary dysentery and as such belong to the group of enteric pathogens that cause disease by overt invasion of epithelial cells in the large intestine. The clinical symptoms of shigellosis can be directly attributed to the hallmarks of *Shigella* virulence that modulate the host innate and adaptive immune systems. This modulation

provides the pathogen the ability to invade intestinal epithelial cells, escape from phagocytic vesicles, multiply intracellularly, spread from cell to cell, induce an inflammatory response, and ultimately produce typical symptoms of shigellosis such as diarrhea.

The overall picture of *Shigella* pathogenesis parallels that of other enteric bacterial pathogens. After ingestion, the organism transits the stomach and small intestine and eventually enters M cells that overlie lymphoid nodules in the colon, specifically the follicle-associated epithelium (150, 151). Exploiting the arsenal provided by the T3SS, the bacteria induce their uptake by colonic M cells and, posttranscytosis, are released into the intraepithelial pocket. Macrophages engulf the pathogens, which survive phagocytosis and use effector proteins to kill the macrophages (152, 153). After macrophage cell death, proinflammatory cytokines are released, thereby causing an acute inflammatory response. Current thought is that the host response provides the pathogen with the ability to evade the host innate and adaptive immune response and that controlling the host response may limit the severity of the disease. Bacterial cells released after the destruction of macrophages enter the basolateral membranes of adjacent epithelial cells by a macropinocytic-type process of actin polymerization and depolymerization to form filopodial and lamellipodial extensions of the epithelial membrane that result in bacterial engulfment (12, 154, 155). Lysis of the macropinocytic vacuole enables *Shigella* to enter the host cell cytoplasm, where the pathogen multiplies. Through actin polymerization, the bacteria are propelled throughout the cytoplasm and into adjacent cells through the formation of "actin rockets," similar to those observed with *Listeria monocytogenes* (see chapter 17) (156). This mechanism of intercellular spread enables the bacteria to temporarily evade host immune responses.

Shigella colonizes the small intestine only transiently and causes little tissue damage (157). Recent data demonstrate that *Shigella* forms a biofilm in response to the bile salts present in the small intestine (60). Based on their results, the authors of that study

present a model in which biofilm formation enables the bacteria to transit the small intestine, with subsequent biofilm dispersion in the terminal ileum as bile is reabsorbed into circulation. The dispersion event permits *Shigella* invasion of the colon. It is hypothesized that this biofilm formation enables the bacteria to successfully survive and transit the small intestine under otherwise bactericidal conditions. The study also identified important gene transcription changes in response to bile that included induction of virulence genes as well as genes important for anaerobic respiration. Furthermore, separate analyses have demonstrated an altered gene expression profile in response to available oxygen, indicating the genetic alterations that occur as the bacteria transition to a more anaerobic environment (158, 159). These studies highlight the alteration of *Shigella* gene expression, particularly of virulence genes, as the bacteria transit the intestines prior to infection in the colon. Finally, production of enterotoxins by the bacteria while in the small bowel likely results in the watery diarrhea that often precedes onset of dysentery (160–163), the first hallmark of *Shigella* virulence. The jejunal secretions elicited by these toxins may facilitate passage of the bacteria through the small intestine and into the colon, where they colonize and invade the epithelium.

Labrec and colleagues established the essential role of epithelial cell invasion in *Shigella* pathogenesis in a landmark study that employed both *in vitro* tissue culture assays for invasion and animal models (164). They found that spontaneous colonial variants of *S. flexneri* 2a that are unable to invade epithelial cells in tissue culture do not cause disease in monkeys. Gene transfer studies using *E. coli* K-12 donors and *S. flexneri* 2a recipients established the third hallmark, intracellular multiplication, of *Shigella* virulence. An *S. flexneri* 2a recipient that inherits the *xyl-rha* region of the *E. coli* K-12 chromosome retains the ability to invade epithelial cells but has a reduced ability to multiply within these cells. This hybrid strain fails to cause a fatal infection in the opium-

treated guinea pig model and is unable to cause disease when fed to rhesus monkeys (165).

It is necessary but not sufficient for *Shigella* to be able to multiply within the host epithelial cell after invasion. The bacterium must also be able to spread through the epithelial layer of the colon by cell-to-cell spread that does not require the bacterium to leave the intracellular environment and be re-exposed to the intestinal lumen or the host's immune response. Mutants of *Shigella* that are competent for invasion and multiplication but unable to spread between cells in this fashion have been isolated. These mutants established intracellular spread as the fourth hallmark of *Shigella* virulence and are discussed further below.

Along with the ability to colonize and cause disease, an intrinsic part of a bacterium's pathogenicity is its mechanism for regulating expression of the genes involved in virulence. Virulence in *Shigella* spp. is regulated by growth temperature. After growth at 37°C, virulent strains of *Shigella* are able to invade mammalian cells, but when cultivated at 30°C, they are noninvasive. This noninvasive phenotype is reversible by shifting the growth temperature to 37°C. The temperature change enables the bacteria to re-express their virulence properties (166). Temperature regulation of virulence gene expression is a characteristic that *Shigella* shares with other human pathogens, such as *E. coli*, *Salmonella enterica* serovar Typhimurium, *Bordetella pertussis*, *Yersinia* spp., and *L. monocytogenes* (see reference 6 for a review). Regulation of gene expression in response to environmental temperature is a useful bacterial strategy. By sensing The ambient temperature of the mammalian host (e.g., 37°C for humans) to trigger gene expression, this strategy permits *Shigella* to economize energy that would be expended on the synthesis of virulence products when the bacteria are outside the host. The system also permits the bacteria to coordinately regulate expression of multiple unlinked genes that are required for the full virulence phenotype. Temperature regulation in *S. flexneri* 2a operates at the level of gene transcription and is mediated by both positive and negative transcription factors. A

chromosomal gene, *virR* (*hns*), encodes a repressor of virulence gene expression (167), while two plasmid-borne genes, *virF* and *virB*, encode positive activators (168). These genes are discussed below. A more thorough assessment of virulence gene regulation in *Shigella* can be found in several review articles (12, 169, 170).

Genetics

Virulence-Associated Plasmid Genes

Given the complexity of the interactions between host and pathogen, it is not surprising that *Shigella* virulence is multigenic, involving both chromosomal and plasmidborne genes (Table 12.1). Another landmark study on the pathogenicity of *Shigella* demonstrated the indispensable role of a large plasmid in invasion, pINV. A 180-kb plasmid in *S. sonnei* and a 220-kb plasmid in *S. flexneri* are essential for invasion (171). Other *Shigella* spp., as well as strains of EIEC, possess homologous plasmids which are functionally interchangeable and share significant degrees of DNA homology. The DNA sequence of the virulence plasmid of *S. flexneri* was the first to be published (110, 172, 173), and the virulence plasmids of *S. sonnei*, *S. dysenteriae* 1, and *S. boydii* have also been sequenced (174, 175). The virulence plasmid from EIEC has been sequenced and can be accessed from GenBank (accession number CP001064).

A 37-kb region of the invasion plasmid of *S. flexneri* 2a contains all of the genes necessary to permit the bacteria to penetrate tissue culture cells. This DNA segment was identified as the minimal region of virulence plasmid necessary to allow a plasmid-cured derivative of *S. flexneri* (and *E. coli* K-12) to invade tissue culture cells (171, 176). The region contains about 33 genes in two groups transcribed in opposite orientation (Fig. 12.2). These genes encode proteins that are components of the T3SS apparatus, effectors, translocators, transcription activators, and chaperones. Although a precise transcription map of these genes has not been defined,

available evidence and the DNA sequence of the region suggest a multiple-operon organization.

Table 12.1 Virulence-associated loci of *Shigella*

Site and locus	Product	Role in virulence
Chromosome		
cpxR	Response regulator of CpxACpxR two-component system	Activator of *virF*
iucA to *-D; iutA*	Synthesis of aerobactin and receptor	Acquisition of iron in the host
pic	Autotransporter protein	Putative hemagglutinin, mucinase, enterotoxin, and immune-modulating functions
rfa; *rfb*	Enzymes for core and O antigen	Correct polar localization of IcsA biosynthesis
set1AB[a]	ShET1	Enterotoxin
sigA	Autotransporter protein	Enterotoxin activity
slyA	Transcriptional regulator	Activation of virulence genes; role in acid resistance
sodB	Superoxide dismutase	Inactivation of superoxide radicals; defense against oxygen-dependent killing in host
stx[b]	Shiga toxin	Destruction of vascular tissue
vacB (39)	Exoribonuclease RNase R	Posttranscriptional regulation of virulence gene expression
virR (*hns*)	Histone-like protein	Repressor of virulence gene expression
Plasmid		

icsA (virG)	Cell-bound and secreted protein	Actin polymerization for intracellular motility and intercellular spread
icsB	Secreted effector	Shields IcsA from binding autophagy protein Atg5; protects against autophagy
icsP	Outer membrane protease	Role in IcsA unipolar localization
ipaA	Secreted effector	Efficient invasion; binds to vinculin and promotes F-actin
ipaB	Secreted effector	Invasion; lysis of vacuole; induction of macrophage cell death
ipaC	Secreted effector	Invasion; induces cytoskeletal reorganization
ipaD	Secreted effector	Invasion; antisecretion plug (with IpaB) depolymerization; induction of macrophage cell death
ipaH	See below[c]	
ipaJ	Secreted effector	Disrupts entry vacuole (with VirA)
ipgB1 and -2	Secreted effector	Promotes membrane ruffling
ipgC	17-kDa protein	Cytoplasmic chaperone for IpaB and IpaC; coactivator of MxiE; activation of Rac1 and Cdc42
ipgD	Secreted effector	Promotes bacterial entry; enhances epithelial cell survival by targeting Akt
mxi-spa	20 proteins	Type III system for secretion of Ipa and other virulence proteins
mxiE	Transcriptional activator	AraC-family postinvasion activator

ospB	Secreted effector	Regulation of host cell proliferation
ospC1	Secreted effector	Regulation of neutrophil migration
ospC2	Secreted effector	Function unknown
ospC3	Secreted effector	Inhibition of host cell death
ospC4	Secreted effector	Function unknown
ospD1	Secreted effector	Antiactivator of MxiE
ospD2	Secreted effector	Function unknown
ospE1 and -2	Secreted effectors	Maintain bacterial cell integrity postinvasion; required for bile salt-induced adherence
ospF	Secreted effector	Phosphothreonine lyase
ospG	Secreted effector	Targets ubiquitin-conjugating enzymes; downregulates host innate immune response
ospI	Secreted effector	Suppresses TRAF6-mediated signaling
ospZ	Secreted effector	Blocks NF-κB activation
sen (*ospD3*)	ShET2	Enterotoxin; regulation of IL-8 secretion from infected epithelial cells
sepA	Autotransporter	Protease activity; enterotoxin activity; enables *Shigella* to gain access to the basolateral pole of the epithelium
spa15	Chaperone and secreted effector	Inhibition of epithelial-cell apoptosis
virA	Secreted effector	Disruption of entry vacuole (with IpaJ); autophagy (with IcsB)
virB	Transcriptional	Temperature regulation of

	activator	virulence genes
virF	Transcriptional activator	Temperature regulation of virulence genes

[a] The *set* locus and production of Pic and ShET1 are found almost exclusively in *S. flexneri*.

[b] The *stx* locus and production of Shiga toxin are observed only in *S. dysenteriae* 1.

[c] There are four loci located on the chromosome and five located on the virulence plasmid. The role of the *ipaH* genes appears to be to encode E3 ubiquitin ligases (141). Since there are nine genetic loci, the *ipaH* genes have been a common target in many PCR-based assays.

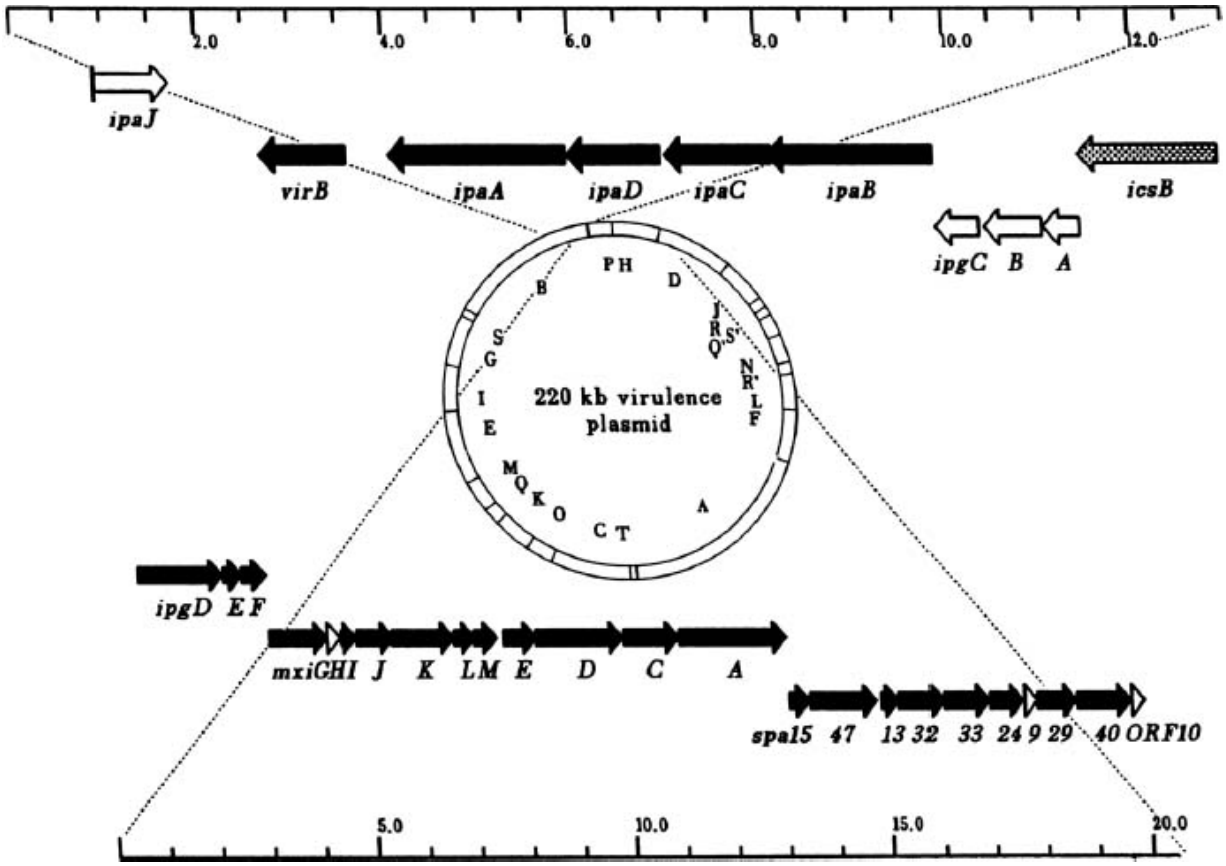

Figure 12.2 *S. flexneri* 2a virulence plasmid map. A SalI restriction map of the 220-kb plasmid is shown in the center. Sections of SalI fragments B and P (upper map) and fragments P, H, and D (lower map) are expanded to illustrate the virulence loci encoded in these regions. The expanded regions are contiguous and cover 32 kb. The ORF for *icsB* is separated from that of *ipgD* by 314 bp.

The genes composing the *ipaBCDA* (invasion plasmid antigens) cluster encode the immunodominant antigens, which were detected with sera from convalescent patients and experimentally challenged monkeys (177). *ipaBCD* have been experimentally demonstrated to be required for invasion of mammalian cells (178), while experiments have shown that *ipaA* facilitates entry (179, 180). The Ipa products act as translocators by interacting with the host cell membrane subsequent to being shunted through the bacterial membrane through the T3SS. IpaB and IpaC form a complex on the bacterial cell surface and are responsible for transducing the signal that leads to entry of *Shigella* into host cells via bacterium-directed phagocytosis (181). IpaD is also required for insertion of IpaBC into the membrane (182). However, when IpaB and IpaC are used to coat latex beads, they form a complex that promotes uptake of the beads by HeLa cells (183). This complex of Ipa proteins also binds to cell surface receptors such as $\alpha_5\beta_1$ integrins (184). Purified IpaC induces cytoskeletal reorganization via actin polymerization and depolymerization, including formation of filopodia and lamellipodial extensions on permeabilized cells (185). IpaA binds to vinculin and promotes F-actin depolymerization (186). This step is thought to facilitate reorganization of the host cell surface structures induced by contact with *Shigella* and modulate bacterial entry (179).

Although the Ipa proteins have no typical signal sequence for recognition by the usual Gram-negative bacterial transport system, these proteins are secreted into the extracellular medium via a T3SS (187, 188). The T3SS pathway requires a dedicated apparatus composed of gene products from the *mxi-spa* (membrane expression of invasion plasmid antigens and surface presentation of Ipa antigens) loci (Fig. 12.2). Secretion through T3SS is extremely orchestrated, as recently reviewed (189). Contact of the bacterium with epithelial cells induces secretion of the cytoplasmic pool of Ipa products (190). Fibronectin, laminin, collagen type IV, Congo red, bile salts, and fetal bovine serum have also been reported to induce Ipa secretion in the laboratory (190–192). IpaD forms an

antisecretion complex, or plug, with IpaB. Consequently, both *ipaD* and *ipaB* mutants are hypersecretors of the Ipa products (193).

MxiC plays a similar role in controlling the secretion of effectors, acting as a gatekeeper for secretion (194, 195). *ipgC* (invasion plasmid gene) is required for invasion and acts as a cytoplasmic chaperone which prevents IpaB and IpaC from forming complexes while in the bacterial cytoplasm (181). In the absence of IpgC, IpaB and IpaC are rapidly degraded. IpgC also plays a role as a coactivator in virulence gene regulation (see below). The product of *ipaB* has also been postulated to be the "contact hemolysin" which is responsible for lysis of the phagocytic vacuole minutes after entry of the bacterium into the host cell (196). The ability of *S. flexneri* to induce pyroptosis (197) in infected macrophages is an additional property assigned to IpaB (198), while IpaD was also recently shown to induce apoptosis in macrophages (153).

The secretion apparatus consists of the inner membrane proteins MxiG and MxiJ and an outer membrane protein, MxiD, which, along with MxiM, is proposed to form a bridge across the periplasmic space to contact MxiJ and MxiG (199). The secretion "needle" is composed of MxiH and possibly MxiI (200, 201). Spa47 plays a critical role in facilitating the transfer of proteins through the needle complex (202), while Spa32 is involved in controlling needle length (203, 204). Spa33 associates with MxiG and MxiJ in the putative C ring of the secretion apparatus and controls secretion of IpaB and IpaC (205). Interestingly, expression of both *spa32* and *spa33*, but not that of other T3SS genes, is reduced under anaerobic conditions prevalent in the lumen of the large intestine, suggesting that effective secretion of TTSS effectors would occur only when the bacteria reach the surface of intestinal epithelial cells, where oxygen is more abundant (158, 206). Nonpolar null mutations in all of the *mxi-spa* genes tested to date result in loss of the ability to secrete the Ipa proteins and loss of invasive capacity for cultured cells. Hence, T3SS is an essential component of *Shigella* virulence. The exception to this statement, i.e., loss of invasive capability, is *mxiE*, which encodes a transcriptional regulator of genes expressed

postinvasion (207). MxiE is addressed below in the section on gene regulation.

The *spa* genes encode proteins that share significant homologies with proteins involved in flagellar synthesis in *E. coli*, *Salmonella* Typhimurium, *Bacillus subtilis*, and *Caulobacter crescentus* (12). Included among these genes is *spa47*, which encodes a protein that probably functions as the energy-generating component of the secretion apparatus, since it shows sequence similarities with ATPases of the flagellar assembly machinery of other bacteria. In addition, there is an even more striking similarity in both gene organization and predicted protein sequence between the *mxi-spa* region of the *Shigella* virulence plasmid and a virulence-associated chromosomal region of *Salmonella* Typhimurium (208). The *Salmonella spa* region contains homologues of the *Shigella spa* genes in the same gene order. Sequence identities between the protein homologues are as high as 86% (Spa9 versus SpaQ). The relatedness of the *spa* regions strongly suggests that these human pathogens evolved similar mechanisms for secretion of the virulence proteins required for signal transduction with the mammalian host. Plant pathogens such as *Pectobacterium carotovorum*, *Xanthomonas campestris*, and *Ralstonia solanacearum* also contain genes that encode homologues of the *mxi-spa*-encoded proteins (209). It is now recognized that the T3SS for transport of virulence proteins is a critical element of both plant and animal bacterial pathogenesis.

The virulence plasmid encodes two distinct families of effector proteins that are secreted by the T3SS. The first, designated Osp (outer *Shigella* proteins), has several functions to regulate intracellular survival once *Shigella* is inside epithelial cells (210). Functions include modulation of host cell signaling pathways, such as the NF-κB and the ERK1/2 and p38 MAPK pathways (OspB [211, 212], OspC1 [213], OspF [212–214], OspG [215], OspI [216], and OspZ [217, 218]), maintenance of epithelial cell integrity (OspE1 and OspE2 [219]), regulation of host cell proliferation (OspB [220]), and inhibition of host cell death (OspC3 [221]). Most of the

consequences of altering host cell signaling appear to modulate the immune response, mostly by affecting interleukin 8 (IL-8) secretion from the epithelial cells and subsequent neutrophil (PMN) migration, a complex interplay during *Shigella* infection (222). Some effectors have been shown to induce IL-8 secretion and PMN migration during early infection to enhance invasion by increasing access to the basolateral pole (213, 223), while other effectors have been shown to decrease this response during later stages of infection to mitigate the immune response (212, 214, 224). OspD3 also alters IL-8 secretion (222), while the induction of PMN migration through hepoxilin A (3) has also been observed during *Shigella* infection (225). Clearly, continued research is needed to fully understand how and why *Shigella* modulates PMN migration during the various stages of infection

Additional functions described for the Osp proteins include negative regulation of virulence gene expression (the OspD1 antiactivator [226]; see below), enterotoxin activity to induce secretory diarrhea (OspD3 [160, 161]; also referred to as *Shigella* enterotoxin 2 [ShET2]), and adherence to the apical surface of epithelial cells that is mediated by bile salts exposure (OspE1 and OspE2 [227]).

The second family of T3SS effectors encoded on the virulence plasmid is the IpaH family, encoded by five separate genes (228). Most of the proteins in this family have E3 ubiquitin ligase activity, which is important for modulating NF-κB signaling and immune response signaling in epithelial cells (224, 229, 230) and enhancing pyroptosis in macrophages (231). There are an additional four *ipaH* genes (plus an additional three annotated pseudogenes or gene fragments) present on the *Shigella* chromosome whose protein products have been shown to be secreted through the T3SS (232). Thus far, function has been described only for IpaH0722, which ubiquitinates TRAF2 to further control NF-κB signaling (233).

A plasmid-borne virulence gene which is unlinked to the 37-kb region shown in Fig. 12.1 is not required for invasion but is crucial for intra-and intercellular motility. This gene, known as *virG* or *icsA*

(intracellular spread), encodes a protein that catalyzes the polymerization of actin in the cytoplasm of the infected host cell (234). The IcsA protein belongs to a family of autotransporter proteins that are large and are secreted through type V secretion (235, 236). IcsA is unusual in that it is expressed asymmetrically on the bacterial surface, being found only at one pole. The polymerization of actin monomers by IcsA forms a tail leading from the pole and provides the force that propels the bacterium through the cytoplasm. Hence, unipolar expression of IcsA imparts directionality of movement to the bacterium. A plasmid-encoded protease, SopA/IcsP, cleaves IcsA and is proposed to play a role in unipolar localization of IcsA (237). Synthesis of a complete LPS is also crucial for correct unipolar localization of IcsA (238), while the periplasmic chaperones DegP, Skp, and SurA further facilitate IcsA presentation to the outer membrane and subsequent unipolar localization (239). The use of translational fusions between IcsA and green fluorescent protein defined the amino acids that are sufficient for polar localization and confirmed correct polar localization of IcsA when it is expressed in *E. coli* as well as *Salmonella* Typhimurium, *Yersinia pseudotuberculosis*, and *Vibrio cholerae* (240). Interestingly, surface-expressed IcsA is a trigger for autophagy once the bacteria are inside the cytoplasm of epithelial cells. To protect the bacteria against this host intracellular degradation system, IcsB is secreted via the *Shigella* T3SS, which acts to shield IcsA from binding the autophagy protein Atg5 and thus protects the bacterium from being trapped and degraded within the infected host cell (241).

Characterization work has been performed on additional genes located on the virulence plasmid whose protein products encompass a variety of functions. Most of these proteins are secreted through the T3SS. First, additional proteins that facilitate bacterial entry have been identified. IpgD activates the small GTPase ADPribosylation factor 6 to promote bacterial invasion of epithelial cells (242). Invasion is further facilitated by IpgB1 and IpgB2, which activate Rac1 and RhoA, respectively, to promote bacterial entry

(243–245). Second, T3SS effectors have been shown to enhance IpaB-and IpaC-mediated bacterial escape from the macropinocytic vacuole (181) and enable *Shigella* entry into the host cell cytoplasm. IpaJ and VirA fragment the Golgi apparatus to disrupt the entry vacuole and allow the bacteria to gain access to the host cell cytoplasm (246, 247). VirA may also facilitate IcsB to disrupt autophagy (248). Third, a few T3SS effectors enhance epithelial cell survival during infection. The chaperone Spa15 (249) has also been shown to be secreted during later stages of infection to inhibit epithelial cell apoptosis upstream of caspase-3 activation (250), but a mechanism remains to be determined. IpgD further enhances epithelial survival by activating the Akt–phosphatidylinositol 3-kinase signaling pathway by phosphorylating Akt (251). Overall, *Shigella* induces several mechanisms of apoptosis inhibition during epithelial cell infection (221, 252) that require further exploration.

Regarding non-T3SS effectors, the genes in the *shfwabB-virK-msbB2* operon have been implicated in cell wall biosynthesis (253–255). MsbB2 is a second copy of the myristoyl transferase involved in lipid A synthesis. Interestingly, *msbB2* is regulated by the PhoPQ two-component regulatory system under low-magnesium conditions, which was hypothesized to be important for LPS modifications to enhance virulence (255). Shf (or SfPgdA) has been characterized as a peptidoglycan deacetylase also controlled by PhoPQ and involved in bacterial persistence in the presence of neutrophils (254). Finally, SepA is another autotransporter protein that does not require the T3SS apparatus for secretion. Originally, SepA was demonstrated to be important for the overall infection process through the rabbit ileal loop model, while subsequent studies identified proteolytic activity (256, 257). Separate research identified SepA as an overall contributor to *Shigella* enterotoxin activity (160), while recent work has demonstrated that SepA disrupts the epithelial cell barrier to enable *Shigella* invasion at the basolateral pole of the epithelium (258). A mechanism was presented in which SepA degraded the activated form of LIM kinase 1, which resulted in increased activation of cofilin and subsequent

opening of tight junctions. As epithelial barrier disruption and enterotoxin activity are related (259), this result is interesting in that it helps to explain previous research findings for SepA and provides us with a better understanding of how *Shigella* accesses and efficiently invades the basolateral pole of the epithelium.

Chromosomal Virulence Loci

Although *Shigella* and *E. coli* are very closely related at the genetic level, there are significant differences beyond the presence of the virulence plasmid in *Shigella*. Pathogenicity islands, clusters of genes that have a role in virulence, have been identified in several virulent bacteria, including *Shigella*. These regions are typically large (20 to 200 kb) and, in addition to virulence genes, may contain transposable elements, insertion sequences, and remnants of mobility plasmid or bacteriophage genes, all indicating possible horizontal transfer of genetic information.

Pathogenicity islands have been identified in the chromosome of *S. flexneri* (Table 12.1). SHI-1 (*Shigella* pathogenicity island 1) contains the *set1A* and *set1B* genes, which encode *Shigella* enterotoxin 1 (ShET1) (163). The genes are contained in the opposite orientation within the ORF of another gene, *pic*, which encodes an autotransporter protein with putative hemagglutinin, mucinase, and immune-modulating activities (260–262). The genes for ShET1 are chromosomal and are present in *S. flexneri* but have not been detected in other *Shigella* species. Pic has also been shown to result in enterotoxic activity, since a construct of *pic* with four point mutations to disrupt the *set1A* and *set1B* genes while maintaining the appropriate codons for *pic* was able to complement a mutant with a *pic-set1AB* deletion (160). A second autotransporter encoded on SHI-1, SigA, also displays enterotoxin activity (263). Therefore, data suggest that *Shigella* expresses five enterotoxins encoded on both the chromosome and the virulence plasmid (ShET1, ShET2/OspD3, Pic, SepA, and SigA).

The *iuc* locus and *iutA*, which respectively contain the genes for aerobactin synthesis and transport as well as the aerobactin-siderophore receptor, are present in SHI-2 (264, 265). A similar pathogenicity island was identified in *S. boydii* in which the *iuc* and *iut* genes were conserved, but it was located in a distinct region of the chromosome relative to *S. flexneri* and thus named SHI-3 (266). Aerobactin is a hydroxamate siderophore that *Shigella* uses to scavenge iron. Work with *S. flexneri* demonstrated that when the *iuc* locus is inactivated, the aerobactin-deficient mutants retain their capacity to invade host cells but are altered in virulence, as measured in animal models. These results suggest that aerobactin synthesis is important for bacterial growth within the mammalian host (267, 268). Since *iuc* and *iutA* are important for transport of ferric iron, the predominant form of iron under aerobic conditions, additional analysis of iron acquisition and regulation was performed under anaerobic conditions (269). Under anaerobiosis, the *feoABC* genes were activated while the *sit* and *iuciut* genes were repressed. This regulation was mediated through two transcription factors, AcrA and Fnr, in which ArcA was involved in both the activation and repression of the respective gene clusters while Fnr was also utilized for *feoABC* activation. Furthermore, the *fur* gene that encodes the iron-responsive repressor for bacterial iron acquisition was also repressed under anaerobic conditions by ArcA. These studies highlight the ability of *Shigella* to regulate iron acquisition under both aerobic (more environmental and early *in vivo* settings) and anaerobic (the human colon) conditions.

Finally, the SHI-O pathogenicity island of *S. flexneri* includes the *gtrA*, *gtrB*, and *gtr* genes, which are important for O-antigen modifications and serotype conversion (270). It was demonstrated that glucosylation of *Shigella* LPS results in shortening of the LPS to enable better contact of epithelial cells by the T3SS needle without compromising LPS protection of the bacteria (271).

S. dysenteriae type 1, like *E. coli* O157:H7, produces Shiga toxin and is responsible for some of the symptoms of HUS. Acquisition of the Shiga toxin genes *stxA* and *stxB* by *S. dysenteriae* has been

postulated to be a consequence of a lysogenic bacteriophage. Over time, the phage became stably integrated due to loss of genetic function of essential phage genes, most likely as a result of rearrangement and transposition events. Shiga toxin inhibits protein synthesis by inactivating 28S rRNA in the 60S subunit of mammalian ribosomes and preventing elongation factor 2 from interacting with the ribosome (272). The Shiga toxin produced by *S. dysenteriae* and the Shiga toxin elaborated by *E. coli* O157:H7 are nearly identical, differing from each other by just one amino acid. A mutation in the *stx* locus does not alter the ability of the bacterium to invade epithelial cells or cause keratoconjunctivitis in the Sereny test. However, when tested in macaque monkeys, the mutant strain causes less vascular damage in the colonic tissue than the toxin-producing parent (273). Hence, production of Shiga toxin may account for the fact that *S. dysenteriae* 1 infections are generally more severe than those caused by the other species of *Shigella*. Recent studies have documented the emergence of *S. flexneri* and *S. sonnei* strains harboring Shiga toxins (16, 101, 274–277), leading to the possibility of HUS and significant renal complications from infections with other species of *Shigella* (278).

Chromosomal Avirulence Loci

The early genetic studies by Formal et al. (165), and reports that select genetic loci are not present in the *Shigella* chromosome but are present in the chromosome of nonpathogenic *E. coli* (279), suggest that the absence of particular genes in *Shigella* has had a direct consequence on its pathogenesis. The absence of these genetic determinants in *Shigella* spp. occurred by either deletions or mutations and is referred to as a "black hole" (Fig. 12.1) (57). When a gene complementary to a genetic locus that is absent in *Shigella* is introduced into the pathogen, the presence of that newly acquired gene product in *Shigella* may inhibit the action of a particular virulence factor. For instance, although lysine decarboxylase activity is present in >85% of *E. coli* strains, it is missing in all strains of *Shigella* spp. and EIEC. Lysine decarboxylase (encoded by the *cadA*

gene) produces cadaverine from lysine. Cadaverine inhibits the action of the *Shigella* enterotoxins that are believed to be responsible for the diarrheal symptoms associated with shigellosis. Therefore, *cadA* is considered an antivirulence gene for *Shigella* (57). Thus, as part of the evolution of *Shigella* to a human pathogen from a nonpathogenic *E. coli* lineage, the acquisition of the large virulence plasmid may have also involved the loss of specific incompatible genetic loci. Recently, Yang et al. reviewed the role of IS elements in the evolution of *Shigella* genomes from an ancestral *E. coli* strain (24).

Virulence Gene Regulation

An important feature of *Shigella* pathogenesis is the ability of the bacterium to modulate expression of its virulence genes in response to growth temperature (12). Several activators and a repressor control the virulence regulon of *Shigella* such that genes are turned on at 37°C and turned off at 30°C. The product of the chromosomal *virR* (*hns*) locus is a histone-like protein, H-NS, which behaves as a repressor of *Shigella* virulence gene expression in response to growth temperature (167). Mutations in *virR* (*hns*) cause deregulation of temperature control and result in expression of genes in the virulence regulon even at the nonpermissive temperature of 30°C. The *virR* (*hns*) locus is allelic with regulatory loci in other enteric bacteria, and like *virR* (*hns*), these alleles act as repressors of their respective regulons (references cited in reference 169). Several different models to explain how VirR/H-NS acts as a transcriptional repressor have been proposed (169). However, because VirR/H-NS is involved in gene regulation in response to diverse environmental stimuli such as osmolarity, pH, and temperature, a comprehensive model to explain its activity has been elusive.

H-NS binds to the promoter regions of two transcriptional activators, *virF* and *virB*, and blocks their transcription at 30°C (280, 281). At 37°C, the H-NS binding sites undergo a conformational transition and no longer bind H-NS, thus leading to

increased transcription of the activator genes (12). Expression of genes in the *ipa* and *mxi-spa* clusters is dependent on VirB, and mutations in *virB* abolish the bacterium's ability to invade tissue culture cells. Transcription of *virB* is dependent on growth temperature and VirF (282). VirB is a DNA-binding protein and shares homology with the plasmid-partitioning proteins ParB of bacteriophage P1 and SopB of plasmid F. Purified VirB shows preferential binding to the intergenic *icsB-ipgD* region (Fig. 12.2) and displays a similar preference for binding to the *spa* and *virA* gene promoter regions (283). Recently, analysis of the transcriptional regulator SlyA demonstrated that the protein can rescue virulence gene expression in the absence of VirB (253). Through various reporter assays, exogenous expression of *slyA* resulted in induction of *mxiC* and *icsP* as well as restoration of the Congo red-binding phenotype. The authors hypothesize that SlyA may recognize VirB binding sites and/or affect H-NS protein levels. Future work will be required to understand the full role of SlyA, especially since the authors also demonstrated that the SlyA regulator was required for acid resistance in *S. flexneri* and that *slyA* expression is regulated by the PhoPQ regulon.

The product of the *virF* locus is a key element in temperature regulation of the *Shigella* virulence regulon. A helix-turn-helix motif in the carboxyl terminal portion of VirF is characteristic of members of the AraC family of transcriptional activators. Consistent with its predicted role as a DNA-binding protein, VirF binds to sequences upstream of *virB* (284). The binding of VirF may act as an antagonist to binding by VirR/H-NS and thereby provide a mechanism for responding to temperature. Expression of *virF* is subject to temperature regulation by H-NS. Repression of *virF* occurs at the critical temperature of <32°C and takes place through the binding of H-NS at two sites within the *virF* promoter (280). Interestingly, a new study demonstrated that VirF can also bind the small noncoding RnaG and *icsA* mRNAs via a 13-bp consensus sequence to disrupt the senseantisense binding of the mRNAs and alleviate RnaGmediated transcriptional repression of *icsA* (285).

This study identifies a new function of VirF that could have important implications in our understanding of *Shigella* virulence gene activation and the role of bacterial transcriptional regulators.

Activation of the T3SS leads to increased expression of a subset of virulence genes encoding secreted effectors. Expression of these genes is regulated by MxiE, a transcriptional activator of the AraC family (207). MxiE-regulated promoters are preceded by a 17-bp MxiE box 33 to 49 bp upstream of the transcription start site (286). Activity of MxiE requires a coactivator, IpgC, the chaperone of IpaB and IpaC (287, 288). Under nonsecretion conditions, IpgC is associated with IpaB and IpaC, whereas MxiE is associated with the T3SS substrate OspD1, which acts as an antiactivator. Hence, both activator (MxiE) and coactivator (IpgC) are bound and unavailable to interact with each other. When the secretion apparatus is activated, IpaB and IpaC are secreted and release IpgC. After OspD1 is secreted, MxiE is released and is free to bind IpgC and activate MxiE-controlled promoters (226). Expression profile analysis defined three classes of T3SS-secreted substrates: (i) those that are controlled by VirB (expressed independently of secretion activity); (ii) those that are controlled by MxiE (expressed only in conditions of secretion); and (iii) those that are controlled by both VirB and MxiE (expressed under conditions of nonsecretion and induced under conditions of secretion) (289).

In all, the virulence genes and related regulation highlight the human-adapted evolution that *Shigella* underwent to target specific pathways and ensure successful infection once inside the human host. Many of the virulence proteins have multiple functions, and as new technologies become available, additional functions may be discovered. However, despite extensive research and characterization work on virulence genes, there are still numerous annotated genes of unknown function on both the chromosome and virulence plasmid. Furthermore, functions have not been described for the T3SS effectors OspC2, OspC4, OspD2, IpaH1.4, IpaH2.5, and most of the chromosomal IpaH proteins. Continued research will certainly enhance our understanding of the *Shigella* pathogenesis

and will have important implications for successful vaccine development.

CONCLUSIONS

Foodborne infections due to *Shigella* spp., in spite of national and international efforts to reduce their incidences, remain a serious cause of diarrheal diseases. These pathogens have the potential for explosive spread due to the low infectious dose that can cause overt clinical disease. In addition, cases of bacillary dysentery frequently require medical attention (even hospitalization) and cause lost time from work, as the severity and duration of symptoms can be incapacitating. As yet, there is no effective vaccine against any *Shigella* spp. These features, coupled with the wide geographical distribution of the strains, the potential rapid spread, and the stark increase in MDR strains, make *Shigella* a formidable public health threat.

We extend our gratitude to Rachel Binet for her contribution to the previous edition of this chapter. 13
Vibrio Species

The genus *Vibrio* contains 130 confirmed species (http://www.bacterio.net/vibrio.html), of which a dozen have been demonstrated to cause infections in humans. As vibrios are natural inhabitants of aquatic environments, infections are usually associated with wound exposure to seawater or consumption of raw seafood. As estimated by the Centers for Disease Control and Prevention (CDC), vibriosis causes approximately 80,000 illnesses and 100 deaths in the United States every year, mostly during the summer months, when water temperatures are warmer. In contrast to illnesses caused by other major foodborne pathogens, the number of *Vibrio* infections is steadily increasing (https://www.cdc.gov/vibrio/index.html). Several reports have recently indicated that human *Vibrio* illnesses are increasing worldwide, as well as the species responsible for these infections. Besides "the big four" (*Vibrio cholerae*, *Vibrio vulnificus*, *Vibrio parahaemolyticus*, and *Vibrio alginolyticus*) (1), additional *Vibrio* species [*Vibrio fluvialis*, *Vibrio mimicus*, *Grimontia* (*Vibrio) hollisae*, *Vibrio metschnikovii*, *Vibrio metoecus*, and *Vibrio furnissii*] have recently been associated with food consumption (2). These 10 *Vibrio* species are the subject of this chapter.

NATURAL HABITATS

Vibrios are natural constituents of estuarine and marine environments. Vibrios spend much of their life cycle outside the human host and have adapted to fluctuating conditions, including temperature shifts, nutrient limitation, osmotic stress, and predation (3). Vibrios tend to be more common in warmer waters, especially above 17°C, and depending on the species, they tolerate a range of salinities (5 to 25 ppt). Because temperature largely defines the environment where vibrios can proliferate, climate change in marine systems is greatly influencing the spread of this genus (1, 4). Reported vibriosis cases are on the rise, especially in northern countries experiencing warming sea temperatures (5). In the aquatic environments, vibrios show a wide range of niche specialization, from free-living forms to those attached to biotic (e.g., copepods, crustacean, fish, and algae) and abiotic surfaces, from symbionts to pathogens (6), contributing to their growth and persistence in the natural environment. *Vibrio* species are commonly isolated from filter-feeding shellfish, such as oysters, where they can be present at concentrations 100-fold higher than those in the surrounding water. For this reason, most foodborne *Vibrio* infections are caused by consumption of oysters and other bivalves that are consumed frequently without processing or cooking.

EPIDEMIOLOGY AND SURVEILLANCE

The cell numbers of most *Vibrio* spp. in both surface waters and shellfish exhibit a seasonal variation, generally being greatest during the warm months. Infection seasonality is most notable for *V. vulnificus* and *V. parahaemolyticus* from environmental sources, whereas some other vibrioses, such as *V. fluvialis* infections, occur throughout the year.

At the time of writing (January 2018), more than 2,000 scientific papers addressing *Vibrio* contamination of seafood and the food chain were available online. However, while cholera cases caused by *V. cholerae* O1 and O139 are notifiable for the World Health Organization, other vibrioses do not entail this requirement. Therefore, epidemiology of these infections is partial, as most cases go unreported worldwide.

In the United States, the Cholera and Other Vibrio Illness Surveillance System (COVIS) (https://www.cdc.gov/vibrio/surveillance.html) has been in use since the 1970s for reporting human infections caused by all pathogenic species of the family *Vibrionaceae*, but only in 2007 did vibriosis become a nationally notifiable disease to the CDC. The CDC also monitors vibriosis through the 10-state Foodborne Diseases Active Surveillance Network (FoodNet). Together, these systems conduct passive and active surveillance for laboratory-confirmed *Vibrio* infections. *Vibrio* infections were reported as the most common cause of seafood-associated outbreaks between 1973 and 2006, with substantial year-to-year variability observed in the number of outbreaks of *Vibrio* infections (7). This trend was confirmed by more recent COVIS data, which shows that the incidence of vibriosis in the U.S. population has been steadily increasing from 1996 to 2010, mostly for *V. parahaemolyticus*, *V. vulnificus*, and *V. alginolyticus* infections (8).

The most recent data from COVIS reported 1,252 *Vibrio* infections (excluding toxigenic *V. cholerae* O1 and O139) in 2014 (2). The most frequently reported species was *V. parahaemolyticus* (48%), followed by *V. alginolyticus* (19%) and *V. vulnificus* (10%). The majority of infections (56%) were confirmed as foodborne, were associated with mollusk (particularly oyster) and crustacean consumption, and were reported in Pacific (34%), Atlantic (26%), and Gulf (26%) Coast states. The only seven cases of cholera reported in 2014 were travel associated and caused by *V. cholerae* O1 (2).

ISOLATION

In marine and estuarine environments, vibrios are commonly isolated from sediment, the water column, and vertebrate and invertebrate animals. A complete description of the U.S. Food and Drug Administration (FDA) protocol for *Vibrio* isolation and identification can be found elsewhere (9), whereas ISO methods and guidelines are available at https://www.iso.org/obp/ui/#iso:std:iso:21872:-1:ed-1:v1:en. A schematic representation is provided in Fig 13.1. Briefly, for food and environmental samples, it is highly recommended to use a pre-enrichment step in alkaline peptone water with plating after 6 to 8 hours (to prevent overgrowth by other species) or overnight incubation (9), followed by streaking for isolation onto one or a combination of media to improve detection or isolation.

Specific solid media include thiosulfate-citrate-bile salts-sucrose (TCBS) agar, taurocholate-tellurite-gelatin agar, and CHROMagar *Vibrio*. Metabolic differences among species are the differentiating traits when these media are used. For example, TCBS agar inhibits the growth of *Enterobacteriaceae* and Gram-positive species and allows *Vibrio* differentiation between sucrose-positive (*V. cholerae*, *V. metschnikovii*, *V. fluvialis*, *V. furnissii*, and *V. alginolyticus*) and sucrose-negative (*V. mimicus*, *V. parahaemolyticus*, and *V. vulnificus*) species. Selective media have been developed for single species, such as modified cellobiose-polymyxin B-colistin and *V. vulnificus* medium (10), specific for *V. vulnificus*. New chromogenic technologies have been applied to differentiate species that show the same metabolic profile, e.g., *V. parahaemolyticus* and *V. vulnificus*, which are both sucrose negative on TCBS agar. Therefore, the use of more than one medium is suggested for completeness and convergence on the best results. A comprehensive review of media, their modes of action, their use, and typical results is presented elsewhere (11).

IDENTIFICATION

Presumptive *Vibrio* colonies isolated from these media can be confirmed by a standard series of biochemical media used for identification of *Enterobacteriaceae* and *Vibrionaceae*. Accurate phenotypic identification of *Vibrio* species is problematic, largely because of the great variability in biochemical characteristics that they exhibit. Both conventional tube tests and commercially available enteric identification systems are suitable for identifying this species, although the accuracy of commercial identification kits can range from 50 to 97% (12, 13). An updated description of the differentiating features of the 10 human-pathogenic vibrios associated with food can be found in the Bacteriological Analytical Manual

(https://www.fdagov/food/foodscienceresearch/laboratorymethods/ucm070830.htm). The main differentiating features of the 10 human-pathogenic vibrios associated with food are shown in Table 13.1.. Specific biochemical tests help discriminate ambiguous species, such as *V. fluvialis* versus *V. cholerae* or *Aeromonas* spp., thanks to their reactions to lysine, ornithine decarboxylases, arginine dihydrolase, and l-arabinose (14). The simplest trait for differentiation from *Aeromonas* spp. (especially *Aeromonas hydrophila*) is the inability of *V. fluvialis*, being halophilic, to grow in media lacking NaCl. Most members of the genus are halophilic, and the addition of NaCl is often required for isolation; however, the concentration of NaCl can affect the biochemical profile and lead to erroneous identification.

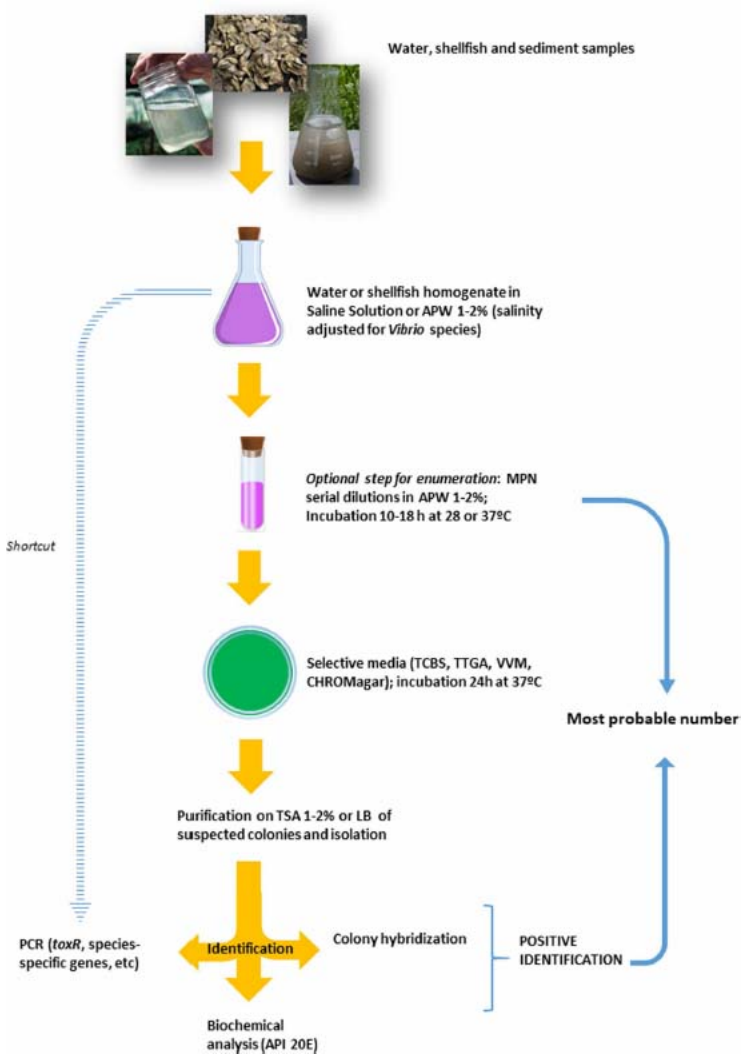

Figure 13.1 Scheme for the isolation and identification of *Vibrio* spp. from seafood, water, and sediment samples; adapted from FDA protocols (9). Once the bacterium has been isolated and identified, the pure culture should be maintained at −80°C in LB or tryptic soy broth supplemented with 15 to 20% glycerol. MPN, most probable number; APW 1-2%, alkaline peptone water containing 1 to 2% NaCl; TTGA, taurocholate-tellurite-gelatin agar; VVM, *V. vulnificus* medium. For more details and species-specific PCR, see "Isolation" and sections on individual *Vibrio* species in the text.

Molecular methods that utilize PCR and nucleotide sequence determination overcome many of the limitations of phenotypic methods and can lead to identification of an isolate within hours, including those that are not viable or are otherwise unculturable. This field of research is in continuous evolution, and new molecular techniques are available every day.

Among them, one of the latest tools to discriminate among closely related pathogenic *Vibrio* species is based on *groEL* PCR-restriction fragment length polymorphism (RFLP) analysis, where the highly conserved gene *groEL* is a better phylogeny marker than 16S rRNA gene (15). This technique can be applied for accurate identification and differentiation of *V. mimicus*, *V. cholerae*, *V. parahaemolyticus*, *V. alginolyticus*, *V. vulnificus*, *V. fluvialis*, *and V. anguillarum*. Other techniques were developed to discriminate among different *Vibrio* species in food samples and for food safety assessment. This is the case for a tetraplex PCR for simultaneous detection of *V. cholerae*, *V. parahaemolyticus*, *V. vulnificus*, and *V. mimicus* in cockles (16) and for a DNA microarray for the direct identification and pathogenic characterization of harmful strains of *Vibrio* in shellfish (17). To establish the relatedness of *Vibrio* isolates from disease epidemics, discriminate among strains with more or less potential to cause disease or epidemics, and explore the population biology of these bacteria, several DNA-based techniques are employed. For species-specific methods, see the sections on individual *Vibrio* species below.

ENUMERATION

Due to the public health risk that *Vibrio* causes, it is important to have a rapid and reliable method for isolation and enumeration of *Vibrio* densities in seafood products. Depending on the pathogen, different standard methods are recommended. Most-probable-number titration of replicate samples in enrichment broth cultures and direct plating onto selective agar plates followed by incubation and membrane filtration are the most commonly used (9). Implementation of enumeration techniques is ongoing, and new protocols have been developed to address isolation and enumeration of *Vibrio* species in specific food products (18). Among others, a new selective and differential medium, *V. vulnificus* X-Gal, was developed for direct enumeration of *V. vulnificus* organisms from oyster samples (19), and a colony hybridization method was developed for the enumeration of total and potentially enteropathogenic *V. parahaemolyticus* organisms in shellfish (9, 20).

Table 13.1 Key differential traits of pathogenic food-associated *Vibrio* species[a]

					% of strains positive[b]				
Test	*V. cholerae*	*V. parahae-molyticus*	*V. vulnificus*	*V. algino-lyticus*	*V. fluvialis*[c]	*V. furnissii*[c]	*G. hollisae*	*V. mimicus*	*V. metschnikovii*
Growth on TCBS agar	Y	G	G	Y	Y	Y	NG	G	Y

[b] After 48 h of incubation at 36°C. Most positive reactions occur during the first 24 h.

[c] *V. fluvialis* and *V. furnissii* can be differentiated by the production of gas from D-glucose.

[d] *V. metoecus* characteristics are expressed as positive (+) or negative (-), as in reference 326. Diversity between *V. metoecus* strains exists for utilization of cellobiose (±).

CONTROL MEASURES TO MINIMIZE *VIBRIO* CONTAMINATION

Control strategies to prevent seafood-associated illnesses include consumer education, monitoring of harvest waters, and postharvest *Vibrio* reduction treatments. Consumers should be aware of the potential health risks associated with eating raw or undercooked shellfish, particularly persons with medical conditions, such as liver disease, that predispose them to severe illness. Thoroughly cooking shellfish and preventing raw seafood from cross-contaminating other food are effective measures consumers can take to reduce risk. Like other microbes present in water, vibrios can be concentrated in the tissues of filter-feeding bivalve mollusks.

Depuration is a common practice used to eliminate fecal bacteria from seawater in depuration plants, usually via treatment with either ozone or UV light (21). Depuration of naturally occurring bacteria such as vibrios presents additional challenges, since bacteria and oysters coexist in the environment and are adapted to each other. Recent data on high-salinity depuration proved this method to be promising for *V. parahaemolyticus* and *V. vulnificus* reduction in oysters (22–24). Postharvest processing methods are available to make oysters safer and greatly reduce the risk to consumers (25). The National Shellfish Sanitation Program of the FDA is constantly updating the guidelines for optimal shellfish handling and processing (26). The main postharvest treatments to reduce microbiological occurrence in seafood are summarized here.

Cold

Several options for temperature control to limit postharvest *Vibrio* growth include ice, mechanical refrigeration, and other approved means of lowering the temperature and maintaining it at 10°C or less. While reports generally indicate that vibrios are sensitive to cold temperatures, this adverse condition may also enhance virulence and resistance of the stressed bacteria (27–29), potentially increasing risks with regard to food safety. Recent proteomic studies demonstrated that *V. metschnikovii* is cold adapted (30), an advantageous feature for surviving temperature downshifts during food processing and storage. Psychrotrophic strains of *V. mimicus*, *V. fluvialis*, and *V. parahaemolyticus* from frozen seafood were found to survive well at 10, 4, and −30°C (31). The response of *V. vulnificus* to cold temperatures has been extensively investigated, and its persistence in oysters following freezing and storage at −20°C has been shown to be dependent on the length of frozen storage time and the application of vacuum-packaged samples.

Heat

The most common thermal process used to reduce microbiological occurrence and growth of vibrios in food is pasteurization. Heat shock at or above 60°C for several minutes right after harvesting, as well as boiling or steaming during cooking, is the most common method. All of the vibrios are sensitive to heat, although a wide range of thermal inactivation rates have been reported. The major pathogens targeted are *V. parahaemolyticus* and *V. vulnificus*, which are known to grow between 5 and 45°C. The FDA recommends steaming oysters, clams, and mussels for 4 to 9 min, frying shucked oysters for 10 min at 190°C, or baking oysters for 10 min at 232°C.

The heat-cool pasteurization method was developed in the mid-1990s for application to postharvest raw Gulf of Mexico oysters to reduce *V. vulnificus*. It consists of minimal heat application in shelled oysters to destroy *V. vulnificus* immediately followed by cooling. This process requires three consecutive steps: washing with potable water, immersion in water at 53°C, and immersion in water at 4°C.

Irradiation

The FDA has approved the irradiation of oysters and seafood (32). The use of gamma irradiation and, more recently, that of X rays are becoming efficient alternatives to thermal treatments.

A 6-log reduction in the number of CFU of *V. parahaemolyticus* has been observed both via X-irradiation (3.0 kGy) and gamma irradiation (3.0 kGy) treatments in ready-to-eat shrimp (33) and oysters (34), respectively, with no oyster mortalities registered. Similar results were obtained for *V. vulnificus* in oysters when X-ray irradiation was applied (1.0 and 3.0 kGy for half-and wholeshell oysters, respectively) (35).

High Pressure

High-pressure processing (HPP) is a commercial nonthermal process capable of inactivating and eliminating pathogenic and food spoilage microorganisms inside an oyster. It is applied to lower the overall bacterial load at a range between 200 and 600 MPa for 1 to 2 minutes (36). By destroying biological cells, HPP causes oyster meat and fish to become whiter, two factors that limit consumers' acceptance. Nevertheless, HPP was proved to reduce *V. vulnificus* (37) and *V. parahaemolyticus* CFU counts at low temperatures (38) in oysters.

Other Treatments

The use of phages (viruses of bacteria) to control *Vibrio* populations in the environment and within animal hosts has also been investigated. When applied to contaminated oyster meat, the *Siphoviridae* phages pVp-1 and VPp1a can significantly reduce *V. parahaemolyticus* concentrations, from 1.4×10^6 to 1.9 CFU/g within 12 h (39). However, the large and uneven surface area of the in-shell oyster represents a challenge for phage treatment on a large scale.

While the various postharvest treatments are effective at killing seafood-associated bacteria, most of these treatments also kill the mollusks. Because consumer preferences for raw, live shellfish persist, biological approaches for reducing the load of shellfish-associated *Vibrio* spp. and promoting microbiological safety of live product, such as the use of probiotics or inhibitors of quorum sensing and attachment, are also under study (40).

V. CHOLERAE

V. cholerae is a non-spore-forming curved rod naturally occurring in brackish and estuarine environments around the planet, and it is classified according to its major surface antigen, the O antigen, into ~206 serogroups (41). Historically, seven distinct cholera pandemics caused by *V. cholerae* O1 have occurred since the onset of the first report in 1817, with the seventh ongoing pandemic starting in Egypt in 1961 (42). Important distinctions within this species are based on the production of cholera enterotoxin (Ctx), serogroup, and the potential for epidemic spread. Serogroups O1 and O139 have been associated with epidemic cholera disease (42, 43). Conversely, there are occasional strains of serogroups other than O1 or O139 that are clearly pathogenic, because of the production of Ctx or other virulence factors; however, none of these other serogroups has caused large epidemics or pandemics (see "Virulence Mechanisms" below). The subject of cholera has been reviewed elsewhere, and readers are referred to these reviews for primary references, particularly in the older literature (42).

Classification

V. cholerae O1

V. cholerae organisms of the O1 serogroup that produce Ctx have long been associated with epidemic and pandemic cholera (42). Ctx-negative *V. cholerae* O1 strains are generally considered nonpathogenic, although they have been isolated from occasional cases of diarrhea or extraintestinal infections. The O1 serogroup is further classified according to the presence of somatic antigens into two major serotypes (Inaba and Ogawa) and an unstable intermediate type (Hikojima) (1). *V. cholerae*

O1 can also be divided into two biotypes, classical and El Tor, that differ in several phenotypic and genotypic characteristics, including pathogenic potential, survivability, and infection patterns in humans (43). Phenotypic tests (sheep erythrocyte hemolysis, chicken cell agglutination, Voges-Proskauer, sensitivity to polymyxin B and specific phages), *ctxB* epityping, and genotypic analyses of specific genes (*tcpA*, *rstR*, and *ctxB*) are most commonly used to differentiate the two biotypes (43–45). However, both genetic and phenotypic diversity have arisen among strains of *V. cholerae* El Tor circulating in Asia and Africa, generating new pathogenic variants known as atypical El Tor variants (43, 45). Such variants include *V. cholerae* O1 hybrids, which cannot be biotyped based on phenotypic tests and can produce cholera toxin of either biotype, and altered El Tor variants, which produce cholera toxin of the classical biotype but can be biotyped as El Tor by conventional phenotypic assays (46–48). These new variants have subsequently replaced the prototype seventh-pandemic *V. cholerae* O1 El Tor strains with respect to frequency of isolation from cholera clinical cases.

V. cholerae O139 Bengal

In early 1993, the first reports of a new epidemic of severe, cholera-like disease emerging from eastern India and Bangladesh appeared (49). Further investigations revealed that the bacterium causing the disease did not belong to the O1 serogroup but to a new serogroup, which was given the designation O139 and the synonym "Bengal," in recognition of the origin of this strain. *V. cholerae* O139 is indistinguishable from typical El Tor *V. cholerae* O1 strains in terms of clinical manifestations and Ctx sequences (49). However, this bacterium does not produce the O1 lipopolysaccharide (LPS) due to the insertion of a 35-kb region encoding the O139 antigen (50). Furthermore, it produces a polysaccharide capsule. When it initially appeared, the O139 serogroup replaced the O1 serogroup in some parts of Southeast Asia and was feared to represent a new pandemic (the eighth pandemic) of cholera. However, few cases of O139 disease were reported beyond Southeast Asia, and O1 cases rapidly became dominant again in this part of the world (51).

V. cholerae Non-O1/Non-O139

In recent years, all *V. cholerae* isolates that were identified as negative for the O1 serogroup were referred to as *V. cholerae* non-O1, or nonagglutinating vibrios. Most nonagglutinating strains do not produce Ctx and are not associated with epidemic diarrhea (50). Since the emergence of the O139 serogroup, these strains are collectively referred to as *V. cholerae* non-O1/non-O139. While most of these strains do not produce Ctx, some strains may produce other toxins and are generally associated with self-limited gastroenteritis or mild extraintestinal symptoms (although fatal cases of necrotizing fasciitis and septicemia associated with *V. cholerae* non-O1/non-O139 have also been reported [52, 53]). Strains of the O141 serogroup have been isolated from sporadic cases of severe diarrhea and have been found to produce Ctx and the toxin-coregulated pilus (Tcp) colonization factor typical of O1 and O139 strains (54). Toxigenic and nontoxigenic non-O1/non-O139 strains have caused several disease outbreaks in Asia and other countries in recent years (55), which appears to be related to ongoing climate change and ocean warming (5, 56).

Identification

Together with standard culturing techniques (see "Isolation" and "Identification" above), the key confirmation for identification of *V. cholerae* O1 is agglutination in polyvalent antisera raised against the O1 antigen. Polyvalent antiserum for *V. cholerae* O1 and O139 is commercially available and can be used in slide agglutination or coagglutination tests. Monoclonal antibody-based coagglutination tests suitable for testing isolated colonies or diarrheal stool samples for O1 or O139 are also available commercially. Oxidase-positive bacteria (determined using colonies grown on nonselective media) that agglutinate in O1 or O139 antisera can be reported presumptively as *V. cholerae* O1 or O139 and then forwarded to a public health reference laboratory for confirmation. Antisera for serogroups other than O1 or O139 are not commercially available.

Nucleic acid probes are not routinely employed for the identification of *V. cholerae* due to the ease of identifying this species by conventional methods. However, DNA probes and PCR techniques have

been extremely useful for direct detection of the bacterium in environmental (57) and complex (58) samples and in distinguishing cholera toxin-encoding strains of *V. cholerae* (59). This distinction is particularly important in examining environmental isolates of *V. cholerae*, since most of these strains lack Ctx. Subtyping of *V. cholerae* strains using a variety of techniques, such as RFLP analysis by pulsed-field gel electrophoresis (RFLP-PFGE), ribotyping, and multilocus sequence typing (MLST), has yielded significant insights into the molecular epidemiology of *V. cholerae*. MLST using only three housekeeping genes (*gyrB*, *pgm*, and *recA*) has discriminating ability superior to that of other methods, including PFGE (60). Another approach is to use a single multiplex PCR assay to simultaneously amplify 95 "diagnostic" regions from *V. cholerae* and other *Vibrio* species (e.g., species- and serogroup-specific genes, toxin genes, etc.) that are hybridized to a microarray containing these genes (61). This approach allows rapid and definitive inter-and intraspecies discrimination that can be helpful in epidemiological, environmental, and health risk assessment surveillance. Strain heterogeneity is most comprehensively captured by genomic DNA sequencing. In particular, third-generation single-molecule real-time sequencing is much faster and more productive than previously developed methods (62). Next-generation sequencing techniques combined with whole-genome enrichment protocols have also proven useful for the direct genotyping and metagenomic analysis of low-abundance (<50 genome units/liter) *V. cholerae* DNA from environmental samples (63).

Foodborne Outbreaks

The critical role of water in transmission of cholera has been recognized for more than a century (42). In developing countries, ingestion of contaminated water and food is probably the major vehicle for transmission of cholera, whereas in developed countries, foodborne transmission is more important (64). The role of food, especially shellfish, in transmitting *V. cholerae* O1 has been reviewed elsewhere (65). The spectrum of food items implicated in transmission of cholera includes crabs, shrimp, raw fish, mussels, cockles, squid, oysters, clams, rice, raw pork, millet gruel, cooked rice, street vendor food, frozen coconut milk, and raw vegetables and fruit. One shared characteristic of the implicated foods is their neutral or nearly neutral pH (66). Survival and growth of *V. cholerae* O1 in food are also enhanced by low temperatures, high organic content, high moisture content, and absence of competing microbiota. Survival is increased when food is cooked before contamination; cooking eliminates competing microbes and has also been suggested to destroy some heat-labile growth inhibitors and produce denatured proteins that the bacterium uses for growth.

In addition, food buffers *V. cholerae* O1 against killing by gastric acid. While many different food items can provide this buffering capacity, the protection provided by chitin is noteworthy because crustaceans are frequent vehicles of disease (67). In the United States, both domestically acquired and imported cases of cholera have occurred (7, 68). For domestic cases, crabs, shrimp, and oysters have been the most frequently implicated vehicles, although the largest single outbreak (16 cases) was due to ingestion of contaminated rice (66). The risk of imported cholera has greatly increased since the establishment of endemic cholera in South America in 1991. The largest such outbreak (75 cases) involved crab salad served on an airplane flying from Peru to California. Importation of cholera from Asia can also occur, even in commercially imported food. Most cases of gastroenteritis caused by *V. cholerae* non-O1/non-O139 have been linked to the consumption of raw oysters (69), and infection is enhanced in food with alkaline pH. Outside the United States, outbreaks have also been linked to consumption of contaminated potatoes, chopped eggs, pre-prepared gelatin, vegetables, and meat samples (69).

Environmental Reservoir

In the 1970s, it was widely accepted that asymptomatic and convalescent human carriers were the primary reservoir for cholera. With the recognition that *V. cholerae* is part of the normal, free-living (autochthonous) microbiota in estuarine and coastal marine areas, greater attention has been given to identification and characterization of environmental reservoirs (70). *V. cholerae* non-O1/non-O139 strains are much more commonly isolated from the environment than O1 strains, and outside areas where epidemics occur, O1 environmental isolates are almost always Ctx negative. However, it is clear

that Ctx-producing *V. cholerae* O1 can persist in the environment in the absence of known human disease, and this is most likely explained by the existence of environmental reservoirs, defined as locations outside the human body favoring bacterial persistence and replication in the environment and pathogen transmission to susceptible hosts (71). Persistence of *V. cholerae* within the environment can be facilitated by several factors, such as its ability to assume survival forms, including a viable-but-nonculturable (VBNC) state, biofilms, and a rugose survival form. In the dormant VBNC state, *V. cholerae* is still viable but not culturable in conventional laboratory media (72), and cells are reduced in size and maintain virulence properties (60). *V. cholerae* produces a chitinase and is able to bind to chitin, which is the principal component of crustacean shells (67), enabling *V. cholerae* strains to colonize zooplankton such as copepods, with 104 to 105 attached *V. cholerae* cells per copepod (73). Other aquatic biota, such as water hyacinths, filamentous green algae, and insects, as well as abiotic substrates (e.g., sediments) are also colonized by *V. cholerae* (70). *V. cholerae* can also form biofilms that can enhance survival in the environment (74) and allow toxigenic strains to persist alongside nontoxigenic strains in the aquatic environment (75). A phenomenon that is closely related to biofilms is the formation of rugose, or "wrinkled," colonial morphology due to the production of an exopolysaccharide (42). In this state, the cells are protected against adverse environmental conditions and have an enhanced capacity to form biofilms.

According to the "cholera paradigm," the establishment of cholera endemicity requires the presence of aquatic environmental reservoirs, with seasonal and weather-related increases in toxigenic *V. cholerae* O1 in these reservoirs serving as the primary trigger for human epidemics (71). A dynamic relationship between human and environmental sources of the bacterium is apparent, with carriage and amplification by human populations playing a critical role in the epidemic spread of Ctx-producing *V. cholerae*. Environmental bacteriophages capable of lysing *V. cholerae* O1 or O139 are also involved in this relationship, and a 3-year study in Bangladesh revealed that the presence of cholera phages was inversely correlated with the occurrence of viable *V. cholerae* in the environment and the number of cholera cases in the local community (76). Susceptible hosts become infectious after consuming *V. cholerae* from an environmental source, sometimes accompanied by lytic bacteriophages. Infected individuals recover through the actions of their immune systems and possibly those of lytic bacteriophages or succumb to the infection. Lytic phages and *V. cholerae* in a transient hyperinfectious state are shed in varying concentrations and can rapidly passage to the next host, can persist in the environment as culturable cells with unknown infectivity, or can transform into a VBNC state.

Characteristics of Disease

Long-term carriage of *V. cholerae* in humans is extremely rare and is not considered significant in transmission of disease. However, short-term carriage of *V. cholerae* by humans is quite important in transmission of disease. Even after cessation of symptoms, patients who have not been treated with antibiotics may continue to excrete vibrios for 1 to 2 weeks. Furthermore, a high percentage of persons infected with *V. cholerae* in areas where the organism is endemic have inapparent illness (asymptomatic carriers) and can still excrete the bacteria, although excretion generally lasts for less than a week. There have also been studies indicating that *V. cholerae* O1 can be sporadically carried by household animals, including cows, dogs, and chickens, but no animal species consistently carries the bacterium.

Cholera

The explosive, potentially fatal dehydrating diarrhea that is characteristic of cholera is actually seen in only a minority of persons infected with Ctx-producing *V. cholerae* O1 or O139. Most infections with *V. cholerae* O1 are mild or even asymptomatic. It has been estimated that 11% of patients with O1 classical infections develop severe disease, compared with 2% of those with O1 El Tor infections. An additional 5% of El Tor and 15% of classical infections result in moderate illness (42).

The incubation period of cholera can range from several hours to 5 days and is dependent in part on inoculum size. In healthy North American volunteers (77), doses of 10^{11} CFU of *V. cholerae* were required to consistently cause diarrhea when the inoculum was given in buffered saline (pH 7.2).

When stomach acidity was neutralized with 2 g of sodium bicarbonate immediately prior to administration of the inoculum, attack rates of 90% were seen with an inoculum of 10^6 CFU. Under natural field circumstances, the inoculum size needed to cause cholera may be even lower, because attack rates are lower than in volunteer studies, and many patients have low gastric acid production. Further studies revealed that most volunteers who received as few as 10^3 to 10^4 vibrios developed diarrhea, although lower inocula correlated with a longer incubation period and diminished severity.

After the *V. cholerae* inoculum is ingested, the onset of illness may be sudden, with profuse, watery diarrhea, or there can be premonitory symptoms, such as anorexia, abdominal discomfort, and simple diarrhea. Mucus in the stool imparts the characteristic "rice water" appearance. In its most severe form, termed cholera gravis, the rate of diarrhea may quickly reach 500 to 1,000 ml/h (excreting up to 10^{11} to 10^{13} CFU of *V. cholerae* per gram of stool), leading rapidly to tachycardia, hypotension, and vascular collapse due to dehydration. Such severe dehydration can lead to death within hours of the onset of symptoms unless fluids and electrolytes are rapidly replaced.

Gastroenteritis and Extraintestinal Infections

While cholera gravis is a striking clinical entity, milder illnesses are not readily differentiated from gastroenteritis due to other causes in areas of cholera endemicity. Gastroenteritis associated with *V. cholerae* non-O1/non-O139 is generally of mild to moderate severity, although severe, cholera-like illness has also been reported occasionally. Strains of *V. cholerae* non-O1/non-O139 have also been studied in volunteers (69). Of three non-Ctxproducing strains fed to volunteers, only one strain caused diarrhea. This strain produced a heat-stable enterotoxin-like toxin and caused diarrhea in six of eight volunteers at doses of 10^6 to 10^9 vibrios after neutralization of stomach acid with sodium bicarbonate. The severity of disease was generally mild, but in one volunteer, diarrheal stool volume exceeded 5 liters.

V. cholerae non-O1/non-O139 is also frequently isolated from extraintestinal infections such as septicemia and wound and ear infections; these infections usually involve exposure to fresh or brackish water (5). The case fatality rate of extraintestinal infections can exceed 50%, and individuals with preexisting liver disease are particularly at risk.

Virulence Mechanisms

In order to cause a diarrheal disease, *V. cholerae* must successfully colonize the intestine. After passing the acid barrier of the stomach, *V. cholerae* enters the mucus layer covering the epithelium of the small intestine and proliferates on its surface (Fig 13.2). Recent developments on the detailed mechanisms facilitating this colonization are thoroughly summarized elsewhere (78). We describe here the major virulence factors that take part in the development of cholera and other vibrioses and their association with different *V. cholerae* serotypes.

Cholera Toxin

Cholera is caused by the action of the cholera toxin (Ctx), which is encoded by *V. cholerae* O1 and O139 and is rarely found in other nonpandemic serotypes. The *ctxAB* genes, encoding Ctx, reside on a filamentous bacteriophage (CTXφ) that is capable of transducing *ctx* genes into nontoxigenic strains (79) and has played a critical role in the evolution of pathogenic *V. cholerae* (43). Ctx is among the best-characterized bacterial toxins and has been extensively reviewed (Fig 13.2) (80, 81). It consists of two subunits, A and B, organized in a pentamer of identical B subunits and a single A subunit, formed by an active A1 subunit and a bridging A2 portion. The B pentamer binds the GM1 ganglioside eukaryotic receptor, whose conversion triggers toxin A internalization via endocytic vesicles. Binding of Ctx to epithelial cells is enhanced by the neuraminidase NanH, which catalyzes the conversion of higher-order gangliosides to GM1, thus enhancing Ctxspecific receptors. Once translocated into the cell cytosol, the A1 subunit possesses specific enzymatic activities (ADP-ribosyltransferase and NAD-glycohydrolase) that irreversibly ADP-ribosylate the G proteins. G proteins regulate an extensive set of metabolic pathways, including the adenylate cyclase (AC) complex, which mediates the transformation

of ATP to cyclic AMP (cAMP), a crucial intracellular messenger for a variety of cellular pathways. Activation of adenylate cyclase and the subsequent increase in intracellular level of cAMP lead to protein phosphorylation of, among others, the major Cl– channel in epithelial cells. Increased Cl^- secretion by intestinal crypt cells and decreased NaCl-coupled absorption by villus cells result in a transepithelial osmotic gradient that causes water flow into the lumen of the intestine. The massive volume of water overwhelms the absorptive capacity of the intestine, resulting in diarrhea.

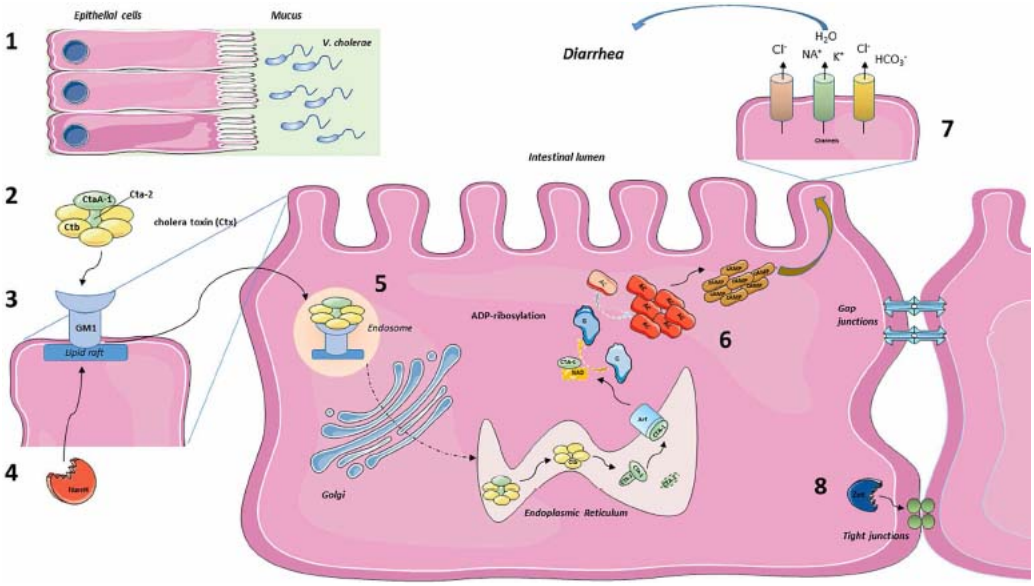

Figure 13.2 Cholera toxin mechanism. After ingestion, *V. cholerae* cells colonize the intestinal lumen (step 1), where they start secreting cholera toxin (Ctx), which is composed of two toxic subunits (A1 and A2) and five binding (B) units (step 2). The complete toxin binds to the GM1 ganglioside receptors on the cell membrane (step 3) via the binding subunits. NanH facilitates Ctx binding to host cells by converting cell surface gangliosides to GM1 gangliosides (step 4). This interaction triggers the internalization of the toxin via an endosome in the cell (step 5). Once in the cell, the reduction of the A and B subunits occurs in the endoplasmic reticulum, leaving the B subunits in the endoplasmic reticulum. The active A1 subunit is then released into the cytosol, where it catalyzes the ADP-ribosylation of the G regulatory protein, which regulates the activation of the adenylate cyclase (AC) system (step 6). The constant active state of G provokes a persistent activation of AC, which results in accumulation of cyclic AMP (cAMP) along the cell membrane. The cAMP causes the active secretion (step 7) of sodium (Na^+), chloride (Cl^-), potassium (K^+), bicarbonate (HCO^{3-}), and water (H_2O) into the intestinal lumen, which is clinically associated with profuse diarrhea and dehydration. The accessory toxin Zot (step 8) induces modifications of cytoskeletal organization that lead to the opening of tight junctions, increasing the permeability of the small intestine. Data are from reference 328.

Other Toxins Produced by *V. cholera*

A variety of studies on the first recombinant *V. cholerae* vaccine strains showed that volunteers administered *V. cholerae* strains not producing Ctx still experienced mild to moderate diarrhea, abdominal cramps, and lowgrade fever. These results triggered the search for and eventually underlined the role of additional toxins produced by *V. cholerae*.

The zonula occludens toxin (Zot) induces modifications in cell cytoskeletal organization that lead to the opening of intercellular tight junction, or zonula occludens, increasing the permeability of the small intestine (82). The accessory cholera enterotoxin (Ace) causes fluid accumulation in rabbit ligated ileal loops and increases potential difference in intestinal tissue, although its role in the infection is not completely clear yet (83). The *ace* and *zot* genes are located immediately upstream of the *ctx* genes and are also believed to be components of the CTXφ filamentous phage, which encodes

cholera toxin (79). *V. cholerae* also produces the small soluble cytotoxin hemagglutinin/protease (HA/P). This zinc-dependent metalloprotease can perturb the barrier function of epithelial cells by digesting the host protein occludin and rearranging the distribution of ZO-1 in tight junctions, suggesting an important role in microbial pathogenesis (84).

The El Tor hemolysin (also called cytolysin or hemolysin) consists of two major toxin groups, the *V. cholerae* O1 group (VCC1) and the *V. cholerae* non-O1/non-O139 group (VCC2). The hemolysin triggers an outward transcellular flux of chloride that, in association with the movement of Na^+ and water, contributes to diarrhea caused by certain nontoxigenic strains of *V. cholerae* (85).

Finally, the RtxA toxin possesses cytotoxic activity for HEp-2 cells *in vitro*, and its gene is physically linked to the cholera toxin phage in the *V. cholerae* genome (86). RtxA is the representative member of the multifunctional autoprocessing repeats in toxin (MARTX) family produced by various Gram-negative bacteria (see "*V. vulnificus*" below) (87).

Although *V. cholerae* non-O1/non-O139 strains generally do not produce cholera toxin, other factors contribute to their pathogenicity, including the El Tor hemolysin, RtxA, and HA/P. The heat-stable enterotoxin (also called nonagglutinable *Vibrio* heat-stable enterotoxin) was identified as a secondary factor in volunteers who received *V. cholerae* non-O1/non-O139 and showed diarrhea and abdominal cramps (88).

Overall, the role of toxins other than Ctx in the pathogenesis of disease due to *V. cholerae* is mostly unknown, although they may contribute in a secondary secretogenic mechanism when conditions for producing cholera toxin are not optimal.

Colonization Factors

Toxin-Coregulated Pilus

Besides Ctx, a type IV pilus, the toxin-coregulated pilus (Tcp) is the most important virulence factor of *V. cholerae* and is essential for colonizing the intestine of the host. The name of the pilus derives from the fact that its expression is correlated with Ctx expression and that Tcp is also the receptor for CTXφ on the *V. cholerae* cell surface (89). The synthesis of the Tcp pilus is complex, and there are up to 15 open reading frames in the *tcp* gene cluster (90). The *tcp* gene cluster along with *toxT* (see "Virulence Regulation" below) is present on a 40-kb pathogenicity island (called the *Vibrio* pathogenicity island) that is present in all O1 and O139 clinical isolates and absent from nearly all *V. cholerae* non-O1/non-O139 strains (91). The role of Tcp in *V. cholerae* colonization has been proven in volunteers ingesting *V. cholerae* strains with specific mutations in the *tcpA* gene; these volunteers did not experience diarrhea, and vibrios were not recovered from their stools. Direct binding of Tcp to epithelial cells has not been observed, and the role of this factor may be to mediate interbacterial aggregation and thereby facilitate intestinal colonization.

Other Potential Colonization Factors

A number of potential colonization factors have been described for *V. cholerae*. The sialidase NanH has been shown to provide *V. cholerae* with the capacity to utilize sialic acid as a carbon and energy source, an advantage in the mucus-rich environment of the gut. Mutants for the gene *nanH* are defective in early intestinal colonization, suggesting a role in bacterial pathogenesis (92). A type 3 secretion system (T3SS) enables *V. cholerae* to translocate effector proteins directly into the host cytosol without passing through the extracellular environment; these proteins can elicit diarrhea and can induce pathological changes in the intestine (93). A type 6 secretion system (T6SS) confers cytotoxic effects against both prokaryotic and eukaryotic cells, suggesting its employment by *V. cholerae* to compete with commensal bacteria in the human intestine and/or environmental reservoirs (94). Finally, a mannose-sensitive hemagglutinin type IV pilus is crucial for surface selection and attachment (95), and although it has been proven not to be necessary for human colonization, it appears to be involved in biofilm formation and adherence to zooplankton (96). The LPS of *V. cholerae* O139 has also been

implicated in intestinal colonization, probably by multiple mechanisms involving direct mucosal adherence and increased intestinal survival in the presence of bile and other factors (97).

Flagella and Chemotaxis

V. cholerae cells rapidly enter the mucus gel overlying the intestinal epithelium by means of a single, polar, sheathed flagellum, and organisms can be found in intervillus spaces within minutes to a few hours after ingestion of the organisms (98). The role of chemotaxis in *V. cholerae* infection is complex and involves modulating the direction or speed of flagellar rotation in response to the surrounding environment. Even though chemotaxis surprisingly inhibits the ability of *V. cholerae* to colonize the small intestine, this outcompeting phenotype correlates with a reduction in the number of bacteria that are required to cause infection (99). The increased infectivity of nonchemotactic *V. cholerae* might contribute to the transient "rice-water stool" state of *V. cholerae* to improve its chances of infecting new human hosts.

Virulence Regulation

Regulation of virulence gene expression in *V. cholerae* is highly complex, and this is understandable in light of the different environments—the human intestine and the aquatic environment—that are involved in the *V. cholerae* life cycle (3). Two important systems that allow the pathogen to respond to its environment and regulate virulence gene expression are briefly described.

The ToxR regulon is a virulence regulatory cascade that controls the expression of several critical virulence factors, including Ctx and Tcp, and is the most extensively characterized regulatory system in *V. cholerae* (100). The key activator of Ctx and Tcp expression is ToxT, which binds upstream of *tcpA* and *ctxA* genes. Expression of ToxT itself is modulated by ToxR in concert with ToxS and Tcp proteins, which are encoded upstream of *toxT*. These protein complexes permit the transmission of environmental signals to modulate expression of *toxT*. This intricate signaling pathway is essential to ensure maximal virulence factor induction within the human intestine.

Quorum sensing (QS) is a microbial signaling process for monitoring population density and complexity. Small molecules termed autoinducers act as signaling molecules among bacterial cells to coordinate gene expression, allowing unicellular microbes to act as multicellular organisms. Contrarily to other bacteria, high densities of *V. cholerae* cells lead to repression of virulence factors (101) and biofilm formation (102). Thanks to four parallel signaling receptors (CqsS, LuxPQ, VpsS, and CqsR), a common response regulator, LuxO, is regulated by phosphorylation. Early in infection, at low cell densities, Tcp and Ctx are expressed along with biofilm, which helps intestinal colonization. Later in the infection, at high cell densities, phosphorylation of LuxO ultimately leads to repression of toxin genes and to activation of HA/P, allowing *V. cholerae* to exit the host and adapt to an environmental reservoir, where toxin expression is not necessary.

V. PARAHAEMOLYTICUS

V. parahaemolyticus represents an important cause of foodborne illness in Asia, South America, and the United States, and it is recognized as the leading cause of human gastroenteritis associated with seafood consumption, particularly raw fish and shellfish. Since its first description in 1950 as the etiological agent of a severe foodborne outbreak in Osaka (Japan) following consumption of a small, semidried fish ("*shirasu*"), *V. parahaemolyticus* has been implicated in several outbreaks of diarrheal disease throughout the world. Presently, CDC FoodNet data on laboratory-confirmed cases indicate a *V. parahaemolyticus* incidence rate of 0.24 per 100,000 persons in 2015, confirming this microorganism as the *Vibrio* species most frequently isolated from clinical specimens in the United States (59.5% of the infections attributed to members of the *Vibrionaceae*). Overall, considering underreporting and underdiagnoses, an estimated 35,000 cases of foodborne *V. parahaemolyticus* infection occur each year in the United States (103).

Identification

Beside standard phenotypic identification (see “Isolation” and “Identification” above), a peculiar biochemical feature of *V. parahaemolyticus* is its variable expression of urease, encoded by the *ure* gene, which is associated with relevant virulence factors, such as those encoded by the *trh* genes (see “Virulence Factors” below), and is therefore used for phenotypical screening of potentially pathogenic strains. It should be noted that the reliability of commercial identification systems for the identification of food and environmental isolates of *V. parahaemolyticus* may vary greatly (12), particularly in relation to the requirement for sodium ion of this microorganism, and that media used for testing the biochemical reactions of *V. parahaemolyticus* should contain 2% or 3% NaCl to improve accuracy of identification (9).

V. parahaemolyticus possesses three antigenic components: H (flagellar), O (somatic), and K (capsular). The H antigen is common to all strains and is not used for serotyping, which is instead based on O (13 lipopolysaccharide antigens, named O1 to O13) and K (65 acidic polysaccharide antigens, named K1 to K71, following exclusion of some proposed antigens). Notably, many environmental and some clinical isolates are untypeable by the K antigen (KUT), but most of the strains can be classified by their O type. Until the mid-1990s, there appeared to be no correlation between serotype and virulence, but the emergence of the pandemic strain O3:K6 in 1996 (see “The O3:K6 Pandemic Clone” below) provided a new insight into the value of serotyping for outbreak investigation and for epidemiological studies.

Transmission and Disease

V. parahaemolyticus displays the features common to the genus *Vibrio*, including the natural occurrence in marine and estuarine environments, and is therefore commonly present in seafood products. Additionally, *V. parahaemolyticus* is characterized by remarkably rapid growth, with a replication time as short as 8 to 9 minutes under optimal conditions and in the range of 12 to 18 minutes in seafood, which allows the organism to rapidly reach the estimated infectious dose (10^5 to 10^7 CFU for pathogenic strains) in raw, undercooked, or cross-contaminated seafood products that are incorrectly stored. Foodborne transmission accounts for an estimated 86% of *V. parahaemolyticus* cases (103), the remainder being mainly associated with wound infections following marine recreational activities and, less commonly, handling of sea-food.

Clinical manifestations of *V. parahaemolyticus* infection include watery diarrhea (and in the cases that are most severe, bloody diarrhea), abdominal cramps, nausea, vomiting, fever, and headache. Symptoms usually occur within 24 hours of microorganism ingestion (the incubation period is 4 to 90 hours), and the illness is self-limiting, lasting 1 to 12 days (median duration, 2.4 days), though occasionally hospitalization may be necessary. In individuals with underlying clinical conditions, infection with *V. parahaemolyticus* may also lead to life-threatening septicemia, requiring aggressive antimicrobial therapy.

Foodborne Outbreaks

Many factors (geographical origin, environmental parameters [temperature, salinity, and trophic status] of the fishing/farming areas, animal species, storage and transport conditions, and structure of the supply chain, etc.) may influence the presence and levels of *V. parahaemolyticus* in seafood products; further to this, the wide variation in the analytical methods used may significantly influence the results of studies of prevalence in food matrices (104). To date, most of the studies on *V. parahaemolyticus* prevalence in seafood involve bivalve molluscs and crustaceans, with species detection reported at a frequency of 77 to 79% in oysters collected in the United States, ~10 to 78% in studies on seafood products in European countries, and up to 100% in samples from other countries. An extended review of *V. parahaemolyticus* prevalence data can be found elsewhere (105). Significantly, most of these studies reported a much lower prevalence of pathogenic *V. parahaemolyticus*, ranging from null to ~23%. Similarly to prevalence, quantitative levels of *V. parahaemolyticus* vary widely depending on the studies, though average contamination in products at harvesting mostly ranges between 10^1 and 10^3 CFU/g.

In Japan, several large outbreaks (>500 cases) were reported between 1996 and 2007 following consumption of prepared meals containing boiled crab, sushi, salted squid, or other seafood dishes (106). In China, *V. parahaemolyticus* represented the most relevant etiological agent for bacterial foodborne outbreaks in 1994 to 2005, with 211 disease events and almost 11,000 cases (107). A number of outbreaks have also been reported in several other Asian countries, particularly in relation to the emergence of the pandemic strain O3:K6 (see "The O3:K6 Pandemic Clone" below).

In the United States, outbreaks of *V. parahaemolyticus* gastroenteritis have been reported at least since 1973 (reviewed in reference 108). More recently, several oyster-related multistate outbreaks have claimed attention. In 1997, approximately 1,200 cases were reported in seven states following consumption of raw oysters from the Pacific coast that harbored *V. parahaemolyticus* serotypes O4:K12 and O1:K56 (109). A similar episode, also associated with the O4:K12 serotype, took place in 2006, when 177 cases were reported in three different states after consumption of shellfish from the Northern Pacific region (110). In 1998, 416 gastroenteritis cases (*V. parahaemolyticus* serotype O3:K6) were reported from 13 states in association with eating oysters from Galveston Bay, Texas (111), and in July to September of the same year, a smaller outbreak (23 cases, mostly characterized as being caused by O3:K6) were reported in three states on the northeastern coast after consumption of oysters and clams harvested from Long Island Sound (112). The latter outbreaks represented the first occurrence of the O3:K6 pandemic strain in the United States. In 2004, an outbreak (caused predominantly by serotype O6:K18) was surprisingly recorded in Alaska among participants in boat cruises who had consumed locally produced oysters (113), an event that highlighted the presence of pathogenic strains of *V. parahaemolyticus* in waters previously thought to be too cold to support the growth of the microorganism. The Alaskan *V. parahaemolyticus* isolates and the O4:K12 serotype responsible for the 1997 and 2006 outbreaks have historically been linked to the aquatic environment of the Pacific Northwest coast of the United States (and are therefore sometimes referred to as Pacific Northwest [or PNW] strains). In the summer of 2012, however, the O4:K12 serotype was reported in gastroenteritis cases associated with the consumption of oysters harvested in Oyster Bay Harbor, New York. In 2013, the same strain was traced to shellfish harvested along the eastern coast of the United States and was responsible for 104 gastroenteritis cases in 13 states (114), highlighting the spread of the PNW *V. parahaemolyticus* strain to the Atlantic coast.

Similar to what has been observed in the United States, *V. parahaemolyticus* outbreaks associated with O3:K6 and O4:K12 strains were repeatedly reported in Latin America in the period between 1989 and 2009 (115), with outbreaks as large as 3,700 cases (Chile, 2005). In Europe, the pandemic strain O3:K6 appeared in 2004 in Spain and in samples from cases in France and Italy (116–118), while the serotype O4:K12 was reported in 2012 in Galicia (northwestern Spain), simultaneously with the spread of the PNW complex to the Atlantic coasts. This outbreak, affecting 100 passengers travelling on a cruise ship and associated with consumption of cross-contaminated shrimps, revealed the presence of genetically undistinguishable O4:K12 strains in both the U.S. East Coast and Western Europe, suggesting that these strains may be becoming endemic in an expanding area of the Atlantic Ocean (119).

Virulence Factors

Toxins

Although *V. parahaemolyticus* occurs naturally in the marine environment, only a minority of environmental isolates have been proved to be pathogenic. A key feature of *V. parahaemolyticus* pathogenicity is the ability of certain strains to produce hemolysins (120). The production of the thermostable direct hemolysin (TDH) was first detected in the late 1970s in clinical strains showing beta-hemolytic activity on a special blood agar called Wagatsuma agar, a process designated the Kanagawa phenomenon (KP). KP-positive strains were therefore associated with pathogenicity. Early studies by Sakazaki and colleagues (121) on the production of TDH hemolysin showed that the vast majority of clinical isolates (96.5%) were KP positive, whereas the prevalence of the KP in environmental isolates was around 1%. This significant difference has been confirmed in subsequent studies, both through assessment of the KP and by detection of genes responsible for TDH production,

with the prevalence of KP-positive isolates among environmental strains being on the order of 1 to 2% (122). TDH is an amyloid, pore-forming toxin with a variety of biological activities that include hemolytic activity, cytotoxicity, cardiotoxicity, and enterotoxicity (123). The fairly large (~2-nm) pore formed in erythrocyte membrane allows both water and ions to flow through the membrane. These alterations in ion flux in the intestine are the basis of the mechanism causing the diarrhea observed during *V. parahaemolyticus* infection. To date, five alleles of the *tdh* gene with 96 to 98% nucleotide homology have been described, and with the exception of *tdh3*, located on a plasmid, all the variants are chromosome borne, with TDH-producing strains usually harboring both *tdh1* and *tdh2* (124, 125). TDH production in such strains is mainly contributed by *tdh2* (>90%) (126), while other *tdh* genotypes, probably in relation to different transcriptional control or nucleotide changes within the promoter region, were shown to have very low levels of gene expression (127). In addition to being unevenly distributed among environmental *V. parahaemolyticus* isolates, *tdh* genes are sporadically present in other *Vibrio* species, including *V. mimicus*, *V. cholerae* non-O1/non-O139, and *G. hollisae* (122).

Investigation of an outbreak in the Maldives in 1985 highlighted the fact that *V. parahaemolyticus* can express pathogenicity even in the absence of *tdh*, and this finding led to the discovery of a second hemolysin, the TDH-related hemolysin (TRH), which, although it is immunologically similar to TDH, is heat labile, being inactivated following treatment at 60°C for 10 min (128). Later studies on the *V. parahaemolyticus* type strain isolated by Fujino and colleagues in 1950 (strain EB101, WDCM 00037) proved that it is also KP negative and expresses TRH (129). TRH is believed to act similarly to TDH by the activation of Cl^- channels, resulting in altered ion flux in intestinal epithelial cells. The *trh* genes show a higher strain-to-strain sequence variation than the *tdh* genes and can be clustered into two main subgroups (*trh1* and *trh2*), which share 84% identity with each other (130) and approximately 68% identity with *tdh* sequences (131). The two variants usually do not coexist in the same strain (132), and their distribution among environmental isolates, where *trh* prevalence varies between <1 and 17% (133, 134), seems to indicate a preponderance of *trh2* (135). As for *tdh*, *trh* genes are occasionally detected in *Vibrio* species other than *V. parahaemolyticus*, such as *V. alginolyticus* (136), and have been recently identified also in non-*Vibrio* species (*Aeromonas veronii* isolates from subjects with acute diarrhea [137]). Strains carrying both *tdh* and *trh* genes are also detected in a nonnegligible number of cases and were found to produce TDH at far lower levels than isolates harboring only the *tdh* genes (138).

A third, unrelated hemolysin, called thermolabile hemolysin (encoded by the gene *tlh*), is often reported in *V. parahaemolyticus*, being present in all strains of clinical and environmental origin (139), irrespective of their virulence. Given its distribution, *tlh* is often used as a species-specific marker for detection or identification of *V. parahaemolyticus*.

Secretion Systems

The pathogenicity of *V. parahaemolyticus* and the presence of *tdh* and *trh* have been clearly correlated by molecular epidemiological analysis (140). An increasing number of studies, however, have reported the absence of both *tdh* and *trh* in about 10% of strains isolated from human clinical cases (120), indicating that other virulence factors exist and may play a significant role in the pathogenesis mechanism of *V. parahaemolyticus*. A first step to elucidating such a contribution was the genome analysis of *V. parahaemolyticus* strain RIMD 2210633, belonging to the pandemic clone O3:K6, which emerged in 1996 (see "The O3:K6 Pandemic Clone" below). Whole-genome sequencing of this strain identified the presence in the genome of genes for two novel T3SSs, named T3SS1 and T3SS2, respectively, located on chromosome 1 and chromosome 2 (141). Such apparatuses usually consist of 20 to 30 proteins, assembled in a basal body (stretching through the inner and outer bacterial membranes), a needle structure (extending through extracellular space), and a translocon pore (inserting into the eukaryotic cell membrane). The most common targets of the effectors translocated via T3SSs are actin cytoskeleton, innate immune signaling, and autophagy (142).

T3SS1 is conserved in all environmental and clinical *V. parahaemolyticus* strains, irrespective of their pathogenicity or lack thereof. The T3SS1 gene cluster is composed of 42 genes showing similarity to the

genes encoding the Ysc secretion system in *Yersinia*, and cytotoxic activity against several cell lines has been demonstrated. Depending on the pathogen's needs, the systems can be either up or down regulated. The three main effectors translocated by T3SS1 (VopQ, VPA0450, and VopS) provide destabilization of the eukaryotic cell structure by causing detachment of the plasma membrane from the actin cytoskeleton (blebbing of plasma membrane) and collapse of the actin cytoskeleton (cell rounding and shrinkage) and by inducing autophagy, which, by sequestering of membrane resources, antagonizes phagocytosis of the infecting bacteria.

The T3SS2 genes are present on a *V. parahaemolyticus* pathogenicity island (VPaI; see "Pathogenicity Islands" below) present on chromosome 2 and carrying several virulence-related genes. T3SS2 is found in clinical isolates, being responsible for both cytotoxicity and enterotoxicity. Two distinct lineages (T3SS2α and T3SS2β) have been reported, correlating with the presence of *tdh* and *trh* genes, respectively (143). T3SS2α was first identified in strain RIMD 2210633 in close association with a pathogenicity island (VPaI-7) and flanked by two *tdh* genes, which appear to be coregulated with T3SS2α (144). The six effectors associated with T3SS2α (VopC, VopT, VopA/P, VopL, VopV, and VopZ) allow *V. parahaemolyticus* to invade, survive in, and replicate in nonphagocytic host cells (144) through the induction of several responses, including changes in the actin cytoskeleton and activation of the mitogen-activated protein kinase signaling pathway. T3SS2β was first identified in strain TH3996 by sequencing of the region surrounding the *trh* gene (143). T3SS2β was also confirmed to be part of a pathogenicity island (which also includes the *ure* gene cluster, previously reported to be in association with *trh*), and the effectors VopC, VopA/P, and VopL have been described. Interestingly, different studies on clinical and environmental strains have shown that while T3SS2α and T3SS2β are reliably found in *tdh*-positive, *trh*-negative strains and in *tdh*-negative, *trh*-positive strains, T3SS2-related genes may also be found in *tdh*-negative, *trh*-negative strains (145). Additional details on T3SSs are provided in references 142 and 146.

To further enhance the complexity of *V. parahaemolyticus* pathogenic mechanisms, a second set of secretion systems was recently described, namely, the T6SSs. T6SSs, which usually contain 13 to 20 proteins, have been reported in different *Vibrio* species (i.e., *V. cholerae*, *V. alginolyticus*, and *V. harveyi*) as well as in several non-*Vibrio* genera (e.g., *Pseudomonas*, *Aeromonas*, *Burkholderia*, etc.) (147) and are present in *V. parahaemolyticus* in two sets, T6SS1 and T6SS2, encoded by genes located on chromosome I and chromosome II, respectively (148, 149). Although the exact functionality of T6SS1 has not yet been demonstrated, preliminary data suggest its involvement in competition against other bacterial species and against other strains of the same species, as environmental signals (temperature, salinity, cell density, etc.) and the master QS regulator (OpaR) regulate T6SS1 activity and expression (150). As for T6SS2, available data suggest that this secretion system is functional to the adhesion to host cells in the first step of infection (151). Furthermore, since T6SS2 and T3SS2 coexist, it has been suggested that the two systems might cooperate during an infection, with T6SS2 acting primarily on adhesion and T3SS2 expressing virulence by inducing enterocytotoxicity.

Pathogenicity Islands

Acquisition of genetic material by horizontal transfer plays a key role in the evolution and the ecological fitness of *V. parahaemolyticus*, and recent comparative studies on available genomes have highlighted the presence of several genomic islands in this species. Genomic islands have been classified based on the different functions they encode, and the different types include metabolic, degradation, resistance, symbiosis, and pathogenicity islands (VPaI in *V. parahaemolyticus*). Seven VPaIs (VPaI-1 to VPaI-7) have been identified in the pandemic *V. parahaemolyticus* RIMD2210633 genome sequence (148, 152), while two further VPaIs (VPaI-8 and VPaI-9) were described in the *tdh*-positive prepandemic strain AQ3810 (92) (for further definitions of pandemic and prepandemic strains, see "The O3:K6 Pandemic Clone" below). Since their first description, VPaIs have been reported in several studies on clinical and environmental *V. parahaemolyticus*, with variable genomic distribution among different isolates. VPaIs are characterized by a G+C content lower than that of the overall genome (~45%); they possess a phage-like integrase gene and are flanked by repeated sequences, although there are exceptions (e.g., VPaI-7, where the integrase gene is replaced by several

transposase genes) (152). Comparative studies showed that VPaI-1 and VPaI-5 are harbored only by pandemic strains, whereas VPaI-7 and T3SS2 are closely associated with *tdh*-positive strains of *V. parahaemolyticus*. In particular, VPaI-1 (~23 kb and 24 open reading frames) encodes a DNA methyltransferase (VP0394) that is regarded as an additional colonization factor (152), and VPaI-7 (formerly known as Vp-PAI or *tdh*VPA; ~8 kb and 87 open reading frames) was shown to be consistently present in KP-positive strains and undetectable in KP-negative strains, suggesting that not only *tdh* but the entire region is required for pathogenicity of KP-positive clinical *V. parahaemolyticus* (149). Compared to VPaIs of *tdh*-positive strains, islands containing *trh*, T3SS2β genes, and the *ure* cluster (described as Vp-PAI$_{TH3966}$ or *trh*VPA) have scarcely been investigated. Interestingly, recent studies on emerging pathogenic lineages in the northeastern United States highlighted the reassortment of genes within VPaIs, demonstrating the mosaic nature of these genomic islands (153).

Adhesion Systems

The first stage in bacterial infection is adhesion to the host cell, a step that is a prerequisite for the efficient translocation of effectors and triggering of signaling pathways that facilitate subsequent pathogen invasion. To date, several adhesive organelles, including T6SSs, capsular polysaccharide, and mannose-sensitive hemagglutinin pilus, have been reported to contribute to attachment of *V. parahaemolyticus* to host cells, and other adhesin genes are periodically discovered. The major adhesion factor, crucial for the expression of pathogenesis, is MAM7 (multivalent adhesion molecule 7), a constitutively expressed transmembrane protein conserved in many Gram-negative bacteria that consists of a hydrophobic stretch of 44 amino acids at its N terminus (transmembrane domain) and seven mammalian cell entry domains that mediate its adherence to different types of cells by binding fibronectin and phosphatidic acid (154).

Iron Uptake Systems

V. parahaemolyticus, like other bacteria of the genus *Vibrio*, requires iron (Fe) for growth and has developed systems to acquire Fe for sustaining metabolism and replication. The Fe concentration in coastal waters ranges from ~1 to almost 600 nM, while the level of free Fe in mammalian bodily fluids is variable (~10^{-18} M) but always far below the concentrations required for bacterial growth. In the human host, *V. parahaemolyticus* can utilize host sources, such as the iron proteins hemoglobin, heme, hemin, and transferrin, for its metabolic needs. One of the strategies of *V. parahaemolyticus* to obtain the iron from the host iron proteins is to secrete siderophores (vibrioferrin) or to use siderophores produced by other bacteria (e.g., aerobactin and enterobactin). Other strategies may include expression of transferrin receptors, for which putative genes have been found in the *V. parahaemolyticus* genome. A review of the strategies adopted by *Vibrio* species for iron uptake is provided in reference 155.

The O3:K6 Pandemic Clone

In 1996, in Kolkata, India, a sudden increase of gastroenteritis attributed to *V. parahaemolyticus* serotype O3:K6 was recorded (156). Analysis of these O3:K6 isolates highlighted a specific pattern that included a *tdh*-positive, *trh*-negative and urease-positive profile. Within a few months, strains with the same characteristics were isolated in several Southeast Asian countries as well as in Japan and Korea (157). Further analysis demonstrated other distinctive molecular properties, including an associated filamentous phage (*f*237) with a unique open reading frame (*orf8*) and different sequences of the *toxR* and *toxS* genes (158), subsequently used for the development of specific PCR for the detection of the pandemic strain (group-specific PCR). The screening for such a molecular profile, together with the evidence obtained through RFLP-PFGE, rapidly led to the detection of genetic patterns indistinguishable from that of the epidemic O3:K6 clone in isolates belonging to different serotypes, such as O4:K68, O1:K25, O1:K41, O1:KUT, and O6:K18 (159). All these clonal serotypes showing different antigenic formulas (to date, 27 different serotypes have been reported [160]) are collectively referred to as O3:K6 serovariants, the O3:K6 pandemic clone, or the pandemic clonal complex. By the end of 2006, the O3:K6 *V. parahaemolyticus* serovariants had been isolated in Europe, Africa, the

United States, and several South and Central American countries (157), marking the first pandemic of *V. parahaemolyticus*. An extended review of the emergence, spread, and evolution of the O3:K6 pandemic strain is provided in reference 161.

The emergence and rapid diffusion of the O3:K6 pandemic clone have provided significant insight into the molecular epidemiology of *V. parahaemolyticus*, leading to the discovery of the above-mentioned virulence factors, including T3SSs and VPaIs (see "Virulence Factors" above). Furthermore, the need for a reliable assessment of the clonality of pathogenic strains, which is challenged by the serological heterogeneity and high genome plasticity shown by *V. parahaemolyticus*, has led to the progressive implementation of an MLST scheme for *V. parahaemolyticus* based on seven loci representing housekeeping genes (*recA*, *dnaE*, and *gyrB* on chromosome I and *dtdS*, *pntA*, *pyrC*, and *tnaA* on chromosome II) (162, 163). Based on MLST analysis, a sequence type (ST) can be attributed to clinical or environmental isolates and, based on phylogenetic relatedness, STs (to date, over 1,800) can be assigned to defined clonal complexes (CCs). Based on this typing scheme, the O3:K6 pandemic strains are described as ST3, CC3, with CC3 including the O3:K6 serovariants, while another relevant *V. parahaemolyticus* strain, the O4:K12 strain, which was responsible for repeated and diffused outbreaks on the Pacific (1997 and 2006) and Atlantic (2012) coasts of the United States as well as in Spain (2012), is reported as ST36, CC36.

V. VULNIFICUS

V. vulnificus is responsible for the majority of seafood-associated deaths worldwide (164). This pathogen is classified as accidental (i.e., "accidentally" infecting humans) as well as opportunistic or secondary (i.e., causing severe disease only when the host's immune system is impaired).

Ecology and Animal Reservoirs

V. vulnificus is an autochthonous inhabitant of coastal brackish water ecosystems located in tropical, subtropical, and warm temperate areas (164); it can survive in cold water (below 10°C) by entering the metabolically inactive VBNC state (165). Ecological data on the isolation of *V. vulnificus* from the environment suggest that water salinity and temperature determine its geographical distribution (166). The ideal salinity for *V. vulnificus* survival in nature ranges between 2 and 25 g of salt per liter (‰), with an optimum around 10 to 18‰, and a temperature between 10 and 33°C, with an optimum around 25 to 28°C (165). However, because of the combined effect of both parameters, the true temperature limits for *V. vulnificus* survival depend on salinity, being narrower (22 to 33°C) at high salinities (>10‰) and wider (10 to 33°C) at low salinities (5 to 10‰) (167). According to this, *V. vulnificus* would be an inhabitant of water bodies of higher salinity in the tropics and of lower salinity in warm temperate areas. Lately, global climate change has extended the geographical distribution of *V. vulnificus* to colder areas; it has been isolated from coastal habitats located in Northern Europe, mainly in association with heat waves (1, 168).

V. vulnificus, like the other *Vibrio* species, switches between free-swimming and sessile lifestyles during its life cycle in water (165). Sessile *V. vulnificus* is mainly associated with abiotic (i.e., sediment) and biotic (i.e., the chitinous exoskeleton of crustaceans and the internal and external mucosa of fish) surfaces by forming biofilms. In addition, free-living and microparticle-associated *V. vulnificus* can be concentrated to more than 100 times the concentration found in the surrounding waters by filter feeders, such as small crustaceans and bivalves (clams, oysters, etc.) (169). Oysters, shrimp, and fish are considered the main environmental reservoirs for *V. vulnificus*, whose presence in these hosts is mainly controlled by the same parameters that control its survival in water (169, 170). Figure 13.3 shows a model for the life cycle of *V. vulnificus* in nature.

Identification

V. vulnificus can be isolated from water and seafood samples by using the FDA protocol (Fig 13.1). Experiments with seawater microcosms revealed that the *V. vulnificus* recovery rate increases significantly when the selective and differential medium modified cellobiosepolymyxin B-colistin is

replaced with *V. vulnificus* medium (10) or TCBS agar (170). Then, identification can be performed by Southern blot hybridization or PCR by targeting the species-specific cytolysin gene *vvhA* (9). In addition, multiple systems have been reported for identification and differentiation of *V. vulnificus* from the main pathogenic *Vibrio* species, including multiplex PCR and real-time PCR, mostly targeting *toxR*, or even analyzing new DNA targets by comparative genomics (171, 172). Among them is a multiplex assay for the simultaneous identification of 10 bacterial pathogens (including vibrios and other common pathogens) in a single reaction by using a multiplex ligation reaction based on probe melting curve analysis (173). This protocol was used with 100% accuracy in the case of environmental and clinical *V. vulnificus* strains. According to the authors, the assay can be used directly on blood and skin tissue samples or even tissues from the suspected prime source of the infection and could be implemented in public health and food laboratories.

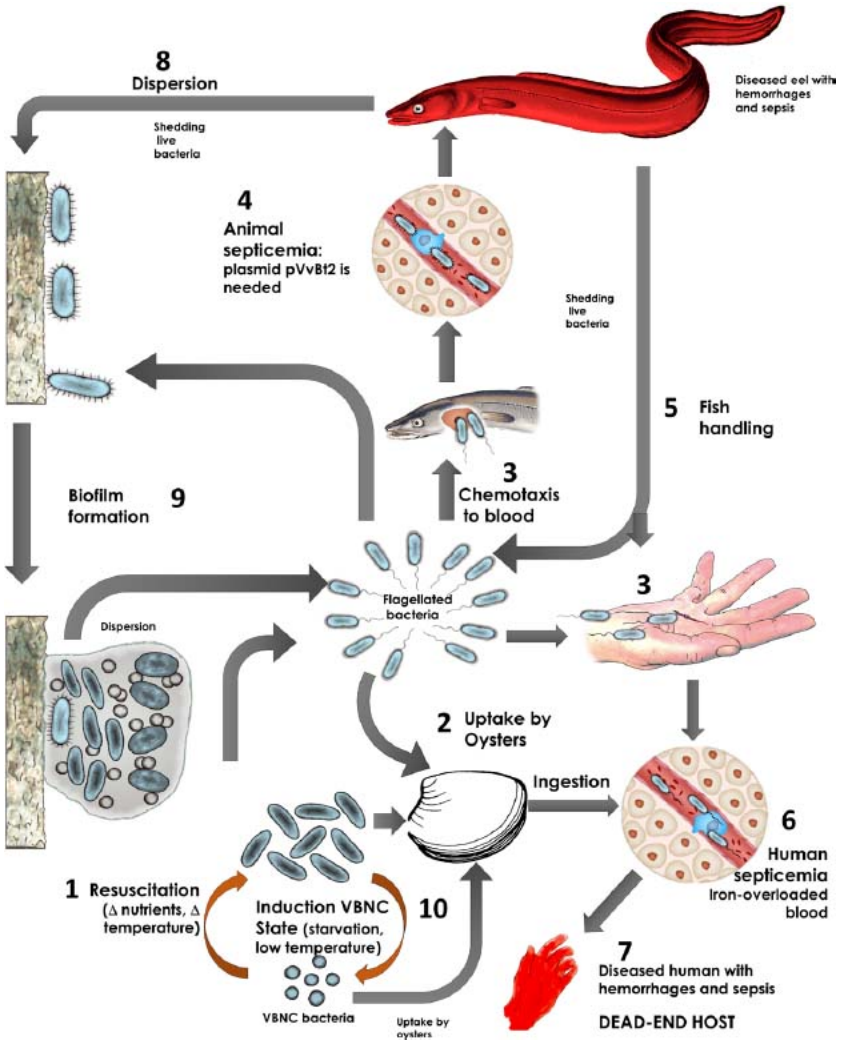

Figure 13.3 Life cycle of *V. vulnificus*. (Step 1) Resuscitation. VBNC bacteria resuscitate when temperature increases to more than 10°C. (Step 2) Uptake by filter feeders, ingestion by humans, and infection. Bacteria with or without flagella can be taken up by filter feeders, such as oysters, which, in turn, can be ingested by humans. (Step 3) Chemotaxis through blood. Flagellated bacteria can be attracted by blood and colonize wounds on animal and human surfaces. (Step 4) Animal septicemia: fish vibriosis. In the case of animals, only bacteria possessing the virulence plasmid pVvBt2 colonize and invade blood, causing fish vibriosis. (Step 5) Human infection by fish and seafood handling. (Step 6) Human septicemia. In the case of humans, regardless of the route of infection (ingestion or contact), bacteria have success in invasion and in causing septicemia, mainly in iron-overloaded patients. (Step 7) Humans are the end hosts for *V. vulnificus* infection. (Step 8) Dispersion of *V. vulnificus* cells from infected aquatic animals into the water. (Step 9) Bacteria can form biofilms on mucosal and inert surfaces, from which they can be dispersed again into the water. (Step 10) Induction of the VBNC state. When the temperature drops below 10°C, bacteria enter the VBNC state, closing the cycle. Adapted from reference 207.

Intraspecific Variability and Virulence

V. vulnificus was defined as a bacterial species by Farmer in 1979 from a series of lactose-and indole-positive vibrios isolated from the environment and clinical cases reported in the United States (174). The isolation of vibrios that had similar characteristics but were indole negative from diseased farmed eels was simultaneously reported in Japan. Subsequently, the indole-positive and -negative strains

were assigned to two different biotypes (175). Later, a third biotype was established in Israel to group atypical isolates (cellobiose, salicin, and lactose negative) from human infection outbreaks associated with handling of farmed tilapia (176). The three biotypes can cause human diseases, but only biotype 2 (Bt2) is also able to cause fish vibriosis, an ability that relies on a plasmid (pVvBt2) encoding a resistance system to the fish innate immunity (177). Moreover, among Bt2 strains, only those belonging to the clonal complex Bt2-SerE are recognized as truly zoonotic (178, 179). Although strains of the three biotypes could originally be phenotypically and genetically discriminated, diversity as well as the number of isolates has increased, and at present, there is no test or set of tests that clearly differentiate among them, with the exception of Bt2, which can be targeted by PCR for unique plasmid genes (180). A recent phylogenomic analysis of the core genomes of 80 *V. vulnificus* strains belonging to the three biotypes demonstrated that this species is subdivided into five well-supported phylogenetic groups or lineages that do not correspond to biotypes (181). Lineage 1 comprises a mixture of clinical and environmental Bt1 strains, most of them involved in human clinical cases related to raw seafood ingestion. Lineage 2 accounts for a mixture of Bt1 and Bt2 strains from various sources related to the aquaculture industry. Lineage 3 comprises exclusively all Bt3 strains, and lineages 4 and 5 comprise a few Bt1 strains associated with specific geographical areas. This study also found strong evidence that pVvBt2 has been acquired independently by different clones, probably in fish farms, and proposes a new updated classification of the species based on phylogenetic lineages rather than on biotypes, as well as the inclusion of all Bt2 strains in a unique pathovar with the particular ability to cause fish vibriosis (*V. vulnificus* pv. piscis).

Regardless of lineage and biotype, a single strain or clone can be virulent or avirulent. There have been several unsuccessful attempts to find a genetic virulence marker by comparing environmental and clinical strains. However, it seems that there are differences in several polymorphisms and in repetitive extragenic palindromic sequences that could be used to predict the virulence potential of a strain. The most used genetic markers for virulence-related polymorphisms are *pilF* (pilus type IV assembly gene; clinical [C] strains are positive and environmental [E] strains are negative) (182), *vcg* (open reading frame VV0401; virulence-correlated gene of strain YJ016; C or E) (183), capsular polysaccharide (type 1 [C] or 2 [E]) (184), and 16S RNA (type A [E] or B [C]) (185). A multiplex PCR that combines some of these genetic markers would probably be more discriminant than a PCR that uses only one, since none of them is infallible when used in a single PCR. Another approach is to use MLST analysis based on housekeeping gene sequencing (https://pubmlst.org/vvulnificus/info/primers.shtml) (179, 186). However, this analysis is also not completely reliable, since there are multiple exceptions. At present, our conclusion is that all *V. vulnificus* strains should be considered potentially virulent for humans. This conclusion is supported by the phylogenomic study of Roig et al. (181), who found that most of the described virulence genes were present in the core genome of the species.

Disease

V. vulnificus is an extremely diverse pathogenic species. This pathogen can accidentally infect fish, shrimps, and even humans, causing diseases with multiple clinical manifestations. There are two main forms of human vibriosis according to the transmission route, i.e., contact or ingestion. In the first case, the pathogen causes severe tissue necrosis after wound contact with contaminated seawater or any carrier species (mainly during handling of farmed fish and seafood) that can lead to debridement and/or amputation or even secondary septicemia (164). Since people infected by contact are usually swimmers, bathers, and fishers, this pathogen is sometimes known as the “marine flesh-eating bacterium.” In the second case, *V. vulnificus* causes gastroenteritis and/or primary septicemia after ingestion of raw or undercooked seafood (mainly oysters in Western countries and shrimp in Asia) (164) (Fig 13.3), and for this reason, it is considered a foodborne pathogen.

Fish vibriosis is a hemorrhagic septicemia produced by contact with water or fish (carrier or diseased) that has a short incubation time (around 24 h on average) in common with human vibriosis (177). Thus, *V. vulnificus* can be also considered an extremely fast-acting multihost septicemic pathogen. Finally, *V. vulnificus* can be transmitted from diseased fish to humans, which suggests that it is also a zoonotic agent (177). From here, this section focuses mainly on foodborne human infections and the

particular relationship that *V. vulnificus* establishes with the most studied reservoir for this type of disease, the oyster.

Epidemiology

From its first isolation by the CDC in 1964, *V. vulnificus* has been extensively isolated in the United States, especially in the Gulf Coast states, where it is considered a human pathogen of concern. The most complete epidemiological data set on *V. vulnificus* isolation comes from COVIS, and no similar databases are available anywhere else. The most recent COVIS data differentiate between contact and foodborne infections and permit some relevant conclusions to be drawn: (i) foodborne infections occur as sporadic cases in warmer months (May to October), with a maximum in the hottest months (July and August), in the geographical areas where *V. vulnificus* is a native bacterium; (ii) although the prime vehicle for foodborne infections in the United States is oysters, there are other aquatic animals of concern, such as clams, crabs, and finfish, all of them thought to be ingested raw or undercooked; (iii) the average human target host is 60.5 years old and male; (iv) confirmed foodborne infection cases are extremely low (~125 cases per year, with ~21% caused by seafood ingestion) considering the abundance of *V. vulnificus* in edible filter feeders in the warmer months (i.e., more than 10^7 CFU/g of oyster), likely due to the majority of cases not being severe enough to require medical assistance at home or hospitalization; (v) among reported medical cases, the hospitalization rate is high (84% of total cases), and the case fatality ratio is also high (25% considering total cases and up to 31.2% considering only hospitalized cases). Although COVIS data do not distinguish mortality caused by ingestion from that caused by contact, previous studies report values of ~50% and 15%, respectively, which correlate with the reported epidemiological data. It is safe to extend COVIS conclusions globally, since they do not differ substantially from recently reviewed data from Europe (France, Denmark, and Germany), Asia (Japan, Korea, and Taiwan), and the United States (187–189), although the primary source of infection varies according to dietary habits (i.e., oysters and clams in the United States versus mud shrimp in Japan) (190). Recently, a tendency toward an increase in *V. vulnificus* infection cases in COVIS data from 1988 to 2010 was detected (187). However, our analysis reveals that the case number in the United States seems to have been stable from 2011 to 2014. Therefore, our conclusion is that the preventive measures applied in the most heavily affected states appear to have counteracted this global tendency.

Pathogenesis of Foodborne Infections

The infectious dose of *V. vulnificus* probably depends on the variant of the pathogen present in the ingested animal species (see “Intraspecific Variability and Virulence” above) as well as on the health status of the consumer. In healthy people, the disease seems to be self-limiting, but in susceptible populations, fewer than 100 total bacteria may cause primary septicemia (septic shock), with fever, chills, altered mental status, and hypotension as the main clinical signs (164, 188). More than 60% of septicemic patients develop secondary lesions on the extremities, similar to those found in wound infections (cellulitis, bullous lesions, and necrosis) (188), which makes it difficult to discriminate primary from secondary septicemia when the source of infection is unknown (Fig 13.4). Primary septicemia occurs when the pathogen crosses the intestinal barrier, arrives in the bloodstream, resists the immune defenses, and multiplies, causing sepsis. In case of *V. vulnificus*, there is a clear correlation between sepsis and an underlying disease (<5% cases occur in individuals without any identifiable risk factor) (188). The main reported risk factor is chronic liver disease (cirrhosis, hepatitis, liver transplantation, or liver cancer), followed by hemochromatosis, a hereditary blood disease (188, 189). Additional risk factors are a compromised immune system (chemotherapy, immunosuppressive medication, AIDS, etc.), diabetes, and chronic renal or intestinal diseases (188). Nutritional immunity due to iron sequestering by transferrin seems to be the key defense mechanism to keep *V. vulnificus* under control. Specifically, the two main risk factors (chronic liver diseases and hemochromatosis) can lead to an iron overload in serum because of low transferrin and hepcidin (an iron-regulatory hormone) production and hereditary hepcidin deficiency, respectively. Another innate mechanism that can fail and contribute to the rapid expansion of *V. vulnificus* is bacterial killing either

by phagocytoses or by complement, both of which are impaired in immunodeficient patients. Individuals with chronic liver disease or various immunodeficiencies have been reported to be 80 times more likely to develop primary sepsis than healthy individuals (191).

Figure 13.4 Clinical signs of human sepsis caused by *V. vulnificus*. The photo shows typical clinical signs of primary and secondary sepsis caused by *V. vulnificus*: swelling, erythema, development of vesicles or bullae, and tissue necrosis. Virulence Factors

The animal models most often used to study host-pathogen interaction in *V. vulnificus* are normal or iron-overloaded (by preinjecting different sources of iron) mice that are intraperitoneally (model for sepsis) or intragastrically infected. Of all the *V. vulnificus* virulence factors that have been discovered by using these models, we have selected a handful with a clear role in the three main steps of the infection process: colonization, invasion, and sepsis (Fig 13.5).

Colonization

V. vulnificus can resist, although only partially, the acidic pH of the stomach due to the combined action of CadA and CadB, a lysine/cadaverine antiporter and a lysine decarboxylase that synthesize and excrete cadaverine to counteract external pH (192). Antacids or deficiencies in the natural pH of the stomach are considered another risk factor for foodborne infections caused by this pathogen. Surviving *V. vulnificus* organisms arrive at the intestine, where they can resist the bactericidal action of bile salts and/or microbicidal peptides thanks to a sialic acid-containing LPS, the outer membrane protein OmpH, and a potassium pump (TrkA), among other factors (193–195). Resistant bacteria must adhere to the intestinal epithelium or they will be eliminated by the constant turnover of the mucus layer together with the peristaltic movements of the intestine. According to recent literature, *V. vulnificus* can first attach weakly to the intestinal epithelium thanks to the interaction between mucin and the mucin-binding outer membrane protein GbpA and then thanks to the interaction between mucin on the bacterial surface and different mucin receptors on the intestinal cells (196). Upon initial attachment, bacteria can then produce the multifunctional protease VvpE, which can inhibit the expression of mucin (mucin 2), facilitating a stronger and direct attachment (193), in this case through the interaction of different adhesins (flagellin, type IV pilin, and several outer membrane proteins, such as IlpA and OmpU, among other factors) and their putative receptors on intestinal cells (194, 195). Once firmly attached, *V. vulnificus* multiplies by using as nutrients different carbon sources naturally present in the mucosa (e.g., *N*-acetylneuraminic acid) (197).

Invasion and Spreading

V. vulnificus produces a protein known as multifunctional autoprocessing repeats-in-toxin (MARTX or RtxA1) that is directly involved in invasion and spreading (198). MARTX is an early-expression protein that is expressed upon contact of the bacterium with multiple types of eukaryotic cells. MARTX toxins are modular proteins of high molecular weight with conserved external modules (in particular, N-and

C-terminal repeat regions) that form pores in the eukaryotic membrane, through which the toxin's central module is translocated (199). Then, the effector domains in the central module are liberated after activation of the cysteine protease domain, an endoprotease with autoproteolytic activity, in the cytosol (199). Several types of MARTX have been described in *V. vulnificus* according to the repertoire and organization of the effector domains. The best known is MARTX type I or RtxA11 (Fig 13.6), which induces a rapid intestinal barrier dysfunction and increases paracellular permeability prior to onset of cell lysis. In conjunction with cytolysin VvhA, MARTX causes intestinal tissue damage and inflammation contributing to *V. vulnificus* dissemination to the bloodstream and other organs (200). The metalloprotease VvpE also collaborates in this step by triggering a local inflammatory response that culminates in the disruption of tight junctions (201). Once in the blood, *V. vulnificus* uses the sialic acid-like LPS plus the capsule to resist the bactericidal action of complement and/or phagocytosis/opsonophagocytosis (202). It is possible that TrkA could also contribute by increasing serum resistance (203). Recently, it was demonstrated that capsule biosynthesis and *trkA* gene expression are up-regulated under iron excess conditions, which could partially explain the highest susceptibility to septicemia of patients with high iron levels in the blood (Fig 13.3) (207). *V. vulnificus* can also use MARTX to inhibit phagocytosis and kill phagocytic cells by diverse mechanisms (205, 206). Finally, surviving bacteria multiply in the blood by using either free iron in iron-overloaded patients or, in the case of healthy patients, two high-affinity iron uptake systems that are expressed only under iron starvation conditions (207), a siderophore called vulnibactin together with its receptor, VuuA, and a heme receptor, HupA (208). Additionally, *V. vulnificus* can use sugars naturally present in blood as nutrients. Recently, it was reported that MARTX can act on endothelial cells, thus favoring the spread to and invasion of internal organs (209). Once the bacteria are there, the combined action of these and other factors (collagenase, hyaluronidase, etc.) could contribute to cause lesions in the organs.

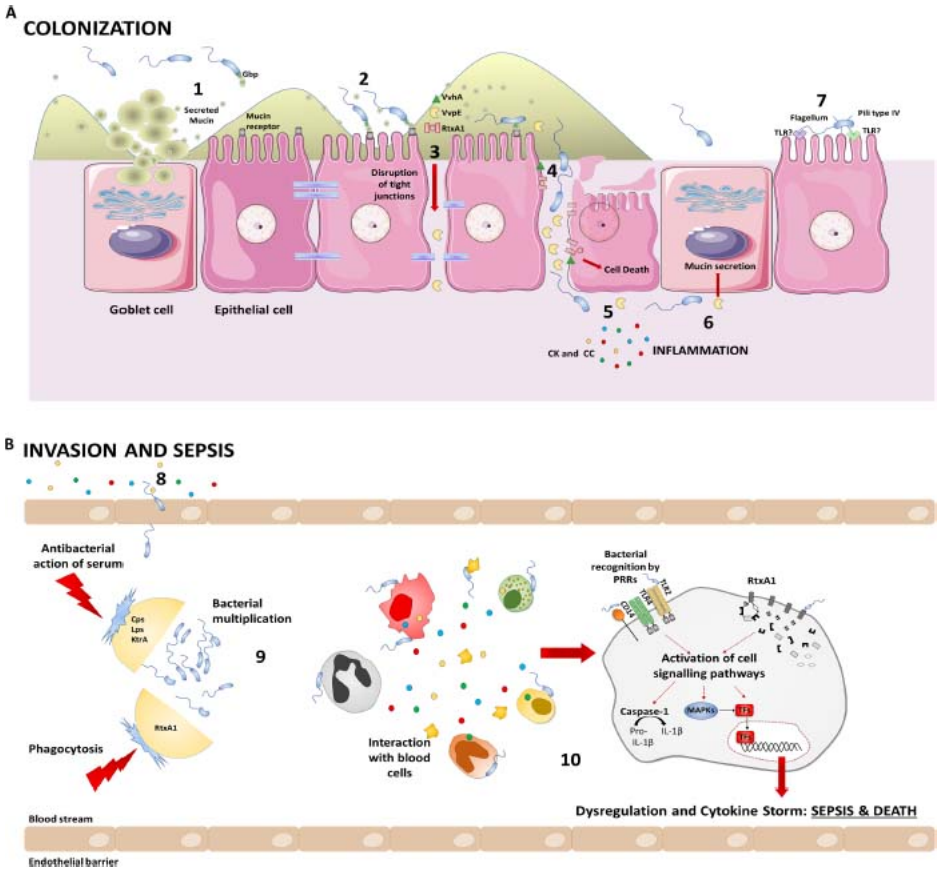

Figure 13.5 Steps in colonization, invasion, and sepsis caused by *V. vulnificus* and role of selected genes. (A) Colonization. *V. vulnificus* cells arrive at the intestine; some are eliminated, but others are attracted by mucin and bind to it by Gbp (step 1). Mucin-coated *V. vulnificus* cells bind to mucin receptors on epithelial cells (step 2). Attached cells produce VvpE, VvhA, and RtxA1, whose joint activity results in increased permeability and tight-junction disruption (step 3). Cells pass through the epithelium and continue producing Vvp, VvhA, and RtxA1, which cause cell death by different mechanisms (step 4). Attacked cells secrete cytokines (CK) and chemokines (CC), which triggers local inflammation (step 5). VvpE inhibits mucin secretion (step 6), which in turn facilitates vibrio adhesion, in this case probably by the interaction between pili/flagellin and Toll-like receptors (TLR) (step 7). Established bacteria will multiply on the epithelium. (B) Invasion and sepsis. Inflammation alters endothelial cells, enabling bacteria to cross the endothelial barrier (step 8). Bacteria multiply in blood thanks to the combination of a series of protective mechanisms in which capsule, LPS, KtrA, and RtxA1 are involved (step 9). Bacteria interact with different immune cells and, finally, cause sepsis and death, probably by inducing a cytokine storm (step 10). The figure is not to scale. PRRs, pattern recognition receptors. Adapted from reference 204.

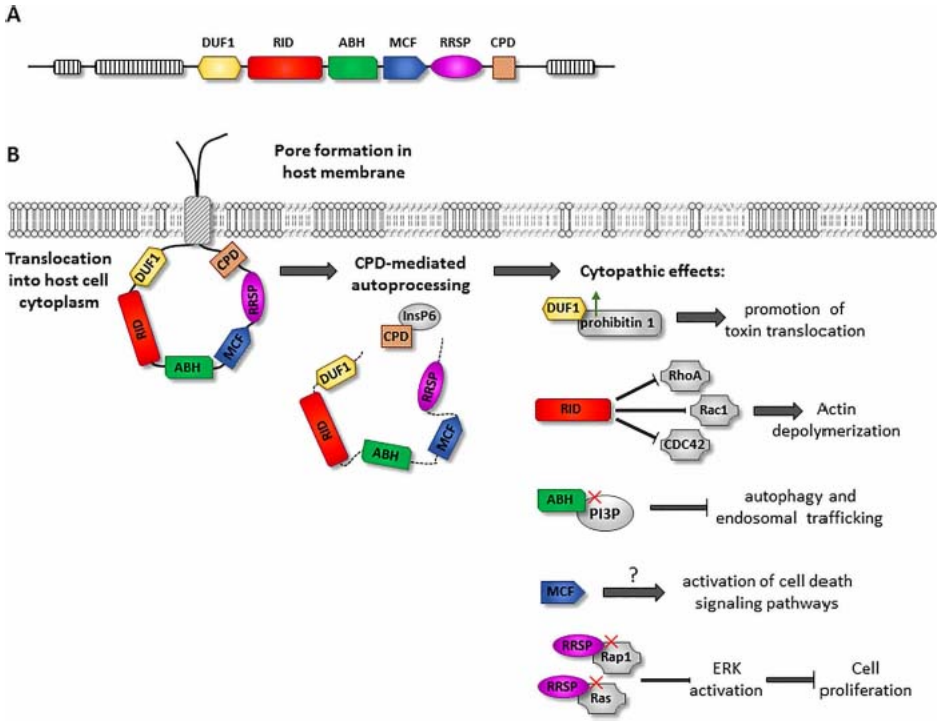

Figure 13.6 Structure (A) and mode of action at the cellular level (B) of MARTX type I of *V. vulnificus* (also called RtxA11). (A) The scheme shows the conserved external modules and the internal module, containing the five effector domains. (B) The toxin is secreted and the external module is associated with the target cell membrane by forming a pore that allows the central module to be exposed to the cytosol. The cysteine protease domain (CPD) catalyzes the release of the rest of internal domains after being activated by binding inositol hexakisphosphate. The domain with unknown function (DUF1) probably binds prohibitin-1, promoting the translocation of the toxin into the cell. The Rho GTPase inhibitor (RID) activates actin depolymerization, altering the cell cytoskeleton. The alpha/beta hydrolase domain (ABH) binds inositol 3-phosphate and inhibits autophagy and endosomal trafficking. The MCF (makes caterpillars floppy)-like domain induces depolarization of the mitochondrial membrane potential, which causes activation of cell death. The Ras/Rap1 specific endopeptidase domain (RRSP) suppresses the ERK–mitogen-activated protein kinase pathway by proteolytically processing Ras and Rap1 GTPases, preventing Ras from activating ERK, and then inhibiting cell proliferation. For more details on MARTX action at the cellular level, see reference 198. The figure is not to scale.

Sepsis

Sepsis caused by *V. vulnificus* is mainly due to the action of the immune system against the bacterium that, eventually, causes severe injury to tissues and organs, including the endothelium. Almost every cell of the body has Toll-like receptors to detect pathogen-associated molecular patterns and is able to secrete cytokines and chemokines when attacked by a microorganism. Neutrophils, macrophages, and probably endothelial cells are the master cells in articulating the early response against pathogens. Several of the cytokines secreted by these cells can mediate the systemic inflammatory response syndrome caused by *V. vulnificus*. In accordance with this, the proinflammatory cytokines interleukin 1β (IL-1β), IL-6, IL-8, and tumor necrosis factor alpha have been detected in the blood of patients with sepsis caused by *V. vulnificus* (210). However, patients with chronic liver diseases, who should be predisposed to sepsis by *V. vulnificus*, are paradoxically deficient in these cytokines (211). The key is probably not the quantity but the quality of the immune response: *V. vulnificus* likely induces a dysregulated and unbalanced immune response in which these and other cytokines and chemokines can be involved. Recently, MARTX type III produced by *V. vulnificus* zoonotic strains (all of them

related to infections by contact) was shown to be clearly associated with an early and unbalanced cytokine storm by using an animal model of sepsis (204). These strains present two copies of the gene, one on pVvBt2 and another on chromosome II, which is unusual in *V. vulnificus*, and cause sepsis without evidence of multiplication in the blood (204). Although the role of MARTX in foodborne infections is not clear and more studies are necessary, it seems that *V. vulnificus* multiplies in the bloodstream and that LPS (a potent inducer of tumor necrosis factor alpha) (212), IlpA (213), and the capsule (214) can act as strong inducers of cytokine and chemokine production, contributing to death by sepsis. However, the key factor inducing the hypothetical early and dysregulated cytokine response associated with foodborne infections, if any, remains to be determined. Figure 5 summarizes some of the mechanisms used by *V. vulnificus* to colonize, invade, and cause sepsis.

Diagnosis, Treatment, and Prevention of *V. vulnificus* Foodborne Diseases

Patients who show clinical symptoms of foodborne infection caused by *V. vulnificus*, especially signs of septicemia, and who present one or more risk factors should be treated immediately because of the high death rate associated with *V. vulnificus* disease (188, 215). Diagnosis is routinely performed in hospital laboratories from external lesions, diarrheal stools, or blood, and in addition to antibiotics, many patients require supportive therapy and intensive care (215). The mortality rate seems to be strongly dependent on the time after infection of antibiotic treatment (around 30% before 24 h, 53% between 24 and 48 h, and 100% for patients given antibiotics >72 h) (216). Recommended antibiotic therapy for *V. vulnificus* infection includes doxycycline and ceftazidime or other third-generation cephalosporins (188). *V. vulnificus* is usually susceptible to most antibiotics used in clinical practice (215). However, the extensive use of antibiotics in health care, agriculture, and especially aquaculture systems has led to an increase in resistance to antibiotics, including those prescribed for *V. vulnificus* infection treatment (217, 218). Recently, tigecycline, which is active in stopping the passage of *V. vulnificus* to the bloodstream, was successfully tested *in vitro* (219).

The best prevention measure against *V. vulnificus* is to trace the contaminated oysters (geographical area from which they were harvested and the month and/or season, among others) and to apply a series of measures from harvesting to consumption in order to reduce the presence of vibrios below risk levels (ideally no detectable levels, i.e., a most probable number of <30/g) (see “Control Measures to Minimize Vibrio Contamination” above). These measures should be complemented by instructing people to avoid raw or undercooked shellfish ingestion during hazard season(s) in areas where *V. vulnificus* is native. A successful example of these measures is represented by the State of California, which implemented a regulation restricting sales of raw oysters harvested from the Gulf of Mexico during April 1 to October 31, unless the oysters had been previously processed to reduce *V. vulnificus* to undetectable levels. The application of these measures has set to zero the number of deaths due to foodborne *V. vulnificus* infections (220).

V. ALGINOLYTICUS

V. alginolyticus was originally classified as a biotype of *V. parahaemolyticus* (221). The two species are genetically similar, but they can easily be differentiated phenotypically, most readily by the fermentation of sucrose by *V. alginolyticus*. *V. alginolyticus* has been included by Sawabe et al. (222) in the Harveyi clade of the genus *Vibrio*, which comprises several species isolated from seawater, saltmarsh mud, marine animals, and mucus of corals. Some differences in taxonomic traits between clinical and environmental isolates of *V. alginolyticus* have been suggested, but whether these are significant has not been demonstrated. Conventional, multiplex, and real-time PCR assays are now available for the detection and discrimination of *V. alginolyticus* in different sample types (223, 224). Diagnostic methods based on loop-mediated isothermal amplification, matrixassisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry, and aptamer technologies have also been developed (225, 226). An innovative method based on the use of multiwalled carbon nanotubes, which function as immunomagnetic fluorescent sensors for *V. alginolyticus* quantitative detection, was recently developed to be employed in fishery and environmental samples (227).

V. alginolyticus has been reported to inhabit seawater and seafood obtained worldwide. It is easily isolated from fish, clams, crabs, oysters, mussels, and shrimp, as well as water (228). Several studies from different countries revealed this species as one of the most common vibrios in environmental and food samples, and a correlationlation between temperature and its rate of isolation, which is greater in the warm months, has been reported (229–232).

Foodborne Outbreaks

In general, disease due to *V. alginolyticus* mainly affects persons who had direct contact with seawater or handled shellfish. *V. alginolyticus* has been commonly associated with ear infections (otitis media and otitis externa) and superficial wounds after exposure to contaminated water sources (233). In some cases, these infections can progress to bacteremia and necrotizing fasciitis, particularly in immunocompromised patients (234). The implication of this organism as a food-associated pathogen has also been documented. *V. alginolyticus* has been detected and isolated from watery diarrheal stools of patients with acute enterocolitis and also from the seafood they consumed. Chien et al. (234) described a case of *V. alginolyticus* bacteremia in an immunocompromised patient who ate a large amount of seafood.

According to COVIS, the incidence of *V. alginolyticus*, one of the three most common reported vibrios, increased between 1996 and 2010. *V. alginolyticus* accounted for 11.5% of the total cases of vibriosis and for 8.7% of foodborne cases (8). Hospitalization and death rates for infection with *V. alginolyticus* were similar to those for infection with *V. parahaemolyticus*. *V. alginolyticus* wound infections are rare in Europe, with only sporadic cases being reported in the United Kingdom, the Netherlands, and Denmark (235). This species has been isolated from 0.5% of healthy people in Japan, with no clinically associated intestinal disease evident.

Characteristics of Disease

Few reports describe the gastroenteric symptoms caused by *V. alginolyticus*, and acute diarrhea has rarely been associated with this infection. A leukemic patient with *V. alginolyticus* infection displayed confusion, shock, anemia, a temperature of 40°C, and a systolic blood pressure of 80 mm Hg. Despite antibiotic administration and treatment for shock, the patient died 12 days after admission. The exact role of *V. alginolyticus* in this case is unknown, however, as *Pseudomonas aeruginosa* was also isolated from the patient's blood and the presence of the latter pathogen was very possibly a factor in the fatal outcome.

V. alginolyticus is also pathogenic to fish and shellfish. The clinical signs observed in finfish species include septicemia, exophthalmia and corneal opaqueness, ascites, lethargy, melanosis, and ulcers (228). *V. alginolyticus* caused large-scale mortalities in cultured fish throughout the world, and some vaccine formulations for prevention of fish vibriosis by *V. alginolyticus* have been developed (236). In shellfish, *V. alginolyticus* has been associated with necrosis, shell disease and white spot in shrimp, and mass mortalities in clam larvae (237).

While extraintestinal infections are typically selflimiting and relatively mild, systemic infections are generally severe. Most such cases appear to involve patients who are immunocompromised due to severe burns, cirrhosis, or cancer. *V. alginolyticus* infections usually respond well to antibiotic therapy. However, in recent years, multiresistant strains, including extended-spectrum cephalosporins, have been isolated from fish and food products, including shrimp, chicken, pork, and beef (238, 239). The emergence of resistant strains may have important implications in public health. For this reason, phage therapy was suggested as an alternative sanitizing agent for seafood in order to prevent associated *V. alginolyticus* infections (240).

Virulence Mechanisms

The pathogenicity mechanism of *V. alginolyticus* is not yet fully understood, despite its being an important zoonotic pathogen causing disease in marine animals and in humans. Several virulence factors have been described (241). The presence of a capsule and lateral flagella, playing a role in

adhesion and swarming motility, as well as the production of hydroxamate siderophores, may facilitate the first stages of colonization and invasion of *V. alginolyticus*. Genes coding for components ofT3SS and T6SS were found in environmental isolates of *V. alginolyticus*. *toxR* and *ompK* genes, detected in some strains of *V. alginolyticus*, were found to cause bacillary necrosis and mortality in larval and juvenile mollusks. Another common virulence factor is collagenase, which may play a role in wound infections, as it is able to hasten bacterial dissemination through the protein components of the extracellular matrix and causes hemorrhagic tissue damage through destruction of the basement membrane (242). It has been reported that some *V. alginolyticus* virulence factors are derived from pathogenic strains of *V. cholerae* and *V. parahaemolyticus*, as is the case for TDH of *V. parahaemolyticus*, which is variably present among *V. alginolyticus* strains. Finally, QS seems to be an important regulatory system in virulence expression in *V. alginolyticus*, as in other *Vibrio* species (243–245). The alkaline serine protease, known to have toxic effects in oyster and shrimp, is regulated by the QS system through AphB, a LysR-type transcriptional regulator, also essential in other vibrios' pathogenesis.

V. FLUVIALIS

In 1977, Furniss et al. (246) reported the isolation from humans suffering from severe diarrhea of a new bacterium, designated group F, with phenotypic properties intermediate between those of the genera *Vibrio* and *Aeromonas*. In numerical taxonomy studies, Lee et al. (247, 248) determined that group F strains constituted a tight cluster distinct from known species of *Vibrio*, *Aeromonas*, *Plesiomonas*, and *Photobacterium*. Group F strains could be divided into biovars I and II. Biovar I was anaerogenic and isolated from aquatic environments and diarrheal cases, whereas biovar II was aerogenic and not disease associated. Subsequent studies revealed that aerogenic strains were a unique species, and these were reclassified as *V. furnissii* (249) (see "*V. furnissii*" below).

Reservoirs and Identification

V. fluvialis has frequently been isolated from brackish and marine waters and sediments in the United States as well as other countries. It has also been isolated from fish and shellfish, in some cases causing disease in these animals. Its detection rate is usually high in marine mollusks, mainly in bivalves, as they may accumulate the bacterium during the process of filter feeding. Thus, isolation from bivalves has been reported in Senegal, Brazil, Costa Rica, Malaysia, and Taiwan, among other countries. The bacterium has only rarely been isolated from freshwaters.

Alongside culturing methods (see "Isolation" and "Identification" above), molecular tools have been developed for the identification of *V. fluvialis*, including PCR, PCR coupled with denaturing gradient gel electrophoresis, quantitative PCR targeting the *toxR* gene, *groEL* PCR-RFLP analysis, and MALDI-TOF analysis (15, 250–253).

Foodborne Outbreaks

According to the World Health Organization (254), *V. fluvialis* infections are common in areas that have high levels of feces-contaminated water and food supplies and consumption of raw or contaminated seafood. The greatest outbreak occurred in Bangladesh in 1976–1977, where *V. fluvialis* was isolated from over 500 patients during a 9-month period. Since this outbreak, however, *V. fluvialis* has only occasionally been reported as an enteric pathogen. Klontz and Desenclos (255) described 12 persons with gastroenteritis in Florida between 1982 and 1988, and a subsequent survey of vibriosis in Florida during an 8-year period found that 5.6% of 125 gastroenteritis cases were caused by *V. fluvialis* (256). Consumption of raw oysters was implicated in most cases, although shrimp and fish consumption was also sporadically associated. Foodborne diarrheal outbreaks caused by *V. fluvialis* have also been reported in Brazil, Russia, and India (257–259). Incidence of the organism among travelers with diarrheal symptoms seems to be low compared to that of other pathogens.

Characteristics of Disease

V. fluvialis-related illness is characterized by gastroenteritis, nausea, loss of appetite, vomiting, and watery bloody diarrhea with abdominal cramps or significant fever (260). Moderate to severe dehydration, hypokalemia, metabolic acidosis, and occasionally hypovolemic shock can occur in 4 to 12 hours if fluid losses are not replaced. *V. fluvialis* has also been reported to cause necrotizing fasciitis and septicemia in the Gulf of Mexico and Southeast Asia, associated with minor trauma and exposure to fish, raw oysters, shellfish, crabs, or seawater, especially in the summer months (261). A case of biliary tract infection in an immunocompromised patient with end-stage renal disease and liver cirrhosis was also reported (262). The source could not be identified, although ingestion of undercooked seafood or contamination of a cutaneous lesion was highly probable. A case of acute otitis was also reported in a 40-year-old female who had been swimming in a seawater pool (263). Severe infection by *V. fluvialis* is favored by different host factors, including liver disease, an immunocompromised state such as HIV/AIDS, iron overload (e.g., hemochromatosis), and diabetes mellitus (260). In cases of wound infection and sepsis, since *V. fluvialis* causes vascular necrosis, therapeutic levels of antibiotic may not reach the organism and amputation may be necessary to prevent progression.

The infectious dose of *V. fluvialis* is not known. Infections are most common in infants, children, and young adults (264), and successful resolution of infection without antibiotic therapy has been reported; however, treatment with quinolones is generally administered along with intravenous fluids. The emergence of *V. fluvialis* strains that are resistant to quinolones and carbapenem has been a public health concern in recent years (14, 265). Some of these resistance genes are found on large conjugative plasmids that could be easily transferred to other enteric pathogens (265).

Virulence Mechanisms

V. fluvialis strains, of either clinical or environmental origin, express many putative virulence factors, including proteases, cytolysins, enterotoxin-like substance (immunologically indistinguishable from cholera toxin), Chinese hamster ovary (CHO) cell elongation factor, CHO cell killing factor, and hemolysin (14, 260, 264). In addition, endotoxin activity of *V. fluvialis* has been observed *in vitro* (266).

The hemolysin VFH, closely related to the El Tor hemolysin of *V. cholerae* and the heat-labile hemolysin of *V. mimicus* (267), has received special attention as the major *V. fluvialis* virulence determinant. Kothary et al. (268) reported that, in addition to lysing erythrocytes of different animal species, VFH is cytotoxic and elicits fluid accumulation in suckling mice. VFH also plays a key role in mediating IL-1β secretion and histopathology in the colon during *V. fluvialis* infection. In addition, VFH-mediated activation of the NLRP3 inflammasome is involved in the proinflammatory response upon infection (269).

Two QS systems were identified in *V. fluvialis*: an acyl-homoserine lactone-based system and a CAI-1/AI-2-based one (270). QS positively regulates the production of at least two potential virulence factors, an extracellular protease and VFH, and also affects cytotoxic activity against epithelial tissue cultures. Therefore, *V. fluvialis* integrates QS regulatory pathways to play an important physiological role in pathogenesis. Recently, Huang et al. (264) determined that there is at least one functional T6SS in *V. fluvialis* that may play a role in virulence as well as constituting an important factor for successful competition with other microorganisms in the marine environment.

V. FURNISSII

The taxonomy of *V. furnissii*, including phenotypical and genetic traits, was extensively described by Brenner et al. when they reclassified the aerogenic (gas-producing) biogroup of *V. fluvialis* as a new species (249). They compared *V. furnissii* not only with its closest relative, *V. fluvialis*, but also with other vibrios and with *Aeromonas* and *Alteromonas* species. Thus, *V. furnissii* can be differentiated from *V. fluvialis* primarily by its production of gas from glucose and can be differentiated from *A. hydrophila*, another phenotypically similar bacterium, by its ability to grow in 6% NaCl. Different molecular procedures were developed and compared for the detection of *V. furnissii* in different

sample types, as well as to discriminate it from closely related species. Conventional and quantitative PCR assays targeting the *toxR* gene as well as MALDI-TOF analysis proved useful for rapid and reliable identification of this bacterial species (250, 271).

V. furnissii can be considered a widespread marine species (272), and it has been isolated from brackish and estuarine waters and from marine mollusks and crustaceans around the world. Wong et al. (273) determined that approximately 7 to 12% of the oysters, clams, shrimp, and crabs examined in Taiwan are *V. furnissii* positive, whereas Matté et al. (274) observed incidences up to 17% in mussels in Brazil. In addition, an association with eel disease in Spain and with mortalities of tiger shrimp (*Penaeus monodon*) has been suggested (228).

Foodborne Outbreaks

The largest documented outbreaks were reported in 1969, when *V. furnissii* was isolated from American tourists with acute gastroenteritis after returning from Tokyo and Hong Kong. The first outbreak affected 23 out of 42 people, and *V. furnissii* was recovered from stool specimens, sporadically in association with *V. parahaemolyticus*. Epidemiological investigation implicated shrimp and/or crab salad as the possible source of infection. The second outbreak affected 24 of 59 people, and *V. furnissii* was isolated together with several other potentially enteropathogenic bacteria, hampering a reliable etiology. A food vehicle could not be identified. The CDC reported 16 cases of *V. furnissii* gastroenteritis to the end of the 1980s and 10 cases between 1997 and 2008, with isolation of the bacterium from stool, blood, or wounds, although no further epidemiological information was given. According to COVIS, since 2009, the incidence of *V. furnissii* infection accounted for less than 1% of total *Vibrio* infections. Although *V. furnissii* incidence may appear low, this bacterium can be a serious pathogen, causing septicemia by blood poisoning and skin lesions in patients with underlying comorbidities (250, 275).

Characteristics of Disease

V. furnissii gastroenteritis symptoms included diarrhea (91 to 100%), abdominal cramps (79 to 100%), nausea (65 to 89%), and vomiting (39 to 78%), with no fever reported (249). Onset of symptoms is between 5 and 20 hours, with patients recovering within 24 hours. The symptoms of a case of bacteremia and skin lesions were reported, including bilateral lower extremity swelling and erythema associated with burning, weeping lesions (275). The infectious dose of *V. furnissii* is not known, and no significant preference for age or gender can be established after the analysis of the data reported by COVIS.

Virulence Mechanisms

Potential virulence factors of *V. furnissii* include exocellular metalloproteases with elastolytic and hemagglutinating abilities (276), phosphomannomutase implicated in lipopolysaccharide biosynthesis (277), and oligopeptide permeases with multifaceted functions, including solute binding, *in vitro* hemolysis, cytotoxicity, and antibiotic resistance (278). *V. furnissii* also produces the siderophore fluvibactin and has the ability to gain iron from a xenosiderophore, desferrioxamine B, through an outer membrane receptor similar to that of *V. vulnificus* (279, 280). In addition, the siderophore fluvibactin is responsible for the antibacterial activity of *V. furnissii* against other vibrios (281). The complete genome sequence of *V. furnissii* strain NCTC 11218 was recently determined (272, 282). Although *V. furnissii* lacks several features usually associated with virulence in other pathogenic vibrios (*toxRT*, *zot*, *ctxAB*, and a T3SS), it produces a novel RTX-type toxin, which confirmed its potential as an emerging marine and human pathogen, especially in tropical coastal regions.

G. (*V.*) *HOLLISAE*

The species *V. hollisae* was first described in 1982 with the characterization of 16 strains, most of them obtained from stool samples or intestinal contents of patients with diarrhea (283). Twenty years later,

V. hollisae was reclassified into a newly formed genus as *Grimontia hollisae* on the basis of results obtained from fluorescent amplified fragment length polymorphism fingerprinting and from 16S rRNA gene sequence analysis, which demonstrated that this species was quite different from other vibrios (284, 285). *G. hollisae* is unusual among vibrios in its inability to grow on the two media routinely employed for the examination of stool samples, TCBS agar and MacConkey agar. Therefore, it is possible that infections caused by this species are not detected in clinical laboratories. However, *G. hollisae* grows well on blood agar and marine agar, and culture on xylose-lysinedesoxycholate agar recovers this species. *G. hollisae* can be properly identified with the API-20E system. In recent years, several molecular methods were developed for the detection and discrimination of *G. hollisae*, including DNA colony hybridization and PCR protocols targeting *gyrB* or *toxR* (286), loop-mediated isothermal amplification assay (287), and use of a PCR-ligase detection reaction-universal array (17).

Reservoirs

The distribution of *G. hollisae* is not well documented, although it is likely a marine species, and it appears to prefer warm waters (288). *G. hollisae* has rarely been detected in environmental samples, and it has been hypothesized that it may be present in the environment as VBNC cells (286). A possible selective retention in shellfish was suggested for this species, since it could be detected in mussels but not in surrounding waters in southern Italy (289). In addition, it has been isolated from different fish species, such as healthy sharpbeak terapon (*Rhynchopelates* [*Therapon*] *oxyrhynchus*) and diseased amberjack (*Seriola dumerili*) suffering from fish vibriosis (228, 290). *G. hollisae* displays a temperature-regulated rugose phenotype characterized by the production of copious amounts of exopolysaccharide consisting partially of *N*-acetylglucosamine and mannose (291). A role for this phenotype in the survival of *G. hollisae* in the environment has been suggested.

Foodborne Outbreaks

According to the literature, most *G. hollisae* cases correspond to episodes of moderate to severe gastroenteritis in adults, although some extraintestinal diseases and even septicemia were occasionally associated with this bacterium (288, 292). A strong correlation between *G. hollisae* infections and consumption of raw seafood has been suggested, although cases have also been reported following consumption of fried catfish and dried and salted fish, suggesting the ability of *G. hollisae* to survive these treatments. In addition, other sources could play a role as in the case of a 61-year-old male suffering from *G. hollisae*-associated diarrhea who denied recent travel or seafood consumption (288).

Until 1996, all *G. hollisae* cases were reported in the United States, mostly on the Atlantic coast and the Gulf of Mexico and less frequently on the Pacific coast and in Hawaii. Morris et al. (293) described nine cases of *G. hollisae*-associated diarrhea, with raw oysters, clams, or shrimp as the possible source. Between 1981 and 1988, 10% of vibrio illnesses occurring in Florida were due to *G. hollisae* (256). Of these, 62.5% followed ingestion of raw oysters, with development of gastroenteritis or septicemia. The most severe form of gastroenteritis caused by *G. hollisae* was reported in Vietnam in a man presenting with profound hypotension and acute renal failure secondary to hypovolemic shock (292).

Cases of septicemia associated with *G. hollisae* are scarce. The first case was in a 65-year-old male who reported consumption of fried Mississippi River catfish and no history of exposure to saltwater or other seafood consumption (294). This unusual case occurred following consumption of a freshwater fish that had been fried, suggesting that incomplete cooking or recontamination of the fish occurred. An additional case of foodborne septicemia was associated with dried and salted fish that had been obtained from a Southeast Asian food store and eaten uncooked (295). The first case of gastroenteritis and bacteremia reported in Europe was associated with consumption of cockles in France (296), whereas a severe case of gastroenteritis and hepatitis occurred in the Mediterranean area in 2009 after consumption of raw oysters (297). It is noteworthy that of the four cases of septicemia reported, three occurred in patients with underlying liver disease.

Characteristics of Disease

Symptoms of gastroenteritis caused by *G. hollisae* are similar to those caused by *V. cholerae* non-O1/non-O139 (293) and typically include severe abdominal cramping, vomiting, fever, and watery diarrhea (288).

The period of hospitalization, if needed, ranges between 2 and 9 days, and most patients recover with antibiotics like ciprofloxacin (296) or tobramycin and cefamandole for septicemic cases (294). One fatal case due to complications such as encephalopathy and sepsis by *Cryptococcus neoformans* was reported (293). There is no evidence of seasonality-associated infections, and most cases are in healthy individuals, whereas underlying disease appears to be the norm for septicemic cases (288, 293).

Virulence Mechanisms

G. hollisae produces a number of toxins and also invades host epithelial cells (298, 299), indicating that its pathogenicity may be multifactorial. These features are consistent with septicemia, which is an invasive disease, as observed in some patients (294). A hemolysin that is related to the TDH of *V. parahaemolyticus* was characterized in *G. hollisae* (299, 300). The two toxins seem to have similar lethal toxicities in mice, although different lytic activities on erythrocytes from various animals have been described (299). It has been reported that all strains of *G. hollisae* carry the *tdh* gene, which is phylogenetically distant from and dissimilar in prevalence to homologous genes in other vibrios (301). An extracellular enterotoxin which is structurally and functionally different from cholera toxin or the heat-labile toxin of *Escherichia coli* and which elongates CHO cells and causes fluid accumulation in mice has also been characterized (302). In response to iron limitation, *G. hollisae* produces aerobactin as a major siderophore, which may play a role in the ability of this species to cause infection (303). In one of the bacteremia cases, the patient had improperly dosed himself with ferrous sulfate as a supplement for chronic anemia, and such treatment may have exacerbated the disease process.

V. MIMICUS

Given its peculiar biochemical characteristics (no sucrose fermentation), *V. mimicus* was initially believed to be an atypical *V. cholerae* non-O1/non-O139 strain responsible for gastroenteritis and ear infections. Only in the early 1980s was it recognized as a new pathogenic species of the genus *Vibrio* (304). The differences in biochemical metabolism between *V. mimicus* and *V. cholerae* are mainly caused by gene deletion (305). The absence of sucrose fermentation is associated with the loss of genes coding for a sucrose-6-phosphate dehydrogenase and a fructokinase; the different lipase reactions and the negative Voges-Proskauer test for *V. mimicus* are also due to the absence of a lipase and an acetolactate synthase, respectively (305).

V. mimicus relies on a few virulence factors that are either acquired by horizontal gene transfer from other vibrios (306) or species specific. Based on whole-genome sequencing, *V. mimicus* shares almost 64% of its genome with *V. cholerae*, including genes coding for hemolysins and Ctx (cholera toxin) as well as toxin-coregulated pilus pathogenicity islands, which are responsible for the similar pathogenicity observed in *V. mimicus* and *V. cholerae* (305). *V. mimicus* strains carrying the genes encoding the cholera toxin (*ctxAB*) may produce Ctxlike enterotoxins and cause severe watery diarrhea.

The most important virulence factor of *V. mimicus* is a heat-labile hemolysin designated *V. mimicus* hemolysin (VMH) (307). The gene encoding VMH is ubiquitous in clinical and environmental isolates, and this protein is responsible for fluid accumulation in the gut (similar to cholera enterotoxic activity) with consequent severe diarrhea, abdominal pain, and fever (308). The *V. mimicus* protease is another extracellular product that has no enterotoxic activity of its own but has been proven to modulate the activity of VMH and/or its precursor, pre-VMH, through limited proteolysis (309). Recently, a third virulence-associated protein was detected in a *V. mimicus* isolate from brackish water. This protease is an enzyme similar to trypsin and is able to activate pro-VMH to its mature form, VMH (310).

V. mimicus has been recognized as a cause of gastroenteritis transmitted worldwide by raw oysters, fish, prawns, squid, and crayfish (311). In 2014, the CDC reported 31 cases of vibriosis whose etiological agent was recognized as *V. mimicus*, with a 3% death rate and almost 80% of the cases being of

confirmed foodborne origin (2). *V. mimicus* outbreaks are not frequent, and the largest known foodborne outbreak to date, involving 306 people, was caused by the ingestion of contaminated freshwater fish and seafood in Thailand (312). Recurrent outbreaks took place in Taiwan between 2004 and 2006 (313). The first case of *V. mimicus* infection associated with mass mortality in freshwater catfish was recently reported in China, highlighting the risk of cross-contamination to humans, since catfish are the most widely cultured fish and an important food source in China (314).

V. METSCHNIKOVII

Taxonomically, *V. metschnikovii* was defined as a new species of the genus *Vibrio* in the late 1970s, although it is distinguished from other *Vibrio* species by its inability to produce cytochrome oxidase and to reduce nitrate (315). *V. metschnikovii* is a natural inhabitant of the aquatic environment and has been isolated from marine water, estuarine water, and wastewater, as well as from fish, crabs, oysters, and diseased birds. The largest occurrences were documented in rural communities in Peru, Brazil, South Africa, and Nigeria, with seafood, stream water, and final effluent wastewater likely being the causes of human infection.

Although *V. metschnikovii* is present in a wide range of aquatic products and is associated with human diseases, this species has not been extensively studied, and little published work is available. The first clinically significant isolate of *V. metschnikovii* was recovered in the early 1980s from the bloodstream of a patient suffering from peritonitis, and since then, it has been associated with cases of septicemia, wound infection, diarrhea, pneumonia, and, most recently, severe septic shock and cardiac arrest (316). *V. metschnikovii* can act as both a human enteric pathogen and a wound pathogen, and its prevalence accounted for <1% of vibriosis cases in the United States in 2014 (2).

Recent proteomic studies on the prolonged exposure of *V. metschnikovii* to low temperatures have demonstrated differentially expressed genes coding for outer membrane proteins, proteins involved in energy conversion and metabolism (317), and proteins involved in the modulation of fatty acid composition to control membrane fluidity (30). *V. metschnikovii* seems to be cold adapted, an advantage when temperature downshifts during food processing and storage are encountered. Similarly, *V. metschnikovii* shows a pattern of seasonal abundance different from that of other pathogenic *Vibrio* species, as it can be isolated in cold waters (e.g., the Black Sea and the Russian Far East) during winter months (30, 318).

The exact mechanism of pathogenicity is still not clear, although a few virulence factors have been described. *V. metschnikovii* is able to cause hemolysis of erythrocytes from different animal species, with higher susceptibility being observed in human cells. This phenomenon has been associated with a cytolysin responsible for vascular permeability changes and fluid accumulation in the intestines (319). Various extracellular alkaline serine proteases have been found in *V. metschnikovii* strains as early as the 1980s. For two of these enzymes, kinetic properties and substrate specificity for various human blood coagulation-associated proteins (plasminogen, fibrinogen, and fibrin polymer) have also been demonstrated (320, 321). Although the complete genome of *V. metschnikovii* was sequenced in 2009 (GenBank accession no. NZ_ ACZO01000006.1), most of its proteins are hypothetical, and their potential involvement in pathogenicity is yet to be discovered.

V. METOECUS

As of 2014, one case of confirmed foodborne vibriosis by *V. metoecus* was reported by the CDC (2). *V. metoecus* was first described as a new species, closely related to *V. cholerae*, isolated from a water sample from the Chesapeake Bay estuary (Maryland) in 1998 (322). *V. metoecus* is a ubiquitous inhabitant of coastal marine lagoons (323–325). Recently, phenotypic and biochemical analysis showed that although *V. metoecus* strains resemble *V. cholerae*, they are able to grow using *N*-acetyl-D-galactosamine and D-glucuronic acid as sole carbon sources and are negative for the Voges-Proskauer assay, in contrast to *V. cholerae* (326). While 16S rRNA gene sequencing does not differentiate between the two species, multilocus sequence analysis successfully outlined the phylogenetic relationship of *V.*

metoecus to both *V. cholerae* and *V. mimicus* (326). In an effort to further define differences and similarities among these species, the genomes of clinical and environmental isolates of *V. metoecus* from the United States were recently fully sequenced, together with *V. cholerae* strains originating from the same environmental reservoir (Oyster Pond, MA) (327). Overall, *V. metoecus* shares 84% of its open reading frames with *V. cholerae*, but the major *V. cholerae* virulence factors (cholera toxin and toxincoregulated pilus) are absent from both clinical and environmental *V. metoecus*, confirming the absence of toxigenic strain reports. However, *V. metoecus* carries both the entire *Vibrio* pathogenicity island 1 and the core of pathogenicity island 2, suggesting interspecies movement of pathogenicity islands and evolution of pathogenic variants (327). The occasional presence of pathogenicity islands that originated from pandemic *V. cholerae* might play a role in the virulence at the base of *V. metoecus* vibriosis, although the exact mechanism of infection is still unknown.

We thank James Oliver, Carla Pruzzo, and James B. Kaper, who contributed to the previous edition of this chapter. C.A. acknowledges the support of MINECO (Ministerio de Economía Industria y Competitividad, Spain) (projects AGL2017—87723, AGL2014-58933, and AGL2011-29639) and of Generalitat Valenciana, Spain (project AICO$_2$018-123), which funded the research that generated part of the V. vulnificus *results presented here.*

Cronobacter Species

TAXONOMY AND NATURAL HISTORY OF *CRONOBACTER*

Cronobacter species (formerly known as *Enterobacter sakazakii*) represent a genus of foodborne opportunistic pathogens which are characterized as being Gramnegative, rod-shaped bacteria that are non-spore-forming, facultatively anaerobic, oxidase negative, catalase positive, and motile by means of peritrichous flagella (Fig 14.1). In 1980, Farmer et al. (1) reported results of DNA-DNA hybridization studies and phenotypic observations, which led to redefining a group of previously designated yellow-pigmented *Enterobacter cloacae* strains as a new species called *E. sakazakii*, a name which was chosen in honor of the Japanese microbiologist Riichi Sakazaki (1920–2002). These seminal studies described the *E. sakazakii* species complex as a diverse group of microorganisms that embodied 15 phenotypically distinct biogroups. Subsequently, Iversen et al. in 2006 described a 16th biogroup (2), and the novel genus *Cronobacter* was proposed in 2007 by Iversen et al. (3). The genus was further taxonomically characterized by Iversen et al. (4) using a polyphasic approach that encompassed results from full-length 16S rRNA gene-based sequencing, ribotyping, fluorescent amplified fragment length polymorphism analysis, and DNA-DNA hybridization studies, in addition to phenotypic data to help differentiate strains among the seven species. These data together led to the revision of the taxon and the proposal that *Cronobacter sakazakii* subsp. *malonaticus* be given its own species epithet, *Cronobacter malonaticus*. The genus *Cronobacter* currently consists of seven species, including *C. sakazakii*, *C. malonaticus*, *C. turicensis*, *C. muytjensii*, *C. dublinensis*, *C. universalis*, and *C. condimenti* (4, 5).

The ability to reliably and specifically detect and identify *Cronobacter* species and differentiate them from phylogenetically related members of the *Enterobacteriaceae*, which may occupy similar econiches and foods, would contribute immensely toward reducing health risks for at-risk individuals. This chapter summarizes the current taxonomy, epidemiology, and laboratory-based approaches that can be used to detect, characterize, and trace this important human pathogen.

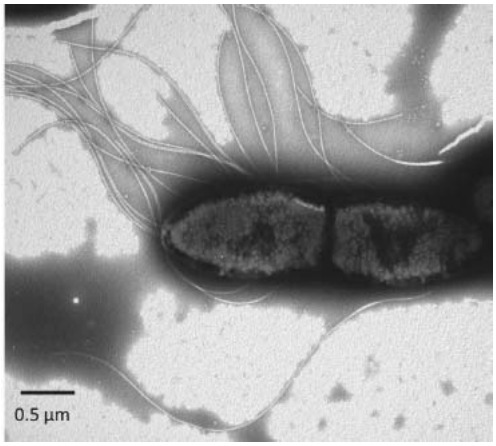

Figure 14.1 Transmission electron photomicrograph of *C. sakazakii* strain BAA-894 negatively stained with 0.5% sodium phosphotungstate (pH 6.8) showing numerous peritrichous flagella. Bar, 0.5 µm.

Epidemiology and Related Public Health Trends

The notoriety of *Cronobacter* was elevated to a global public health concern when contamination of powdered infant formula (PIF) was linked to several neonatal meningitis outbreaks (6). Though historically, PIF was thought to be the source of the infections, it is clear now that contamination of reconstituted, temperature-abused PIF can occur intrinsically and extrinsically, although the main reservoir(s) and routes(s) of contamination have yet to be determined. Except for *C. condimenti*, all species of *Cronobacter* have been isolated from clinical specimens, and currently, *C. sakazakii*, *C. malonaticus*, and *C. turicensis* are the primary human pathogens of interest.

These pathogens cause infantile necrotizing enterocolitis (NEC), septicemia, and meningitis and have mortality rates which have been reported to be as high as 80%, posing a serious threat to neonates, particularly those that present as underweight and are immunocompromised. Because PIF is not manufactured as a sterile product, it poses a significant risk if the product is reconstituted and handled inappropriately. The consensus is that the most likely cause of some of these infections may be poor personal hygiene practices of those involved in PIF preparation. However, Jason (7) recently reported that 7 of 82 (8%) infants surveyed between 1958 and 2010 became ill with invasive disease (defined here as a confirmed culture-positive case of septicemia or meningitis) after ingesting breast milk exclusively (without supplementation with PIF or powdered human milk fortifiers) prior to illness onset. To emphasize this point, Bowen et al. (8) recently reported an infantile case of septicemia and meningitis where the child consumed pasteurized donated human milk and expressed maternal milk (EMM) during the first week after birth. Thereafter, the infant received EMM mixed with a commercial liquid human milk fortifier. The infant did not receive PIF products. Maternal milk was expressed using a dedicated bedside hospital breast pump and the mother's personal breast pump throughout the infant's hospitalization and subsequent home care. *C. sakazakii* was subsequently cultured from the valves of the personal breast pump, frozen EMM samples, and the drain of the kitchen sink at the infant's home. It is thought that the breast pump kit became contaminated and was not adequately cleaned or sanitized, leading to contamination of the milk expressed with this pump kit. Since then, the CDC has developed guidance to optimize breast pump hygiene practices (https://www.cdc.gov/healthywater/hygiene/healthychildcare/infantfeeding/breastpump.html).

As mentioned above, neonates and infants are particularly vulnerable to invasive *Cronobacter* infection; and from the onset of symptoms, death can occur within hours. Recovery from these infections often progresses to lifelong chronic neurological sequelae, such as hydrocephalus, permanent neurological damage, and mental disabilities, which result in later developmental challenges or early death (9).

Until recently, *Cronobacter* was thought to be only a neonatal pathogen. A current trend that has been observed is that more full-term infants leave the hospital only to return with an invasive disease caused by a *Cronobacter* infection. Thus, of primary pediatric concern is that *Cronobacter* causes three types of disease: NEC, septicemia, and meningitis.

Necrotizing Enterocolitis

NEC is the most common inflammatory intestinal disorder observed in neonates, especially in preterm infants with very low birth weights (VLBW; defined as a weight at birth of <1,500 g). Although the exact etiology of NEC remains to be determined, multiple risk factors have been implicated in the pathogenesis of the disease. For example, prematurity (birth at less than 36 weeks of gestation), a history of formula feeding, and underdeveloped microbial colonization of the gastrointestinal tract have been identified as risk factors (10–13). The incidence rate of NEC in VLBW infants has somewhat stabilized over the years, and this disease is currently observed in approximately 5 to 7% of all patients Admitted to neonatal intensive care units (14). Even though NEC has been associated with *Cronobacter* species, to date no single pathogen has been identified as being more involved in pathogenesis than any other (14).

The sequence of events leading to infantile NEC can rapidly evolve over a short span of time (within 6 h) and is complex; damage to the intestinal epithelium is believed to involve weakening of the intestinal barrier by unknown perinatal insults, possibly secreted lipopolysaccharide (LPS), followed by colonization of the luminal epithelial surface and translocation across the weakened epithelium. An "out-of-control" inflammatory response ensues, and exacerbation of the gut barrier damage by host inflammatory factors is thought to lead to the intensive cycle of inflammation-inflicted epithelial damage (13, 15). Infantile disease, mortality, and morbidity vary with the degree of mucosal damage, and pathology can range from mild to severe, affecting both the large and small bowel. Often with newborns, the formation of gas cysts within the bowel wall (called pneumatosis intestinalis) occurs. Pneumatosis intestinalis is considered diagnostic for NEC, and the gas within the cysts is produced as a result of bacterial colonization and metabolism within the cysts. Typically, this is followed by intestinal ischemia, which leads to sepsis, peritonitis, disseminated intravascular coagulation, shock, and death in more severe cases (15). Grishin et al. (13) suggest that nitric oxide (NO), produced by inducible NO synthase (iNOS), and subsequent oxidation of its physiological intermediates play a prominent role in the intestinal barrier damage by inducing enterocyte apoptosis and inhibiting epithelial compensation processes, such as enterocyte proliferation and migration. The factors that govern iNOS upregulation in the intestine are not well understood, a feature that has also hampered efforts in developing NO/iNOS-targeted therapies. However, microbiome studies of hospital-associated outbreaks of NEC reveal an infectious nature of this disease (15, 16). A NEClike disease was observed and described by Hunter et al. (16) using a rat pup infection model. In these studies, exposure to *C. muytjensii* induced apoptosis and caused an increase in the production of interleukin 6 (IL-6) within IEC-6 tissue culture cells and in the rat pup infection animal model, which were hallmarks of the experimental infection. These data suggest that *C. muytjensii* induced NEC and triggered intestinal disease by modulating enterocyte intracellular signaling pathways. However, these animal studies also revealed that the induction of NEC may be related to unknown properties of specific strains rather than a *Cronobacter* species. Nonetheless, a greater understanding of the infectious nature and host response involved in NEC is warranted, but this will require extensive microbiological experiments, genome-wide analysis of bacterial virulence factors, and bacterial and host transcriptomic studies.

Septicemia

It is thought that after successful intestinal colonization by *Cronobacter* species (see the description of adherence factors in "Virulence Factors" below), the pathogen invades the intestinal epithelial cells in a process (either by active adherence and invasion of epithelial cells or via NEC, as described above) that progresses with the pathogen translocating across the intestinal tissue layers to enter the systemic circulatory system, resulting in an extraintestinal infection, such as sepsis or meningitis (17). Much of what is known about this process comes from extrapolating data from adherence and invasion studies using intestinal and immune tissue culture cell lines. Singamsetty et al. (17) suggested that human brain microvascular endothelial cells (HBMECs) are most susceptible to *Cronobacter* invasion, after demonstrating a higher invasion frequency in HBMECs than in endothelial and epithelial cells from different tissues. Townsend et al. (18) determined that *Cronobacter* invasion within HBMECs was strain dependent, and there was no direct correlation between attachment and invasion rates for intestinally derived Caco-2 cells. However, Kim and Loessner (19) reported that *Cronobacter* invasion of Caco-2 cells was accomplished by an active process that needed *de novo* protein synthesis and depended on exposure time and multiplicity of infection. Recently, Giri et al. (20) also determined that *Cronobacter* isolates could undergo transcytosis across tight monolayers of Caco-2 cells and HBMECs, thus mimicking the *in vivo* ability to cross the intestine and subsequently the blood-brain barrier (BBB) to cause meningitis. In addition, the rate of transcytosis of some strains was equivalent to that of the control meningitis-causing *Escherichia coli* K1 strain; however, this rate varied significantly among isolates.

Most pathogenic bacteria that enter a host cell typically manipulate the cytoskeleton of the host cell either through the secretion of effector molecules or by interfering with various phosphorylation cascades that are associated with the intracellular signal transduction pathways (18, 20–22). Adherence and invasion studies (18, 19, 22) clearly revealed that *Cronobacter* exploits host

cytoskeleton elements such as microfilaments and microtubules to invade host cells. Actin microfilaments are the best-known structures involved in this process. This was supported by the fact that treating intestinally derived INT-407 cells, Caco-2 cells, and HBMECs with the actin-depolymerizing agent cytochalasin D completely blocked invasion by *C. sakazakii* (17, 20, 23). It is also thought that *C. sakazakii* invasion of HBMECs involves participation of distinct signal transduction processes in which the phosphatidylinositol 3-kinase (PI3K)–Akt signaling pathway also plays an essential role in initiating the rearrangement of actin filaments followed by bacterial internalization (18, 20, 24). Liu et al. (24) determined that host cytosolic phospholipase A2a is a downstream effector of PI3K-Akt signaling, required for actin reorganization in HBMECs elicited by *C. sakazakii*. In contrast, it was shown that *Cronobacter* severely impaired the phosphorylation of p38, extracellular-signal-regulated kinase 1/2, and c-Jun N-terminal kinase, which are major components of the mitogen-activated protein kinase (MAPK) pathway, and prevented the activation and maturation of dendritic cells by disarming the MAPK pathway, a process that may aid the pathogen in evading the immune system (22).

Meningitis

Meningitis caused by Gram-negative bacteria was first described in the 1940s as a likely cause of mortality and morbidity throughout the world despite advances in antimicrobial chemotherapy and supportive care. *Cronobacter* species are well-known etiological agents of nosocomial meningitis, especially in the neonatal intensive care unit setting. However, its tropism for the central nervous system in neonates and infants still remains a mystery. Our general lack of knowledge about the pathogenesis of meningitis has also contributed to the high mortality and morbidity rates (as high as 80%, as mentioned above) that are seen in infants infected with *Cronobacter*. Meningitis often results in ventriculitis, brain abscess, or cyst formation, as well as late development of hydrocephalus, requiring ventricular peritoneal shunting (25, 26). This disease process has an extremely poor clinical outcome, with a current estimated mortality rate of 42% (27). It usually manifests in infants that are born at full gestational age, and it occurs in the first few days of life (28, 29). Mortality and morbidity associated with *Cronobacter* meningitis are high, and virtually all patients recovering from the central nervous system infection suffered mental and physical developmental delays. Some information describing some of the mechanisms involved in meningitis has come from *in vitro* studies. *Cronobacter* can exploit dendritic cells, and they can persist within human macrophages, enabling them to avoid the host's immune response to reach and penetrate the BBB (19, 22, 30).

In general, pathogens that cause bacterial infantile meningitis and their antimicrobial susceptibilities have changed dramatically in the era of increasing antimicrobial resistance, so use of conjugated vaccines and maternal antibiotic prophylaxis is applicable for pathogens such as group B *Streptococcus*. The outcome of *Cronobacter* meningitis has improved with the availability of the third-generation cephalosporins. However, continued surveillance is warranted, because antimicrobial resistance will continue to provide challenges for clinicians.

Friedemann (28) has summarized the epidemiology of invasive neonatal *Cronobacter* infections between 2000 and 2008. She reported that the overall lethality of 67 invasive infections was 26.9%, whereas the lethality of *Cronobacter* meningitis, bacteremia, and NEC combined was 41.9%. Her report revealed some interesting trends. For example, included as significant factors were the following: (i) a higher gestational age at birth is an important factor which lowers the risk of infection; (ii) having parentage not from Europe leads to a higher probability of reporting neonatal *Cronobacter* meningitis; and (iii) neonates with *Cronobacter* meningitis not originating from North America have a higher risk for a lethal outcome than those with other neonatal *Cronobacter* infections. Also, her study confirmed that neonatal *Cronobacter* infections are mainly associated with the contamination of infant formula and of the relevant cleaning and preparation equipment. However, she also noted 11 neonatal *Cronobacter* infections that were not associated with consumption of contaminated infant formula.

Adult Infections

Cronobacter is also known to cause infections in adults, most notably in elderly and immunocompromised individuals (27, 31–34). For example, recent surveillance data from the United States revealed that there is a higher percentage of *Cronobacter* infections in adults than are reported in infants, even though greater invasive disease or more severe disease and higher mortalities occur in the latter group (31). Adults usually present clinically with extraintestinal infections such as urinary tract (urosepsis) and wound infections, as well as cases of septicemia, osteomyelitis, and pneumonia. Most adult cases are nosocomial in origin (26).

Cronobacter Associated with Foods and Other Natural Habitats: Strategies for Survival, Persistence, and Virulence

Cronobacter species are considerably more widespread than was once thought, and as mentioned previously, besides PIFs and follow-up formulas (FUFs), they have been associated with many low-water-activity (a_w) foods and environments, such as milk protein products, cereals, cheeses (and cheese powders), licorice, candies, spices, teas, nuts, herbs, ready-to-eat foods (such as pastas), and a variety of vegetables, as well as filth, stable flies, PIF and milk powder production facilities, and household environments (35–37). *Cronobacter* can survive in conditions of extreme desiccation (high osmotic stress), such as low-a_w foods, and this property is thought to influence its environmental persistence in PIF and FUF manufacturing facilities and in other dried products and desiccated environments (38, 39). The primary response to highosmotic-stress environments (such as low-a_w foods) involves the rapid accumulation of certain electrolytes (potassium [K^+], trehalose, and glutamate) to increase the cell's internal osmotic pressure, thus counteracting the high external osmolar conditions. When a cell internalizes elevated potassium concentrations, glutamate also is involved. Together, these molecules act as temporary osmoprotectants. The principal compatible solutes accumulated by *Cronobacter* under osmotically stressful environments include glycine betaine, proline, carnitine, and trehalose. For more information about the osmotic response, see the article by Feeney and Sleator (40).

It is now thought that the widespread occurrence of *Cronobacter* and its resistance to desiccation are factors contributing to the commercial distribution of contaminated low-a_w foods (if proper surveillance is not maintained), which pose a risk to susceptible consumers and widen the scope of public health concerns (41, 42). It is likely that a detailed understanding of the *C. sakazakii* osmotolerance response will eventually lead to more effective control measures to limit survival and growth of *C. sakazakii* in low-a_w products, such as PIF.

The ability of *Cronobacter* species, as is the case for any microorganism, to withstand the harmful effects of exposure to different environmental stresses is crucial for their survival, persistence, and virulence. Besides the ability to tolerate osmotic stress, *Cronobacter* spp. have also adapted quite well to exposure to high-growth-temperature conditions (43). For example, Williams et al. (44) identified a biomarker in heat-tolerant *Cronobacter* strains that Edelson-Mammel and Buchanan (43) determined was highly heat resistant. The protein was determined to be a hypothetical protein found in the thermotolerant bacterium *Methylobacillus flagellatus* KT. Gajdosova et al. (45) described an 18-kbp region that contained a cluster of genes, including that for the hypothetical protein found by Williams et al., that had significant homology with other known bacterial gene clusters encoding proteins involved in some type of stress response, including heat, oxidation, and acid stress. However, not every strain that possesses a thermotolerant phenotype has this gene cluster (46), suggesting that another molecular mechanism involving thermotolerance exists. Many studies have revealed that *Cronobacter* species can grow in environments with low pH levels (pH 3.9 to 4.5) and are somewhat more acid tolerant than most other related enteric pathogens (47). However, more information is needed to fully understand how *Cronobacter* species can survive under these stressful growth conditions and whether multiple commercially available treatment regimens can be used to successfully prevent growth in ready-to-eat foods and PIF. A study by Jang and Rhee (48) revealed an inhibitory effect when caprylic acid and mild heat were combined to reduce *Cronobacter* growth in reconstituted PIF. The combined treatment resulted in a "synergistic effect," in which *Cronobacter* populations were reduced much

more rapidly with increased temperatures and concentrations of caprylic acid. Besides providing an understanding of the mode of action of caprylic acid (damage to the bacterial cell wall), these data also reveal that the addition of this natural antimicrobial agent to infant formula may have potential use for controlling this pathogen prior to consumption. The investigation of how *Cronobacter* persists under conditions of osmotic, thermal, and acidic stress is still in its infancy, but it holds the key to controlling this foodborne pathogen within the food manufacturing environment.

There are a few reports revealing that *Cronobacter* is a member of the human intestinal tract flora and may be carried in the intestinal tracts of healthy adults and neonates (41, 42). However, more epidemiologic information is needed to understand its role as a member of the gut microflora and to determine whether its presence represents transient colonization or other host associations. Also, more information regarding its association with the postpartum intestinal microbiota is needed. Lastly, surveillance studies using species-specific identification schemes that include at least results of species-specific PCR assays or at best species identities obtained from whole-genome sequencing (WGS) studies are needed so that a clearer epidemiologic picture can be obtained as to which *Cronobacter* species are responsible for which infections (49–52).

ISOLATION AND DETECTION METHODS

Microbiological Detection and Isolation Procedures

Early culture methods for the detection and isolation of *Cronobacter* from foods, specifically PIF, were developed by Muytjens et al. (53). Each sample was dissolved in buffered peptone water held at 45°C for 5 min until the PIF was dissolved. After overnight incubation at 36°C, a 10-ml volume of the culture was withdrawn from each flask and transferred to 90 ml of *Enterobacteriaceae* enrichment broth. After another overnight incubation, 1 ml of each broth culture was mixed with 20 ml of molten violet red-bile glucose agar (VRBGA) in duplicate and was solidified. The cultures were incubated overnight at 36°C. Suspected colonies were then isolated and identified using an API 20E biochemical test strip and other phenotypic observations, i.e., the production of yellow colonies on nutrient agar after incubation for 48 h at 25°C, the production of extracellular DNase on toluidine blue agar after 6 days at 36°C, and a positive α-glucosidase reaction after 4 h (53, 54). Noted findings from this study were the facts that 52.5% of 141 PIFs, obtained from 35 countries, were contaminated and that the contamination level was low (<1 CFU/g in any product). Since the introduction of this groundbreaking method, other methods utilizing PCR, improved selective enrichment broths and selective agars (such as *Cronobacter* screening broth and chromogenic agars), and more accurate microbial identification schemes (such as the automated Vitek 2 system) have been described.

An example of one of the newer protocols is the International Organization for Standardization (ISO) method published as a technical standard protocol, known as ISO 22964:2017, for the detection of *Cronobacter* species in food products for humans and animal feeds and in environmental samples, which has also gone through a validation study using a 15-laboratory horizontal method for the detection of *Cronobacter* spp. (https://www.iso.org/standard/64708.html). This method, which technically revises an earlier protocol, ISO/TS 22964:2006, in addition to PIF now includes all food products for humans and feeds for animals as well as environmental samples. Other changes include replacing the selective enrichment broth, modified lauryl sulfate tryptose broth, with *Cronobacter* selective broth (55) and the isolation agar, *E. sakazakii* isolation agar (which is a formulation of Druggan-Forsythe-Iversen [DFI]) agar), with chromogenic *Cronobacter* isolation agar.

The U.S. Food and Drug Administration (FDA) established two culture-based methods for the detection and isolation of *Cronobacter* species. The first method was similar to that described by Muytjens et al. (53) and has been since replaced with a revised method (Fig 14.2) utilizing only a buffered peptone water enrichment followed by a real-time PCR assay that incorporated an internal amplification control for rapid screening of products (http://www.fda.gov/Food/FoodScienceResearch/LaboratoryMethods/ucm289378.htm). The revised FDA method utilizes a real-time *Cronobacter* PCR assay designed to detect the partial macromolecular

synthesis operon, consisting of the 3′ end of *rpsU* and the 5′ end of *dnaG* (56). This revised method also replaced VRBGA with two chromogenic agars, DFI agar (synonymous with Brilliance *E. sakazakii* agar) and *E. sakazakii* plating medium, developed by Restaino et al. (55, 57). Both ISO 22964:2017 and the revised FDA method are currently accepted as reference methods for the detection and identification of *Cronobacter* species from foods, feeds, and environmental samples.

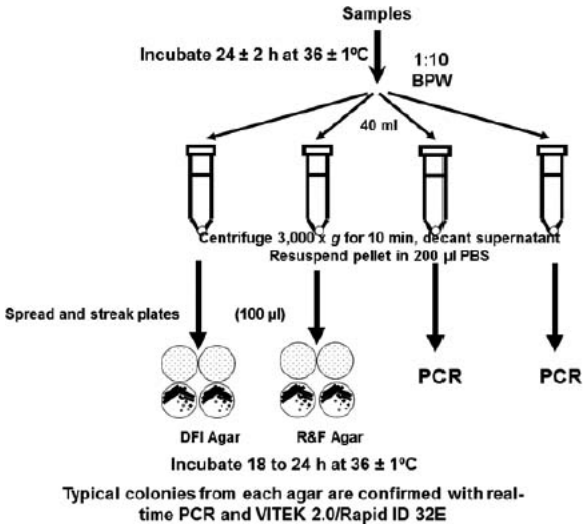

Figure 14.2 Revised FDA *Cronobacter* isolation and detection method, adapted from chapter 29 of the Bacteriological Analytical Manual (https://www.fda.gov/Food/FoodScienceResearch/LaboratoryMethods/ucm289378.htm). BPW, buffered peptone water; PBS, phosphate-buffered saline; R&F, *Enterobacter sakazakii* plating medium.

Alternative Detection and Isolation Procedures

Mullane et al. (58) described in 2006 a protocol utilizing paramagnetic beads in a novel capture system called Pathatrix, which had undergone precollaborative validation studies. The principle behind Pathatrix includes the use of positively charged magnetic beads, which electrostatically attract the negatively charged LPS on the surface of *Cronobacter* cells (and Gram-negative bacteria in general) as the enrichment broth is circulated over a magnet using a peristaltic pump. This method requires a short enrichment period (6 to 8 h, using buffered peptone water and an incubation temperature of 42°C), followed by capture of the bacteria and subsequent identification after plating onto DFI agar. All presumptive *Cronobacter* colonies were confirmed by using the qPCR procedure described by Seo and Brackett (56). The protocol could detect between 1 and 5 CFU in 500 g of PIF in less than 24 h, and a sample-pooling strategy was found to be useful.

Song et al. (59) described another alternative detection and isolation procedure that includes a fluorescence-based liposome immunoassay that was developed as a sensitive and rapid diagnostic system for detection of *C. muytjensii* in broth cultures. This research group further developed other liposome-based detection assays to be used in an indirect noncompetitive enzyme-linked immunosorbent assay (ELISA) for the detection of *Cronobacter* in PIF (60) and in combination with magnetic beads (61). Finally, an immunochromatographic strip assay which combined antibodies and liposomes with the immunochromatographic strip to detect *C. sakazakii* in enrichment cultures has also been described by this research group (62).

ELISA technology has also been applied commercially in the Vitek immunodiagnostic assay system (known as VIDAS; bioMerieux, Marcy l'Etoile, France) for the detection of enterotoxins of several foodborne pathogens, including *Salmonella* species, *E. coli* O157:H7, *Listeria* species, *Campylobacter jejuni*, and *Staphylococcus* species. Kits for *Cronobacter* species detection have been developed (63).

Trinh et al. (64) described a "lab-on-a-chip" device (or flow cell) that was designed to conduct PCR assays that detected *E. coli* O157:H7 and *C. condimenti* in broth cultures. The lab-on-a-chip PCR device

could successfully detect these pathogens by amplifying nucleotide regions of the *E. coli* O157:H7 Shiga toxin and *C. condimenti rpoB* genes (50). The levels of detection for each DNA target were 1 ng/µl and 3 ng/µl, respectively, and the test could be accomplished within 25 minutes. This highly portable system has the potential to enable PCR-based investigations of *Cronobacter* infections as well as many other diseases quickly and accurately.

MOLECULAR GENUS AND SPECIES IDENTIFICATION AND SUBTYPING CHARACTERIZATION METHODS

Iversen et al. (4) and others (49, 65, 66) observed that phenotypic assays as well as 16S rRNA gene analysis could not identify some *Cronobacter* isolates to the species level. Table 14.1. summarizes the phenotypic assays used to typically identify members of the *Cronobacter* species complex and differentiate them from phylogenetically related species. This is the case for many medically important pathogens and has led to the use of DNAbased detection methods, particularly conventional and real-time PCR assays, which now have become routine laboratory procedures to detect and identify foodborne pathogens from foods, including foods contaminated with *Cronobacter* species. Typically, these assays are designed to target unique pathogen-specific genes. Several studies describing a variety of genes used in such assays have been published. Yan et al. (67) provided a summary of common gene targets that have been useful for the detection of *Cronobacter* spp. using PCR-based methods. These gene targets include 16S rRNA genes, the 1,6-α-glucosidase gene (*gluA*), the macromolecular synthesis gene (*dnaG*), a gene encoding zinc-containing metalloprotease (*zpx*), and *ompA*. Many of these were designed prior to the reclassification of the genus, i.e., when *Cronobacter* species were one species, *E. sakazakii*.

Additionally, Ye et al. (68) compared the efficacy of several of these PCR assays, which target the 16S-23S rRNA gene internal transcribed spacer (ITS) region, *ompA*, and *gluA*, with the ISO method for detecting *Cronobacter* in 243 commercial infant formula samples. Twelve samples were positive for *Cronobacter* by all PCR assays used. Only 10 of the samples were positive by the ISO method, and all 10 were positive by all PCR assays. In contrast, four false-positive results were generated with the ITS region PCR assay and one false-positive result was found using the *ompA* PCR assay, whereas there were two false-negative results with the ISO method. The authors also reported that combining the selective enrichment step(s) with either a duplex PCR assay targeting both the ITS region and *ompA* or targeting *ompA* and *gluA* or a single PCR targeting *gluA* was useful for detecting *Cronobacter* in infant formulas. Similar findings were reported by Jaradat et al. (69). Recently, Li et al. (70) described a real-time (quantitative PCR [qPCR]) assay based on *rpoB* that also detects *Cronobacter* species and used this PCR assay to identify the bacterium in 70 food samples that included 3 dry cereal products, 5 maternal milk samples, and 1 infant food formula sample which were positive by qPCR.

[a] Data are derived from reports by Iversen et al. (3, 4) and Joseph et al. (5). Negative tests should be incubated for 7 days prior to being discarded, unless otherwise indicated. Results for some of the phenotypic reactions, such as those for VP and ornithine decarboxylation, can be obtained directly by using the API 20E strip (bioMerieux, Inc.) and by using reagents according to the manufacturer's instructions. +, 90 to 100% positive; V, 20 to 80% of members of the group are positive; –, 10 to 20% positive.

[b] The Voges-Proskauer test was performed by adding 40% potassium hydroxide in water and 5% 1-naphthol in 95% ethanol to cultures incubated for 24 h at 37°C in methyl red–Voges-Proskauer broth.

[c] The methyl red test was performed by adding the methyl red reagent (0.1 g per 300 ml of 95% ethanol) to cultures grown for 48 h at 37°C in 4 ml of methyl red–Voges-Proskauer broth.

[d] Ornithine decarboxylation is shown by an alkaline reaction according to the API 20E instructions.

[e] Acid production from carbohydrates was tested in phenol red broth base with the addition of filtered-sterilized carbohydrate solution (final concentration of 0.5% in cultures incubated for 24 h at 37°C).

[f] Determined using Kovac's reagent after growth in peptone broth (CM0009; Oxoid) of cultures incubated for 24 h at 37°C. The James reagent used in conjunction with the API 20E strip is an alternative test.

[g] Determined using sodium malonate broth in cultures incubated for 24 h at 37°C.

Another gene that was initially designed as a species-specific target is the zinc metalloprotease gene, *zpx* (71). However, due to the reclassification of the genus, including the reassignment of *Siccibacter turicensis*, *Franconibacter pulveris*, and *Franconibacter helveticus* from the genus *Cronobacter* (72), these gene targets (and PCR assays) are now considered genus-level targets and should be used as such.

Species-Specific Gene Targets

Currently there are two PCR assays widely used to identify *Cronobacter* which are based on species-specific single nucleotide polymorphisms (SNPs) and are associated with *rpoB* (49, 50) and *cgcA* (51). Qiming et al. (73) reported on a PCR assay (utilizing the genes ESA_02130, ESA_02797, and ESA_04347-ESA_04349) that could detect *C. sakazakii* in broth culture (detection levels: 1.3 pg/µl to 135 fg/µl) from artificially contaminated PIF at detection levels of 5.5×10^1 CFU/10 g.

Molecular Serotyping

In most members of the *Enterobacteriaceae*, the LPS Oantigen biosynthesis-encoding gene clusters are flanked by the *galF* and *gnd* genes, which contain 6 to 19 genes and are generally conserved within a species (74). To aid in the characterization of *Cronobacter* strains isolated from foods and PIF manufacturing environments, a harmonized molecular serotyping (LPS) identification scheme was designed by Yan et al. (74), which is based on information obtained from studies by Mullane et al. (75), Jarvis et al. (76, 77), and Sun et al. (78). Yan et al. (74) studied 409 *Cronobacter* isolates representing the seven *Cronobacter* species using the Mullane-Jarvis and Sun molecular serotyping schemes. PCR analysis revealed many overlapping results obtained by the two serotyping schemes. The proposed identification of isolates should be accomplished using the *rpoB* species-specific PCR-based assay that has been widely used and validated for species identification of *Cronobacter* in many surveillance studies (72, 74, 76, 77, 79–87) prior to applying serotype-specific primers. Interestingly, many of the LPS biosynthetic gene loci contained species-specific SNPs which could be used to identify these O antigens (75).

Molecular Subtyping

Molecular subtyping has long been regarded as a useful approach to help investigate outbreaks, identify food sources, and understand the nature of bacteria colonizing ecological niches. Mullane et al. (88) applied pulsed-field gel electrophoresis (PFGE) to characterize and track *Cronobacter* species in a PIF processing facility. Since that study, the PFGE protocol was validated and added to CDC's PulseNet international epidemiological laboratory network system, which compares the DNA fingerprints of bacteria from patients to find clusters of disease that might represent unrecognized outbreaks (89–91). PFGE is commonly considered the gold standard for epidemiologic studies, and PulseNet has added WGS to the surveillance network. Using WGS for molecular subtyping will enhance PulseNet's ability to detect and solve outbreaks faster and with more accuracy (92).

Sequence Typing

The taxonomic scheme proposing seven *Cronobacter* species as described by Iversen et al. (3, 4) has been supported by data from many WGS studies (46, 72, 93–96), and the taxonomic genomic separation of *C. sakazakii* from *C. malonaticus* has been determined by multilocus sequence typing (MLST) (52). Evidence revealing that *C. malonaticus* and *C. sakazakii* are separate species is based on SNPs of two genes, *rpoB* and *cgcA* (49, 51). Currently, a database containing defined sequence types covering all *Cronobacter* species is maintained at Oxford University. The database and MLST analytics can be accessed at www.pubMLST.org/ cronobacter (96). Several studies using MLST have determined the genetic diversity of *Cronobacter* in PIF production facilities (82, 87, 97), in PIF and FUFs (98–100), in retail foods (101–106), and in a variety of other sources (106). Results revealed there is considerable genomic diversity among *Cronobacter* species. Presently, *C. sakazakii* sequence type 4 (ST4) predominates in neonatal meningitis cases. Other sequence types associated with meningitis are *C. sakazakii* ST8 and ST1. Similarly, a large number of ST12 *C. sakazakii* strains have been isolated from infants with NEC. The MLST typing scheme includes more than 55 sequence types of *C. sakazakii*.

Microarray Analysis

Within the first 2 years of publication of the first *Cronobacter* genome, DNA microarrays were being used as tools to study the genomic diversity of members of this genus. Healy et al. (107) used a DNA

microarray With 276 selected genes from the genome of *C. sakazakii* strain BAA-894 to compare it with strains representing six of the seven *Cronobacter* species (*C. condimenti* had not be discovered prior to that study). Their results supported the reclassification scheme proposed by Iversen et al. (4) in which each species was separated into clusters, except that some of the *C. malonaticus* strains grouped within a larger cluster of *C. sakazakii* strains. Other strains formed a subgroup within a larger cluster that also contained *C. turicensis*, *Cronobacter* genomospecies 1 (now identified as *C. universalis*), and an unknown *Cronobacter* species. A subsequent study by Kucerova et al. (93) featured an array that used the entire genome (387,000-probe oligonucleotide tiling DNA microarray) of *C. sakazakii* strain BAA-894 for comparison with strains representing five of the seven *Cronobacter* species. Among the 4,382 annotated genes identified in *C. sakazakii* strain BAA-894, about 55% were common to all *C. sakazakii* isolates and 43% were common to all *Cronobacter* strains. Many of the genes absent in more than half of the strains tested were identified as phage genes, which emphasizes the importance of the mobilome in driving the genomic diversity of *Cronobacter*. Both studies used a common method of analysis which incorporated the use of direct comparisons of gene probe intensities obtained for the different species (strains) to probe intensities of similar genes from the reference strain, *C. sakazakii* BAA-894.

In contrast to the two microarray approaches described above, a more extensive multigenome array approach containing the annotated pangenome of 15 sequenced strains of *Cronobacter*, representing all seven species, was applied by Tall et al. (83) and was based on the design of Jackson et al. (108) for *E. coli*. The sequencing of these genomes was accomplished by a five-member international consortium in 2008–2009 (46, 72, 94, 109). The microarray was a custom-designed Affymetrix array which provided an opportunity to survey specific and unique genes from different *Cronobacter* species and within each species group. Gene homologs across the seven species were represented by the smallest number of probe sets that theoretically covered all alleles of a gene target. The microarray consisted of 19,287 independent genes representing 15 *Cronobacter* genomes and 18 plasmids and 2,371 virulence factor genes of phylogenetically related Gram-negative bacteria. It was determined that the *Cronobacter* microarray could distinguish the seven *Cronobacter* species from one another and from non-*Cronobacter* species; within each species, strains grouped into distinct clusters based on their genomic diversity. These results also supported the phylogenic divergence of the genus and clearly highlighted the genomic diversity in each member of the genus.

Since the initial description of the pangenomic Affymetrix microarray, Yan et al. (63, 82) have identified two phylogenetic lineages among ST4 strains which differed in the number of phage-related genes and genes associated with the pESA3-harbored type 6 secretion system (T6SS) gene cluster. Strains from lineage 1 differed from those in lineage 2 by 24 genes, of which 7 were phage related. DNA microarray analysis also revealed that most of the isolates representing each lineage possessed the 5′ end of the T6SS gene cluster. However, none of the ST4 lineage 1 isolates possessed the *vgrG* gene, encoding a known T6SS effector protein (67), whereas eight of nine ST4 lineage 2 isolates did. Chase et al. (87) also used the pangenomic microarray as well as WGS to comparatively characterize a group of ST83 *C. sakazakii* strains that had persisted in a Swiss PIF manufacturing facility for more than 4 years, with 109 other *C. sakazakii* strains isolated from a variety of sources. The phylogenetic analysis revealed that the pangenomic *Cronobacter* microarray could clearly separate the strains according to species and respective STs, with minor exceptions. These results further substantiate the idea that the microarray and its >19,000 *Cronobacter* genes as captured on the microarray are more resolving than the seven-allele MLST scheme. Figure 14.3 provides an example of a phylogenetic analysis developed by using microarray data.

Whole-Genome Sequencing

WGS of *Cronobacter* species will likely continue to facilitate the identification of unknown microorganisms, and it is hoped that its implementation as a standardized tool will enable the identification and subtyping of all foodborne bacterial pathogens worldwide, thereby replacing traditional methods such as PFGE as a strategy to strengthen preparedness and response, reduce the global social and economic disease burden, and enhance the protection of human health (41, 67, 110,

111). WGS can also provide detailed information regarding unique geno-and phenotypic features of foodborne pathogens involved in outbreaks, such as their repertoire of antibiotic resistance genotypes. WGS analysis of pure culture isolates obtained from clinical microbiology infections has the potential to revolutionize the fields of food safety and public health microbiology. Additionally, metagenomics and other "-omics" disciplines may provide solutions to a cultureless future in clinical microbiology, food safety, and public health. Information mined from WGS data obtained from metagenomics assays can be particularly useful for the identification of clinical causative agents or foodborne contamination and the detection of antimicrobial resistance and/or virulence factor genes, in addition to providing high-resolution subtyping information about pathogens (112).

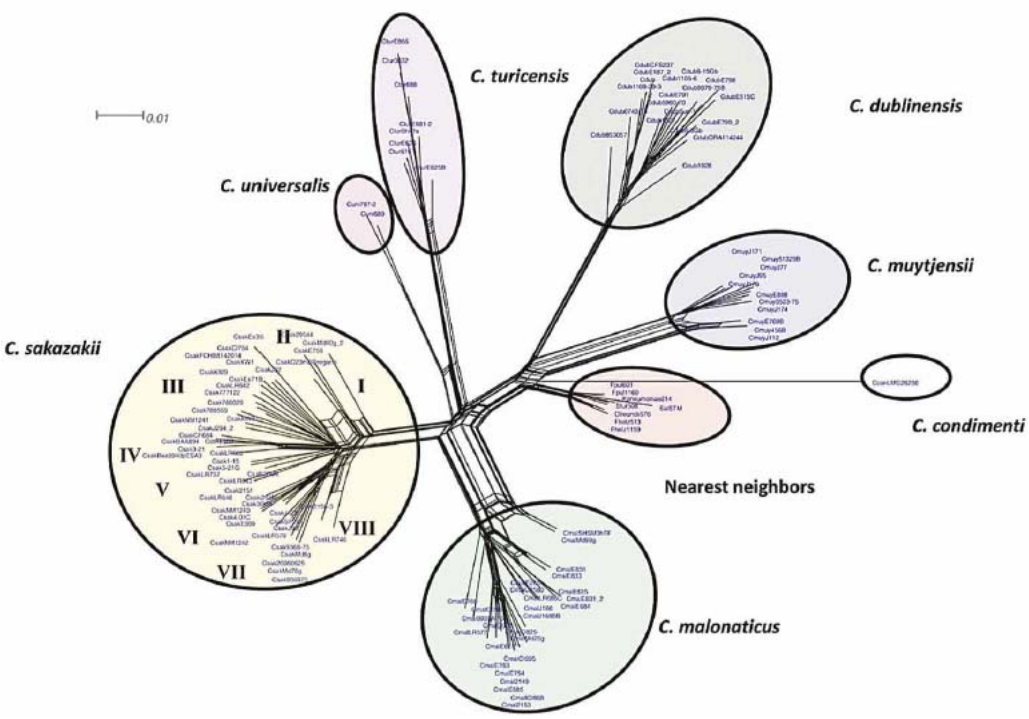

Figure 14.3 Neighbor net (SplitsTree4) analysis of 126 *Cronobacter* and phylogenetically related strains which were generated from the microarray-based gene differences described by Tall et al. (83). The phylogenetic tree illustrates that the *Cronobacter* microarray could clearly separate the seven species of *Cronobacter*, with each species forming its own distinct cluster. *C. sakazakii* subclades are designated with roman numerals I through VII. The scale bar represents 0.01 base substitution per site. Reprinted from reference 83 with permission.

As mentioned above, the first *Cronobacter* species which was sequenced was *C. sakazakii* BAA-894; this was quickly followed by the sequencing of *C. turicensis* strain LMG 23827^T (z3032) (93, 109). There are 174 WGS assemblies currently deposited in the NCBI Genome database for *Cronobacter* (https://www.ncbi.nlm.nih.gov/genome?term=Cronobactercmd=Details Search; accessed 25 September 2017). Table 14.2. summarizes some of the noted genomic features of these genomes from each *Cronobacter* species. An example of a phylogenetic analysis using WGS information is demonstrated in Fig 14.4.

Plasmids

WGS studies have revealed that most *Cronobacter* strains contain plasmids (many possess multiple plasmids), which is consistent with what is known about many other enteric pathogens. One such plasmid group that has been identified is the IncF group of plasmids, which has eight related replicon designations: RepFIA, RepFIB, RepFIC, RepFIV, RepFV, RepFVI, RepFVII, and RepFIIA (79). IncF plasmids range in size from 1 kb to several hundred kilobases and from one copy to several hundred

copies per cell, with some members possessing genes of additional origins of replication, usually RepFIIA. Three highly homologous RepFIB plasmids, pESA3 (131 kb; possessed by *C. sakazakii* BAA-894), pSP291-1 (118 kb; possessed by *C. sakazakii* strain SP291), and pCTU1 (138 kb; possessed by *C. turicensis* strain z3032), contain several putative virulence genes, including two genetic loci encoding iron acquisition systems, namely, an ABC transporter gene cluster and an aerobactin-like or cronobactin siderophore receptor gene cluster, identified as *eitCBAD* and *iucABCD-iutA*, respectively. These genetic components, in addition to the origin of replication gene (defining the incompatibility class; IncFIB or *repA*), together make up a common plasmid backbone. Franco et al. (79) and Grim et al. (81) determined that the *iucABCDiutA* siderophore is the only active siderophore present in *Cronobacter*. Additionally, plasmids pESA3 and pCUNV1 (*C. universalis*) contain a *cpa* (*Cronobacter* plasminogen activator) gene, and plasmid pESA3 also has a 17-kb T6SS locus, whereas plasmid pCTU1 contains a 27-kb region carrying a filamentous-hemagglutinin (FHA)-encoding gene (*fhaB*). The presence of the FHA-specific transporter gene (*fhaC*), of genes for associated putative adhesins (FHA locus), and of *cpa*, T6SS, and FHA loci depends on the species, revealing a strong correlation with the presence of virulence traits, plasmid type, and species. Figure 14.5 demonstrates the sequence homology among pESA3-pSP291-1 and pCTU1-like plasmids.

[a] Values were obtained from data on strains described in NCBI (https://www.ncbi.nlm.nih.gov/genome/genomes/1170; accessed on 9/25/2017) and reference 94.

[b] Values were obtained from only one *C. universalis* and *C. condimenti* strain, as described in NCBI.

[c] Plasmid information was obtained from four *C. sakazakii* strains, as follows: pCSK29544_1p (NZ_CP011048.1/CP011048.1), pCSK29544_2p (NZ_CP011049.1/CP011049.1), and pCSK29544_3p (NZ_CP011050.1/CP011050.1) from *C. sakazakii* strain 29544T; pESA2 (NC_009779.1/CP000784.1) and pESA3 (NC_009780.1/CP000785.1) from strain BAA-894; pSP291-1 (NC_020263.1/CP004092.1); pSP291-2 (NC_020261.1/CP004093.1) and pSP291-3 (NC_020262.1/CP004094.1) from strain SP291; and pCS1 (NZ_CP012254.1/CP012254.1), pCS2 (NZ_CP012255.1/CP012255.1), and pCS3 (NZ_ CP012256.1/CP012256.1) from strain 8155. Plasmid information for *C. condimenti* strain 1330, *C. dublinensis* strain LMG 23823, *C. malonaticus* strain LMG 23826, *C. turicensis* strain z3032, and *C. universalis* was obtained from the following respective accession numbers: NZ_CP012265.1, NZ_CP012267.1, NZ_CP013941.1/CP013941.1 and NZ_CP013942.1/CP013942.1, NC_013283.1/FN543094.1, NC_013284.1/FN543095.1 and NC_013285.1/FN543096.1, and NZ_CP012258.1/CP012258.1 (https://www.ncbi.nlm.nih.gov/genome/plasmids/1170?).

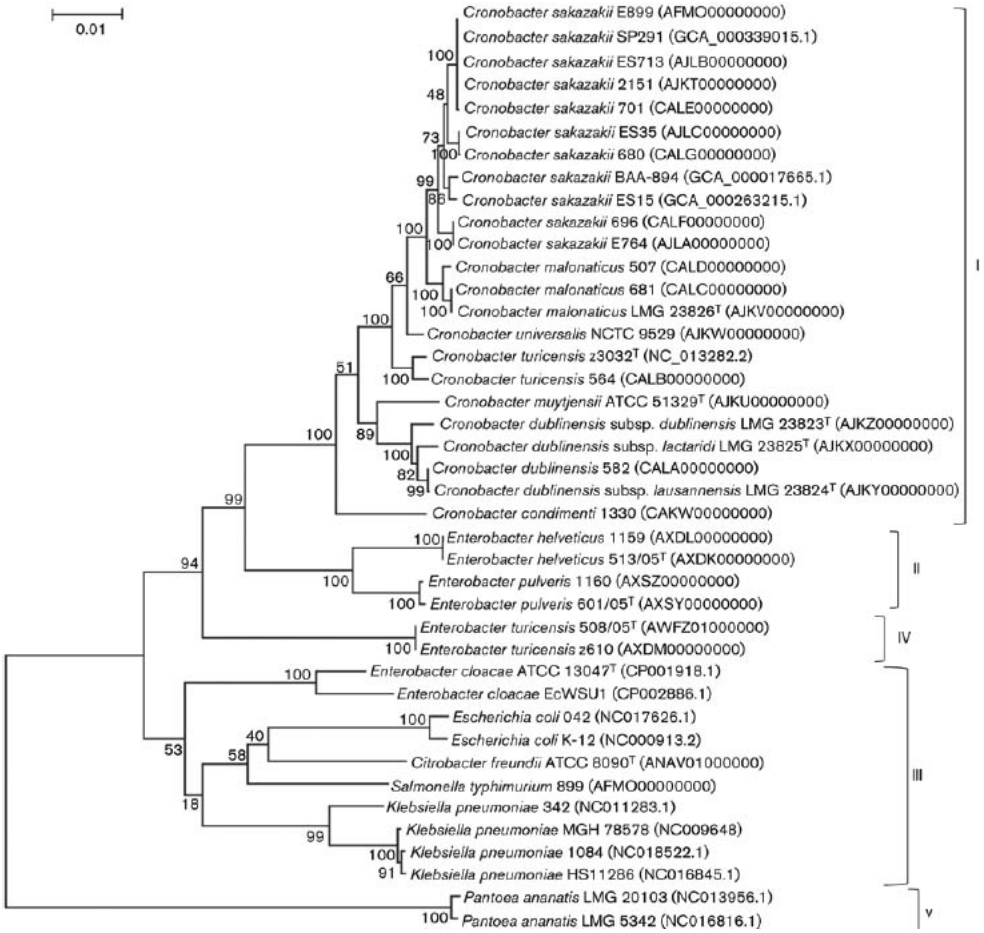

Figure 14.4 Phylogenetic analysis using the neighbor-joining algorithm of 34 *Cronobacter*, 10 *Enterobacter*, and eight *Enterobacter*-related genomes based on the alignment of SNPs from 300 orthologous genes as described by Stephan et al. (72). Clades are represented by roman numerals 1 through V. Clade I represents genomes from *Cronobacter* species. Clade II represents genomes from *F. helveticus* and *F. pulveris* strains. Clade III represents genomes from two *E. cloacae* strains and genomes from *Citrobacter*, *Salmonella*, *Escherichia*, and *Klebsiella* strains. Clade IV represents genomes from *S. turicensis* strains. Lastly, genomes from two *Pantoea* strains are represented in clade V. The scale bar represents 0.05 base substitution per site. Reprinted from reference 72 with permission.

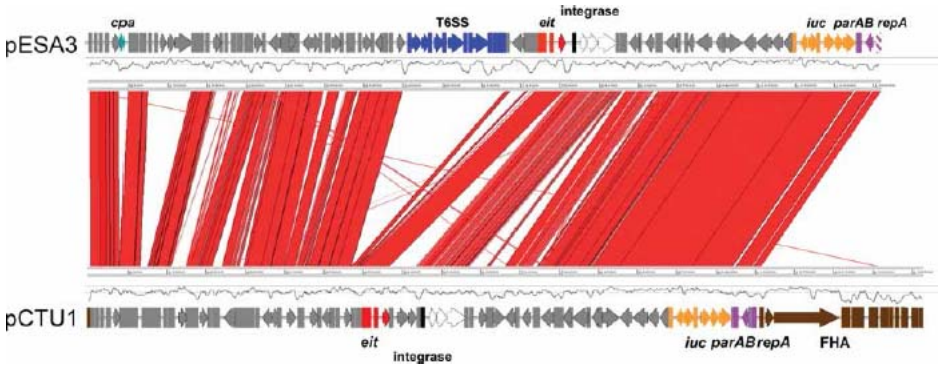

Figure 14.5 Sequence alignment of *Cronobacter* plasmids pESA3 and pCTU1 produced with the Artemis comparison tool as described by Franco et al. (79) and showing regions of homology. In the middle section, the red color indicates significant nucleotide homology, as determined by BLASTn analysis, between pESA3 and pCTU1, and the location on each plasmid, for example, *eit*, *iuc*, *parAB*, and *repA*. White areas indicate regions or loci present on one plasmid and absent on the other, e.g., *cpa*, T6SS genes, and FHA genes. The sequence of pESA3 was modified by rejoining the *repA* gene at the 3′ end, which is split in the GenBank sequence (NCBI RefSeq accession no. NC_009780.1). pESA3 and pCTU1 (NCBI RefSeq accession no. NC_009780.1) possess molecular sizes of 131,196 and 138,339 kb and mean G+C contents of 56.85% and 56.05%, respectively. Selected genes or loci are shown in color as follows: *eit*, red; *iuc*, orange; *parAB* and *repA*, purple; integrase genes, black, and associated genes, white; *cpa*, teal; T6SS genes, blue; and FHA genes, brown. Reproduced from reference 79 with permission.

Other plasmids possessed by many *Cronobacter* species include pCTU2 (*C. turicensis*), pESA2, and pSP291-2 (both possessed by *C. sakazakii*). These plasmids carry a gene cluster responsible for plasmid mobilization and conjugation, which is now considered a T4SS (46, 79, 93, 95, 109). These plasmids contain an IncF2 (incompatibility class) origin of replication site (*repA*). Lastly, another group of plasmids that are represented by plasmid pCTU3 (*C. turicensis*) and pSP291-3 (*C. sakazakii*) possess an IncH1-like origin of a replication gene (incompatibility class). Little is known about this Inc class of *Cronobacter* plasmids except that they possess genes encoding heavy metal resistance. Table 14.2. also describes these plasmids and others which have been identified from closed genomes.

It is interesting to speculate that these heavy metal resistance genes are remnants from when the hypothetical ancestral *Cronobacter* was evolving during the Paleogene geologic period (which occurred approximately 59 million years ago) of the Cenozoic era, when early modern plants appeared and the grassland plants continued to evolve, as proposed by Schmid et al. (113) and Joseph et al. (66). Table 14.3. shows the prevalence and distribution of pESA3 targets which have been identified among 800 strains of *Cronobacter* obtained from diverse food, environmental, and clinical sources throughout the world.

CRISPR-*cas* Subtyping System

In 2016, Ogrodzki and Forsythe (114) described a clustered regularly interspaced short palindromic repeat (CRISPR)-*cas* profiling system for C. *sakazakii*. In general, CRISPR-*cas* systems comprise three genetic components: a *cas* gene cluster and an AT-rich leader sequence, followed by a CRISPR spacer array composed of short (~24-to 48-nucleotide) direct repeat sequences separated by similarly sized, unique spacers which are usually derived from mobile genetic elements such as bacteriophage and plasmids (114). It is thought that CRISPR-*cas* systems provide for a type of adaptive immunity from invasive genetic elements (phages and plasmids), functioning to regulate lysogeny and biofilm formation. It has been determined that the variability of a CRISPR array can provide a greater power of differentiation for genotyping within clonal lineages than other molecular assays such as PFGE (114). This information can also be applied for source attribution of isolates from clinical cases through food sources to a production site. Zeng et al. (115) used CRISPR-*cas* analysis to reveal that prophages

contributed to approximately 16.6% of the genetic diversity of *C. sakazakii* and determined that the gain or loss of prophages and spacers that are associated with CRISPR loci has frequently played a role in the evolution of *C. sakazakii*.

Table 14.3 Plasmidotype patterns observed for 801 *Cronobacter* isolates representative of the seven *Cronobacter* spp.

						No. (%[a]) of isolates with the indicated plasmidotype									
Species	No. of isolates	*repA*	*cpa*	Δ*cpa*	IntL	*vgrG*	R end	IntR	ΔT6SS	*fhaB*	ΔFHA	*dfhaB*	*eit*	*iuc*	*Cc*

Total	801	771 (96)	606 (76)	49 (6)	604 (75)	314 (39)	345 (43)	204 (25)	53 (7)	152 (19)	116 (14)	75 (9)	770 (96)	723 (90)	10 (1

[a] Percent PCR positive for each gene locus in relation to the total number of plasmid-harboring strains of that species, except for the data for *repA*, which are in relation to the total number of strains. The number of strains was updated and adapted from a similar table in reference 79.

[b] Only 44 *C. malonaticus* strains were tested by PCR.

Capsule Profiling or Typing (K Typing)

Ogrodzki and Forsythe proposed a new capsular typing scheme and found a previously uncharacterized capsular region (*kps*) in 104 *Cronobacter* strains (116). The region was homologous to the well-described K-antigen gene cluster of *E. coli*. The gene cluster comprises three regions: K-antigen region 1 (*kpsEDCS*) and region 3 (*kpsTM*) are conserved across the genus, and there are two variants of region 2. Genes associated with K-antigen type 1 are present in all seven species of *Cronobacter*. However, the prevalence and distribution of K-antigen type 2 (specifically of interest is the capsular profile K-antigen gene cluster 2–colanic acid gene cluster 2–cellulose positive) are more limited, and this antigen is found only in *C. sakazakii*, *C. malonaticus*, *C. turicensis*, and *C. dublinensis*. It is thought that the presence of this capsular profile may confer a favorable phenotype for desiccation resistance, persistence, and serum resistance as well as increased macrophage survival, resulting in a more physiologically fit pathogenic microorganism.

VIRULENCE FACTORS

Outer Membrane Proteins

Although the genomics and transcriptomics of *Cronobacter* pathogenesis have not been fully elucidated, considerable information has been obtained in recent years that has enabled the identification of several virulence markers and putative genetic loci that may contribute to its pathogenesis. Two well-characterized virulence genes, *ompA* and *ompX* (encoding outer membrane proteins [OMPs] OmpA and OmpX), are involved in adherence and invasion of brain endothelial cells through the binding of the cells to fibronectin (117, 118). Kothary et al. (86) revealed that both OmpA and OmpX are packaged within outer membrane vesicles (OMVs) expressed in stationary-phase-grown cells of *C. sakazakii*, *C. malonaticus*, and *C. turicensis*, and Ye et al. (119) determined that the expression of these OMPs is greater in a virulent *C. sakazakii* strain than in an avirulent strain.

Other OMPs packaged within OMVs include MipA (peptidoglycan synthesis), OmpC, OmpE, and OmpF (porins), CTP (a conjugative plasmid transfer T4SS protein), GroEL (chaperonin), and an autotransporter secretion T5SS protein named outer membrane transporter protein. Furthermore, PCR and microarray analyses of 240 strains representing the seven *Cronobacter* species revealed that these OMPs are highly conserved among all the species. OMVs were once thought to be artifacts, but they are now recognized as structures possessing very diverse functions. Foremost, OMVs are currently regarded as a secretion system used by bacteria to communicate with host cells and other bacterial cells. Kothary et al. (86) also determined that in addition to OMPs, these OMVs contained substantial amounts of LPS. The existence of LPS components in PIF was already known (120), and their presence may lead to a situation where the LPS in PIF causes a proinflammatory response in a susceptible host which could lead to a fatal "cytokine storm." Townsend et al. (120) determined that the presence of endotoxin along with *C. sakazakii* in infant formula enhanced the translocation of *C. sakazakii* from the rat gut lumen to the meninges and through the BBB. One possible mechanism is thought to be the disruption of the tight junctions by the LPS, thus increasing the permeability of host barriers to the pathogen (47). More information is required to elucidate the process regulating the production of OMVs and their role in disease.

Fimbriae

Comparative genomics studies have revealed that *Cronobacter* possesses genes for several colonization factors, or fimbriae (94, 95, 121). These studies revealed that among members of the genus, there are 11 different fimbria types. For example, Grim et al. (94, 122) determined that the *Cronobacter* genome contains genes for type IV pili in addition to a P pilus homologous to that found in uropathogenic *E. coli* that causes meningitis in infants. Interestingly, not all *Cronobacter* species contain the genes for all of these adherence factors. For instance, *C. sakazakii* BAA-894 and *C. malonaticus* LMG 23826 harbor a type 1 fimbria (GR82) gene which is absent in the other genomes. Furthermore, some *Cronobacter* genomes contain genes for curli fimbriae which are homologous to the curli fimbriae of *E. coli* and the *tafi* fimbriae of *Salmonella* (94). However, little is known about their role in pathogenicity.

Exoproteins

Pagotto et al. (123) were the first to describe the presence of putative enterotoxins expressed by *Cronobacter*. Using the suckling mouse assay, these investigators observed an enterotoxin effect in four of 18 *Cronobacter* isolates tested which also were toxigenic to Vero and Y-1 cells, causing both rounding and cell lysis. Raghav and Aggarwal (124) were the first to partially purify and characterize a putative *Cronobacter* enterotoxin. The molecular mass of the toxin was 66 kDa, and it was stable at 90°C for 30 min, implying that it is a moderately heat-stable toxin. This indicates that the enterotoxin could be resistant to commercial milk pasteurization treatments and thus may be active in pasteurized liquid infant formula. The gene encoding this toxin remains to be identified.

As suggested by Pagotto et al. (123), *Cronobacter* also secretes proteolytic enzymes that in mice lyse cells and create tissue damage at the site of infection. Kothary et al. (71) identified a zinc metalloprotease that deforms Chinese hamster ovary cells, causing rounding and cell damage. The genes for a hemolysin have been identified, but there is controversy regarding its activity (93, 95, 121). To better understand the prevalence and phylogenetic relatedness of the putative hemolysin III homolog (COG1272), Lee et al. (125) assayed 389 *Cronobacter* strains by PCR, DNA microarray, and

WGS analyses. PCR analysis using primers reported by Cruz et al. (121) revealed that COG1272 was present in 285 of 298 (95.6%) *C. sakazakii* strains studied, 3 of 7 (42.9%) *C. muytjensii* strains, 13 of 33 (39.4%) *C. malonaticus* strains, 3 of 12 (25%) *C. turicensis* strains, 4 of 37 (10.8%) *C. dublinensis* strains, and 1 of 1 *C. universalis* strain. *C. condimenti* was PCR negative for COG1272. However, microarray analysis and WGS revealed that *C. condimenti* did possess a COG1272 ortholog and that primers were more *C. sakazakii* specific than was previously thought. Using microarray analysis and WGS in parallel, Lee et al. (125) determined that in addition to COG1272, 27 other hemolysin-related genes were present, including homologs of genes for a hemolysin containing a cystathionine beta-synthase domain, a 21-kDa hemolysin precursor protein, and several putative hemolysins within each *Cronobacter* species. Furthermore, Ye et al. (119) provided transcriptomic data that suggest that the hemolysin III gene (COG1272) is upregulated in a virulent strain of *C. sakazakii* compared to a nonvirulent strain.

GENOMICS AND TRANSCRIPTOMICS OF VIRULENCE GENES

There have been several reports of various genes found genomically that may impart to *Cronobacter* species the ability to be a more physiologically fit pathogen. For example, *ibeB* (a gene synonymous with *cusC*), which belongs to a cluster of genes encoding a copper and silver resistance cation efflux system, was reported (93, 94) to be involved with greater invasiveness of HBMECs. Kucerova et al. (93) reported that they too found that a complete cation efflux operon (*cusA*, *cusB*, and *cusC*) and that its regulatory gene, *cusR*, was present in isolates associated with neonatal infections (including *C. sakazakii*, *C. turicensis*, and *C. malonaticus*) and absent in the other tested strains. Ye et al. (119) recently reported transcriptomic data for a virulent strain of *C. sakazakii* which were compared with those for an avirulent strain; differentially expressed genes included flagellum-associated genes, such as *flhD*, *motA*, *flgM*, *flgB*, and *fliC*, OMP or lipoprotein genes (*ompW*, *slyB*, *blc*, *tolC*, and *lolA*), chemotaxis genes, including *cheY* and *cheR*, a gene for the virulence-related factor hemolysin III (*hlyIII*), a hemolysin expression-modulating gene (*hha*), and genes for important regulation factors (*sdiA*, *cheY*, *bss*, and *fliZ*). Jing et al. (126) reported on the transcriptome profile of *C. sakazakii* BAA-894 after interaction with HCT-8 cells. They determined that expression of some flagellar genes (*flgA*, *flgB*, *flgC*, *flgD*, *flgF*, *flgG*, *fliK*, *fliM*, *fliL*, and *fliE*) and adherence factors was upregulated. High osmolarity and osmotic stress-associated genes (*kdpABC*, *proV*, and *betB*) were highly upregulated, as well as genes responsible for the synthesis of lipopolysaccharides and OMPs (*mltD*, *lpxP*, *yidC*, *spr*, *ompA*, and *ompX*), iron acquisition systems (*fepE*, *entC*, *iutA*, *fhu*, *eit*, and *efe*), and glycerol and glycerophospholipid metabolism.

Several bacterial pathogens produce diffusible signal factor-type quorum-sensing signals to control virulence. Suppiger et al. (127) determined that *C. turicensis* LMG 23827^T possesses a functional quorum-sensing system (*rpfF/R* system) that is involved in the regulation of various phenotypes, including colony morphology, biofilm formation, and swarming motility; results from a zebrafish embryo infection model revealed that this regulatory system also controls virulence by modulating bacterial intracellular c-di-GMP levels.

IN VIVO MODELS

To gain insights into the pathophysiology of *Cronobacter*-induced diseases, the selection and/or development of *in vivo* models that mimic the clinical manifestations of infections is required. The following subsection describes animal models that have been used thus far to identify bacterial and host factors that contribute to *Cronobacter* pathogenesis.

Mammalian Models

The first study of pathogenesis employing an *in vivo* model was published by Pagotto et al. (123), who reported the presence of a putative *C. sakazakii* enterotoxin and cytotoxins as well as providing data on the minimal lethal dose required for challenge studies using either the oral or the intraperitoneal

inoculation routes in a suckling mouse assay. Food and clinical isolates were tested for enterotoxin production, and 22% of these strains tested positive. Challenge studies using intraperitoneal injection revealed that all tested strains were lethal at 10^8 CFU per mouse, but most, including one enterotoxin-positive strain, were nonlethal at high oral doses. It was hypothesized that accessory and yet-unidentified bacterial virulence and/or host factors may be required for these strains to exhibit their full virulence. It is noteworthy that the genetic basis of the proposed enterotoxin in *C. sakazakii* has not been determined.

In subsequent experiments, a variety of animals (nonmammalian and mammalian, including chickens [1 day old], rabbits [2.7 to 3 kg, 2 months old], guinea pigs [300 to 400 g, 3 to 4 months old], and young gerbils [40 to 50 g, 1 to 2 months old]) were tested and evaluated for signs of infection and/or death after being fed various *C. sakazakii* strains suspended in reconstituted infant formula. The neonatal gerbils presented as the most promising nonprimate model to study infections via the oral route (16, 128).

Since milk-based infant formulas contaminated with *Cronobacter* have been implicated in outbreaks of NEC, several research groups have attempted to develop an animal model that mimics the manifestations of human NEC (including mucosal edema, enterocyte apoptosis, and vascular thrombosis) caused by *Cronobacter*. A neonatal rat model, using a combination of formula feeding, hypoxia, and administration of *C. muytjensii* (ATCC 51329^T), was evaluated by Hunter et al. (16) to investigate *E. sakazakii* (*Cronobacter*)-induced NEC. Newborn rats fed infant formula including 10^5 CFU of bacteria exhibited clinical symptoms of grade 3 NEC by day 4 postinfection. The rats that were formula-fed and subjected to hypoxia only (controls) presented less severe pathological symptoms and had a mortality rate of 40%, whereas the mortality rate in *Cronobacter*-infected animals was 70%. Histopathological analysis of intestinal sections from infected rats revealed macroscopic and microscopic features analogous to those observed in human NEC. Infections increased binding of the bacteria to the villus tips as well as enterocyte blebbing and gap formation in the epithelium. It was concluded that epithelial damage was mediated through enterocyte association without direct invasion by bacteria. *C. muytjensii* may cause barrier damage by inducing enterocyte apoptosis and stimulating expression of the inflammatory cytokine IL-6. These findings as well as the role of NO in mediating apoptosis were confirmed by follow-up studies using intestinal epithelial cells (Caco-2) (16, 23).

Emami et al. (30) evaluated a mouse model in which oral feeding of 10^3 CFU of *C. muytjensii* to 3-day-old mice induced NEC-like pathology. It was determined that *C. muytjensii* infection causes epithelial damage by recruiting greater numbers of dendritic cells than macrophages and neutrophils in the gut and suppresses dendritic-cell maturation. This requires OmpA expression in *C. muytjensii*. Interaction of OmpA with dendritic cells mediates epithelial barrier disruption through secretion of pro-or anti-inflammatory cytokines. Destruction of the intestinal epithelium was due to increased production of transforming growth factor β and IL-10. Depletion of dendritic cells in newborn mice protected against *C. muytjensii*-induced NEC, whereas depletion of either neutrophils or macrophages from 2-day-old mice followed by infection rendered the animals susceptible to infection earlier than normally infected littermates (30).

Translocation through the gastrointestinal barrier is a prerequisite to facilitate systemic spread into the central nervous system and penetration of the BBB. Studies to determine the ability of *E. sakazakii* (*Cronobacter*) to penetrate the BBB and cause meningitis in orally induced infections were hindered due to lack of a suitable animal model.

One of the first studies using an animal model to address *Cronobacter*-induced meningitis and brain abscess formation was conducted by Townsend et al. (29). They utilized intracranial inoculation of neonatal rats with *E. sakazakii* (*Cronobacter*) to observe the progression of brain inflammation and the ensuing host inflammatory response. Infiltrating macrophages and neutrophils comprised the inflammatory foci and contained phagocytosed bacteria. In the same study, it was determined that several *Cronobacter* strains were capable of invading rat brain capillary endothelial cells (rBCEC4) and that these could persist in macrophages for up to 96 h. It was noted that intracellular survival may be modulated by the presence of superoxide dismutase (encoded by the *sod* gene), which may influence

survival under acidic conditions and/or in the presence of macrophage oxidase. In addition, it was determined that *Cronobacter* may bias early IL-10/IL-12 cytokine expression in macrophages, suggestive of a type 2 immune response, which is inefficient in fighting intracellular infections, and this may explain the opportunistic nature of this infection.

Since the natural route of infection of this pathogen is via gut colonization, there may be limits to the extrapolation of information from the intracranial infection model to human disease. Mittal et al. (129) used a newborn rat model to identify and characterize the role of *E. sakazakii* (*C. muytjensii*) OmpA protein in the onset of meningitis. An orally administered OmpA-expressing strain translocated the intestinal barrier, multiplied in the blood, and subsequently penetrated the BBB. Cronobacters were present in large numbers in the brains of infected animals and were associated with neutrophil infiltration, hemorrhages, and gliosis. OmpA expression was also involved in the resistance to blood and serum complement killing. Thus, this newborn-rat model without hypoxia was a suitable model for observing translocation of cronobacters into the system, resulting in meningitis (129).

There are, however, also disadvantages in the use of mammalian models, including high monetary costs, ethical issues, and the need for laborious and invasive sample analysis. An alternative infection model using insects has been used in pathogenesis studies.

Nonmammalian Models

Among the invertebrates used, *Galleria mellonella* (greater wax moth) is of special interest because this model can be easily and inexpensively obtained in large numbers and is easy to manipulate. There are no ethical constraints, and their short life cycle makes them ideal for large-scale studies. Although insects lack an adaptive immune response, their innate immune response is remarkably similar to the immune response in vertebrates. In addition, *G. mellonella* can survive at 37°C, which is important in studying temperature-sensitive virulence of pathogens.

G. mellonella larvae were used by Carranza et al. (130), who determined that injection of 7×10^6 CFU of *C. turicensis* 3032 (LMG 23827T) could kill the larvae after 72 and 96 hours postinfection, whereas injection of *E. coli* JM83 was nonpathogenic. More recently, the model was used to test the efficiency of phage therapy against *C. sakazakii* infections (131).

The wax moth model proved useful for prescreening of potential virulence factors and for testing the efficacy and safety of phages prior to confirmation or clinical evaluation in mammalian models. However, in many cases, assays in which death and survival are the only measurements are not sufficient for studying the progression of an infection. There is a need for models in which the interaction between invading bacteria and the individual host immune cells can be followed *in vivo* and, ideally, in real time.

The *Caenorhabditis elegans* model has some advantages, such as ease of cultivation and transparency. It seems particularly efficient in detecting virulence traits in opportunistic bacterial pathogens, because virulence in strict pathogens is often host specific and cannot be universally modeled in the nematode infection system (132).

Sivamaruthi et al. (133, 134) determined that *C. sakazakii* BAA-894, a strain of clinical relevance, can kill *C. elegans* with a 50% lethal dose at 133+3 hours, whereas *E. coli* OP50 (food source of *C. elegans*) had no effect. A gradual multiplication of bacteria was observed during infection of *C. elegans* with *C. sakazakii*, with *Cronobacter* populations at 24 h reaching 3.25×10^4 CFU per worm. These findings suggest that the pathogenicity of *C. sakazakii* was mainly due to bacterial accumulation and persistent infection inside the host. There was notable damage within the infected nematode, particularly in the intestinal region, with induction of apoptosis (cell death confirmed by Sytox staining) identified as the major event. This mechanism is similar to that of human NEC pathogenesis. The study also elucidated the role of genes known to be associated with *C. elegans* innate immune response to pathogenic infections. Subsequent studies by this group revealed that exposure to *C. sakazakii* LPS led to paralysis and death of *C. elegans* (135). Analysis of Fourier transform infrared spectra of LPS revealed that *C. sakazakii* modifies its LPS to escape recognition by the host immune system. Studies using qPCR

revealed that LPS modulated the expression of selected host immune and aging-related genes, and it was determined that the p38 MAPK pathway has a significant role in host immune response against LPS-mediated challenges (135).

One of the drawbacks of this model is that these organisms are genetically not closely related to humans, and their immune system has many differences from that of humans. In addition, in this model, *C. elegans* is typically infected by feeding the bacteria to the worms; hence, it is not possible to determine the exact infective dose.

The zebrafish (*Danio rerio*) embryo model is a hybrid between the mouse and invertebrate infection models. The most impressive feature of this model is the possibility of performing noninvasive, high-resolution, longterm, time lapse and time course experiments in the transparent embryo to visualize infection dynamics with fluorescent markers. Its small size, ease of breeding, high fertility, and genetic tractability are additional features that make the zebrafish embryo an attractive model for high-throughput infection studies. Furthermore, the zebrafish immune system displays many similarities to that of mammals, with counterparts for most of the human immune cell types. The zebrafish's innate immune system begins to develop as early as 24 hours postfertilization; however, the development of the adaptive immune system lags. This fact makes the model especially attractive for studying a pathogen causing disease in neonates and premature babies.

The development and adaptation of the zebrafish embryo model to study *Cronobacter* pathogenesis were first described in 2015 (136). Various parameters, such as infecting embryos by bath immersion versus microinjection of bacteria as well as infection dosages and sites of injection, were evaluated for the ability to model systemic *Cronobacter* infections. Microinjection of 50 CFU of *Cronobacter* into the yolk sac resulted in rapid multiplication of bacteria and dissemination into the bloodstream at 24 h postinfection, followed by the development of severe bacteremia and larval death within 3 days. In contrast, the innate immune response of the embryos was sufficiently developed to control infection after receiving an intravenous injection of up to 10^4 CFU of *Cronobacter*. Infection studies using an isogenic mutant incapable of surviving and replicating in human macrophages (Δ*fkpA*) revealed that this strain was highly attenuated in its ability to kill the larvae. In addition, the suitability of the zebrafish model to study the effectiveness of antibiotics to treat *Cronobacter* infections in zebrafish embryos was confirmed. In this study, light and fluorescence microscopy, as well as CLSM and TEM analysis, were employed to visualize progression of infection and the pathology of infection.

Several studies were published by the same group in which the zebrafish embryo model was used to investigate the divergent virulence potential among species and strains within the genus *Cronobacter*. Eshwar et al. (85) used the zebrafish embryo model to study the role of RepF1B-like plasmids as virulence plasmids in *Cronobacter* and determined that two virulence factors—the *Cronobacter* plasminogen activator (*cpa*) and the zinc metalloprotease (*zpx*)—were involved in *in vivo* pathogenesis. Another study focused on the description and characterization of a novel diffusible signal factor-type quorum-sensing-dependent signaling system in *C. turicensis*. It was determined that this signal/sensor system is functional, is involved in the regulation of various phenotypes, and plays a role in virulence (127). Chase et al. (87) used this model to study *C. sakazakii* strain H322, a highly persistent ST83 strain obtained from PIF. This and other ST83 strains investigated in the study produced substantial mortality in the infection experiments, suggesting an elevated risk for infections and illness in neonates exposed to PIF contaminated with isolates of ST83.

The zebrafish embryo model has great potential for studying systemic *Cronobacter*-mediated infections. It combines many of the advantages present in the above-mentioned models and makes it possible to study infections in real time. In addition, it may be used as a prescreen for bacterial virulence factors and potential host factors involved in the immune response. Such experiments may also be regarded as meeting ethical standards in animal welfare, as up until 5 days postfertilization the central nervous system of the zebrafish embryo is only partially developed and complex behaviors of the juvenile or adult are absent. This is recognized by licenses for fish experimentation, which are necessary only from the stage at which fish can independently feed (i.e., >120 hours postfertilization). Thus, by using the zebrafish embryo model as a prescreen, it will be possible to reduce the number of

experiments with nonhuman mammal models, which will still be necessary for confirmation purposes. Finally, the zebrafish model poses no challenge to the position of rodent models: it is complementary to them, especially in the initial stages of infection.

ANTIBIOTIC RESISTANCE

Prior to 2000, most infections caused by *Cronobacter* were frequently treated with ampicillin, gentamicin, and/or chloramphenicol or a combination of gentamicin and ampicillin (137). However, as early as 2001, *Cronobacter* strains were uniformly found to be resistant to ampicillin, cefazolin, and extended-spectrum β-lactams, whereas they were uniformly susceptible to trimethoprim-sulfamethoxazole and aminoglycosides. By 2015, antimicrobial susceptibility testing by Xu et al. (105) revealed that 84.5% and 46.5% of isolates obtained from ready-to-eat foods in China were resistant to penicillin G and cephalothin, respectively; in contrast, all tested isolates were susceptible to cefotaxime, ciprofloxacin, tetracycline, and nalidixic acid. In another study, multidrug resistance was associated with *C. sakazakii* isolates from domestic kitchens (138), with the greatest percentage of resistance in these strains to penicillin (76.1%), followed by tetracycline (66.6%), ciprofloxacin (57.1%), and nalidixic acid (47.6%). None of the *C. sakazakii* isolates was resistant to gentamicin.

Surveillance has revealed that antimicrobial resistance in *Cronobacter* is changing from most strains being pansusceptible to more strains becoming increasingly resistant. To illustrate this trend, there was a recent report from China of two cases involving multidrug resistance (139). The Cronobacter strains identified in this study were resistant to third-generation cephalosporins, aminoglycoside, and/or trimethoprim-sulfamethoxazole. This was followed by a second report of multidrug resistance in a *C. sakazakii* strain isolated from a sputum sample. The isolate possessed three plasmids, i.e., IncHI2, IncX3, and IncFIB incompatibility groups, which acquired several plasmidborne accessory modules carrying a large number of genes involved in resistance to carbapenems, aminoglycoside, tetracyclines, phenicols, and sulfonamide-trimethoprim. These plasmid-borne antibiotic resistance genes were associated with insertion sequence elements, integrons, and transposons, indicating that the assembly, mobilization, and acquisition of these corresponding accessory modules with complex chimera structures were facilitated by transposition and/or homologous recombination (140).

FUTURE DIRECTIONS

The viewpoint that *Cronobacter* is just a neonatal foodborne pathogen has changed remarkably in the 10 years since its reclassification, and perception of its role will likely continue to evolve. Once considered a harmless inhabitant of the human intestinal tract or a contaminant of dried foods, *Cronobacter* is now seen as an opportunistic group of pathogenic species with remarkable versatility in their abilities to cause disease in humans. It is now realized that infections due to *Cronobacter* can affect neonates, infants, and elderly individuals, and this organism continues to generate national and international attention. Pathogen-specific virulence factors have been discovered that adversely affect a wide range of eukaryotic cell and host processes, including protein synthesis, cell division, and proinflammatory host responses. What little we know about these virulence factors is related to acquisition of a variety of mobile genetic elements, such as plasmids, transposons, and pathogenicity islands. This genomic plasticity implies ongoing reassortment (microevolution) and possibly acquisition of new virulence factors that will challenge our efforts to classify these organisms into various subgroups or into sharply delineated genomopathotypes. Additionally, these results suggest that other unidentified sources or vectors will be involved in the transmission of *Cronobacter*. Thus far, these sources have been difficult to identify. However, the observations of Friedemann (28) and those of Farmer (141) and Jason (7) revealed that environmental sources of infection should be considered and that consistent and sufficiently informative data from *Cronobacter* infections should be recorded in a centralized reporting system. Two such systems are the National Notifiable Diseases Surveillance System, which is maintained by the Centers for Disease Control and Prevention (https://wwwn.cdc.gov/nndss/data-and-statistics.html), and the European Centre for Disease Prevention and Control's Surveillance System (https://ecdc.europa.eu/en/publications-data/european-

surveillance-system-tessy). The dynamic nature of *Cronobacter* will continue to present additional challenges for the global food safety and public health communities in the diagnosis, treatment, and prevention of infections caused by this group of highly diverse, versatile, and opportunistic pathogens.
