Aeromonas

HISTORY AND BACKGROUND

The genus *Aeromonas* contains chemoorganotrophic bacteria that are Gram-negative, non-spore-forming, facultatively anaerobic, oxidase-positive (with rare exceptions), glucose-fermenting, rod-shaped bacteria (occasionally shortened into coccobacilli). This genus comprises both mesophilic and psychrophilic species. The history of *Aeromonas* dates back to 1891, when it was linked to red leg disease in frogs and described as *Bacillus hydrophilus fuscus* (1). Over 50 years later, it was reclassified as *Aeromonas hydrophila* (2). The first description of psychrophilic nonmotile aeromonads was for isolates from diseased trout, which were named *Bacillus der Forellenseuche* (3). Later, Chester proposed that this organism be named *Bacterium salmonicida*, which today is known as *Aeromonas salmonicida* (4).

CLINICAL MANIFESTATIONS

Aeromonads were discovered more than 100 years ago, and their role in human disease was first described in 1954, when the organism was associated with the death of a 40-year-old Jamaican woman with acute fulminating metastatic myositis (5). Diarrhea was later associated with aeromonads isolated from a 10-year-old girl (6). Subsequently, aeromonads have been implicated in various human and animal diseases. Although it is generally accepted that some *Aeromonas* spp. can cause serious clinical manifestations, their status as relevant clinical pathogens has been controversial for decades, especially with regard to human gastrointestinal tract infections. Based upon frequency, the most typical *Aeromonas*-associated diseases involve diarrheal cases (with different manifestations) among young children and immunocompromised populations. Also common are soft-tissue and wound infections subsequent to traumatic injuries, usually in immunocompetent individuals. Other intraabdominal infections and extraintestinal infections are rare and usually occur in individuals with underlying medical conditions (7–10).

A wide spectrum of diseases have been attributed to aeromonads, with four species being predominant in most clinical infections: *A. hydrophila*, *A. caviae*, *A. veronii*, and *A. dhakensis* (10). Table 15.1. lists all *Aeromonas* spp. linked to human diseases. It is important to note some taxonomic nuances regarding clinical *Aeromonas* spp. First, *A. veronii* bv. sobria (*A. veronii*), one of the main species of clinical importance, is often misidentified as *Aeromonas sobria* (9). In fact, *A. sobria sensu stricto* is described as a typical environmental species frequently isolated from waters, sewage, and diseased fish without relevance to clinical microbiology (11). Second, *A. dhakensis* was previously designated *A. hydrophila* subsp. *dhakensis* and/or *A. aquariorum* but is currently identified as a new clinical species. Its frequency in clinical samples is higher than previously thought, due to previous biochemical misidentifications as *A. hydrophila*, *A. caviae*, or *A. veronii* (12–14).

Table 15.1 Clinical diseases associated with *Aeromonas* species[a]

Species	Gastro-enteritis	Wound and soft tissue infection	Bacteremia	Intra-abdominal infection	Respiratory tract infection	Ocular diseases	Urinary tract infection	Other

Gastroenteritis

Worldwide enteric infections are commonly caused by *Aeromonas* spp. and affect young children, elderly persons, patients suffering from underlying maladies (including immune disorders) and, less frequently, healthy individuals (7, 10). *Aeromonas*-associated gastroenteritis is underestimated due to the absence of routine testing for it in diarrheal stools, and the identification of these organisms is sometimes accidental (7, 10). This gastroenteritis presents in various forms, ranging from asymptomatic enteritis to the most common secretory (watery) enteritis and to severe cholera-like or dysentery-like diseases (7). In addition, rare cases of chronic diarrhea (15), traveler's diarrhea (16), and complications such as small bowel obstructions (17), enterocolitis (18), segmental enteric necrosis (19), and hemolytic-uremic syndrome (20, 21) have been described.

Recent decades have been marked by the uncertain and controversial status of *Aeromonas* as a true enteropathogen. Perhaps the strongest argument is that it does not fulfill Koch´s postulates. However, an immunocompetent laboratory worker accidentally ingested an *Aeromonas trota* culture from a clinical isolate and developed "rice-water" stools (22). The same strain was isolated from his stool, thus supporting Koch's postulates, though the extent of illness from the original isolate was unknown. Another case study ribotype matched an *Aeromonas* isolate from a ready-to-

eat shrimp cocktail to the corresponding diarrheal stool from a previously healthy male (23). Challenges to the true enteropathogenic nature of *Aeromonas* spp. still confound scientists, due to its being identified in 1 to 4% of asymptomatic individuals' stool samples (7), indicating that it can colonize without triggering pathogenic processes.

The lack of a perfect animal model to depict aeromonad-induced enteritis presents the next problem in elucidating this organism's pathogenic nature; however, the murine and rabbit ileal-loop models have provided some support. To characterize the role of the enterotoxins Act, Alt, and Ast in virulence, the murine model was used with *A. dhakensis* SSU (previously designated *A. hydrophila* isolate SSU [24]) (25), and this model is depicted in Fig 15.1. A secretory fluid response was quantified in enterotoxin mutants, with Act accounting for the strongest (64%) fluid secretory response, followed by Alt (48%) and Ast (43%). Mutating all three enterotoxins resulted in no detectable fluid response, confirming their roles as virulence factors. The rabbit ileal-loop model was utilized more recently to characterize the pathogenic behavior of a clinical *A. caviae* strain (26). Microscopy revealed massive bacterial colonization in the form of stacked bricks with biofilm formation, accompanied by pathological changes of vacuolization and villus destruction in enterocytes, as well as anatomical cellular disruptions.

Last, a lack of multiple large outbreaks, considering the ubiquitous nature of aeromonads, argues against their being true enteropathogens. However, misidentification and lack of clinical lab work, especially considering that the predominant manifestation is secretory enteritis, could explain the minimal number of reported outbreaks. Investigators of one outbreak did identify *A. hydrophila* from 33 of 55 villagers presenting with loose stools two to four days after beef consumption, but they failed to analyze the meat carcass for the same isolate (27). In Sweden, 24 of 27 guests at a funeral developed diarrhea after consumption of a traditional Swedish shrimp dish, which later tested positive for *A. hydrophila*, but unfortunately, no fecal samples were assayed (28). Similarly, more than 200 students developed gastroenteritis at a college in China, but only 15 fecal samples were collected and only three were positive for *A. hydrophila*, though they were negative for any of the other enteropathogens tested (29). No direct link to food was identified, due to a lack of food source to test. Regarding these studies, it is imperative not only to determine the species of *Aeromonas* associated with gastroenteritis but also to identify the same strain from a food or water source. A common argument against the pathogenicity of aeromonads is based on a human volunteer study conducted by Morgan et al. (30). Only 2 of 57 volunteers challenged with a virulent strain of *A. hydrophila* developed acute enteric symptoms. Given the high challenging dose used (10^4 to 10^{10} CFU), the low infection rate was surprising. Possible explanations include the following: (i) the volunteer study selected healthy individuals (to avoid severe complications), which might have influenced the final outcome; (ii) the challenge strains are often repetitively subcultured under laboratory conditions, which might affect virulence (31).

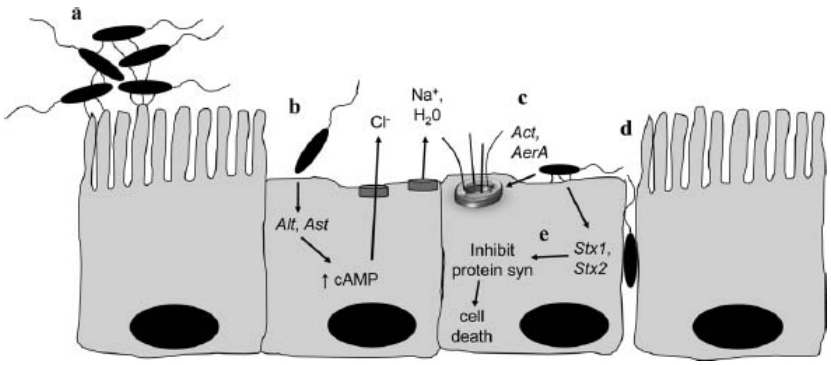

Figure 15.1 Virulence factors associated with *Aeromonas* spp. causing gastroenteritis. Aeromonads encode numerous virulence factors, though their pathogenic roles vary with disease. The image presents the most influential virulence factors associated with gastroenteritis. Adherence to intestinal epithelial cells and mucosa to initiate infection is mediated via lateral flagella. Additionally, adherence is involved in aggregative behavior with other aeromonads, resulting in a "stacked-brick" formation and biofilm formation (a). Once bound to the epithelial cells of the small intestine, *Aeromonas* spp. have an arsenal of enterotoxins they can secrete. Two of the enterotoxins, Alt and Ast, act in a cholera toxin-like fashion, elevating adenylate cAMP in the host. The exact mechanisms are not fully elucidated, but this induces an efflux of chloride ions (b), leading to osmotic leakage of water into the intestinal lumen and causing diarrhea. Other virulence factors associated with gastroenteritis include pore-forming aerolysin-related cytotoxic enterotoxin (Act) and aerolysin (AerA). These enterotoxins cause direct damage to the intestinal wall via enterocyte toxicity (c). The release of enterotoxins during disease distorts enterocyte morphology, including loss of microvilli (c) as well as detachment, providing passages through submucosa and tight junctions (d) (26). Some clinical strains of *Aeromonas* produce Shiga toxin homologs (encoded by *stx1* and *stx2*), causing a ribotoxic stress response, which in turn leads to inflammation and apoptosis (e), though the exact mechanisms of action of these *Aeromonas* homologs have yet to be determined.

The lack of disease correlation highlights the potential importance of host genetic susceptibility and the influence of gut microbiome composition. Teunis and Figueras compared the results of the human volunteer study with results from previous natural outbreaks and determined that the infectious doses for all natural outbreaks were more than a 100-fold lower than those for the volunteer study (31), suggesting a dose-response explanation. In developing countries, rates of isolation of *Aeromonas* spp. from diarrheal children vary between 1 and 88%, compared to a 1 to 48% isolation rate from asymptomatic patients' stools (32). These numbers further support the idea that not every gastrointestinal colonization with *Aeromonas* leads to infection. More studies are needed to determine key factors involved in hostpathogen interactions triggering gastrointestinal maladies.

Wound and Soft-Tissue Infections

Skin and soft tissues are the most common sites of extraintestinal infections caused by aeromonads. Typically, these wound and soft-tissue infections occur in immunocompetent populations, usually upon posttrauma exposure to contaminated water or soil (7–9). However, patients suffering from other injuries, such as burns, surgical wounds, crush injuries, or animal bites, are endangered as well (9, 10). Clinical manifestations include cellulitis, furunculosis, skin nodules, abscesses, necrotizing fasciitis, myonecrosis, and gangrene or osteomyelitis (7, 33). Immunocompetent individuals usually have localized infection with favorable outcomes, while fulminant fatal consequences occur predominantly in immunocompromised hosts (8). The pathogenesis of soft-tissue infections caused by aeromonads remains equivocal, though

degradative enzymes are leading virulence candidates. A new animal model using *Caenorhabditis elegans* to study *A. dhakensis* pathogenicity during necrotizing fasciitis might provide new insights (34) in the future.

Bacteremia and Septicemia

While bacteremia is characterized by the presence of bacteria in the bloodstream and can be eliminated asymptomatically, septicemia represents inflammatory processes associated with multiplication of bacteria in bloodstream, often accompanied by toxin release and a systemic response triggering sepsis (Fig 15.2). Underlying diseases, such as hepatobiliary disease, malignancy, immune disorders, and diabetes, can play a key role in the acquisition and outcome of bacteremia and septicemia caused by aeromonads (7, 10). Immunocompetent populations are also at risk for bacteremia or septicemia when colonization by aeromonads is preceded by injury or trauma or occurs subsequent to specific treatments, such as surgery or leech therapy (10). *Aeromonas* bacteremia/septicemia presents predominantly as a monomicrobial, community-acquired infection and occurs mainly in male populations (10), with high mortality rates (23 to 70%) (35, 36).

Other Infections

A rare presentation of *Aeromonas* infections is pneumonia or other respiratory tract infections. They occur in both healthy and immunocompromised individuals subsequent to bacteremia (37). Near-drowning incidents also result in an increased risk for pneumonia, which presents within 24 h (38). Because members of this genus do not typically cause pneumonia, it may be underdiagnosed by clinicians and laboratory technicians. Ocular diseases are also caused by aeromonads posttrauma, being spread endogenously or via exposure to contaminated environmental sources (7, 39). These infections are usually mild, but some severe cases of endophthalmitis, keratitis (or lens-related keratitis), and corneal ulcerations (7, 8) have been reported.

Intra-abdominal *Aeromonas* infections are typically community acquired and affect patients with malignancy of the hepatobiliary system (often cirrhosis), pancreas, or immune system (40), with subsequent 30% mortality (41). These infections extend beyond the hollow viscus organ into the peritoneal space and include hepatobiliary tract infections, peritonitis, pancreatitis, cholangitis, and hepatic abscesses.

Only a few cases of *Aeromonas* urinary tract infections have been documented, and they were associated with *A. caviae* (42) or *A. popoffii* (43). *A. hydrophila* was identified as the etiologic agent in an acute epididymitis and pyelonephritis case in an immunocompetent 42-yearold patient 24 h after engaging in sexual intercourse in a swimming pool (44), reemphasizing the potential risks associated with water sources containing aeromonads.

CLASSIFICATION

There have been many changes in the taxonomic structure of the genus *Aeromonas* in the last few decades. In the first edition of *Bergey´s Manual of Systematic Bacteriology*, the genus *Aeromonas* was assigned to the family *Vibrionaceae* based on phylogenetic properties (45). Later, based on various studies using DNA hybridization, analyses of 5S and 16S rRNA, and DNA-rRNA hybridization, supported by rRNA gene and rRNA sequencing, *Aeromonas* was confirmed as being evolutionarily distinct from *Vibrionaceae* and *Enterobacteriaceae*. Since the second edition of the *Bergey´s Manual of Systematic Bacteriology*, the family *Aeromonadaceae* has been established within the order *Aeromonadales* and class *Gammaproteobacteria* (46).

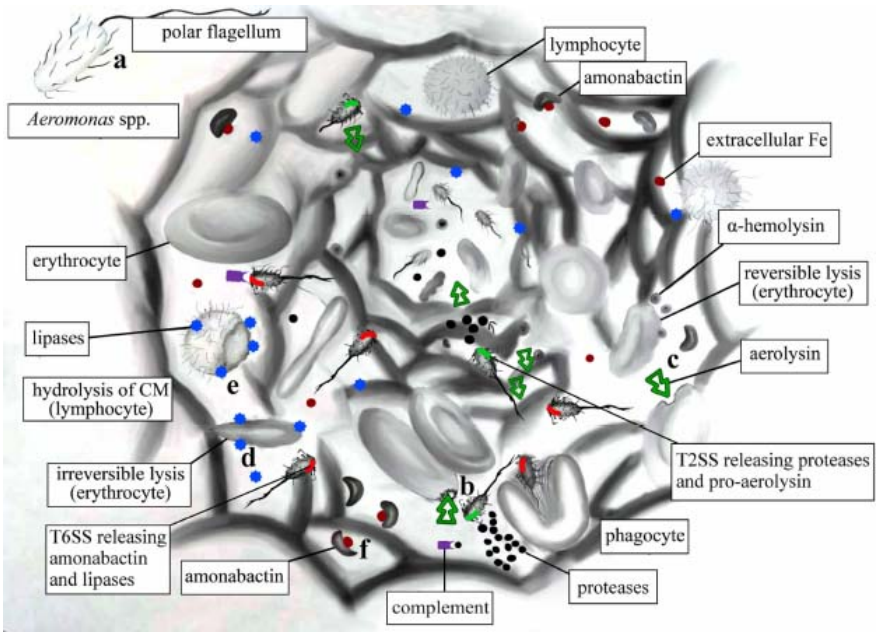

Figure 15.2 Potential role of virulence factors in *Aeromonas*-associated bacteremia. Aeromonads produce a single polar flagellum to aid in motility (a). T2SS releases proaerolysin and proteases, which may either act as activators of aerolysin or break down complement proteins (b). Mature aerolysin is a pore-forming enzyme causing complete lysis of red blood cells (c). Hydrolysis of lymphocytic membranes occurs via secreted lipases mediated by T6SS (d) and can cause irreversible erythrocyte lysis (e). Additionally, T6SS secrete iron-binding proteins (e.g., amonabactin) that enable acquisition of extracellular iron (f). Reversible lysis of erythrocytes may occur following α-hemolysin production. CM, cell membrane. Illustration by Cody Rasmussen-Ivey, Tibor Král, and S. Králová.

Originally, the genus was divided into two main categories (phenotypically and genotypically corresponding). The first category includes mesophilic and motile aeromonads, and the second, a more homogenous group, includes nonmotile psychrophilic species. DNA-DNA hybridization studies later differentiated at least 14 distinct hybridization groups (47). However, the term "hybridization group" is outdated, and its usage is relevant only in specific cases (e.g., unnamed taxonomic groups) (48). With regard to taxonomy, 16S rRNA analysis should be used cautiously due to the high degree of homology (98 to 100%) within 16S rRNA gene sequences among aeromonads, leading to discrepancies in *Aeromonas* phylogeny (47, 49). Additionally, a small number of 16S rRNA microheterogeneities (nucleotide polymorphisms) were detected, leading to inconclusive identification or misidentification, thus affecting *Aeromonas* species classification and taxonomic position (50).

A promising molecular tool for identifying novel *Aeromonas* species (e.g., *A. popoffii*, *A. molluscorum*, *A. bivalvium*, *A. tecta*, and *A. diversa*) is amplified fragment length polymorphism analysis (AFLP). Although AFLP groupings do not always correspond to those obtained with DNA-DNA hybridization studies (48), AFLP application can determine the taxonomic identities of *Aeromonas* isolates with different origins. To establish a more sensitive taxonomic approach regarding *Aeromonas* phylogeny, several housekeeping genes having greater divergence, such as *gyrB*, *rpoD*, *dnaJ*, *cpn60*, *recA*, and *gyrA*, are used either alone or in combination as a more powerful taxonomic tool (51). Currently, *Aeromonas* contains 31 validly described species (Table 15.2.), with three subspecies of *A. hydrophila*, five subspecies of *A. salmonicida*, and two biovars of *A. veronii* (52).

Table 15.2 Origins and dates of identification of *Aeromonas* species

Species	Year	Source
A. allosaccharophila	1992	Diseased eel
A. aquatica	2015	Lake water
A. australiensis	2013	Treated effluent used for irrigation
A. bestiarum	1996	Diseased fish

ISOLATION AND IDENTIFICATION

Many different transport media (e.g., Cary-Blair medium, Amies medium, modified Stuart's medium, and buffered glycerol in saline) for presumptive samples containing aeromonads (mostly stool) are available with good recovery at room temperature (7, 46). Aeromonads grow well for subsequent isolation on common laboratory media (e.g., Luria broth, tryptic soy broth, and Mueller-Hinton broth) and most enteric differential media, except for thiosulfate-citrate-bile salts-sucrose agar (11). However, growth on enteric media can be overlooked due to common microflora presenting as lactose-fermenting strains. Aeromonads can be recovered from nonenteric clinical samples by using various media based on the origin of the sample (e.g., Rimler-Shotts medium, starch-glutamate-ampicillin-penicillin-based medium, mAeromonas medium, *Aeromonas* agar, ampicillin-dextrin agar [ADA], and starch ampicillin agar); however, the use of enrichment procedures for recovery of *Aeromonas* spp. is not recommended (11). Ideal incubation temperatures vary between 25 and 30°C for environmental samples and between 25 and 37°C for clinical strains of *Aeromonas*. Isolation of *Aeromonas* spp. from food and water samples uses more standardized procedures utilizing starch-ampicillin agar and ADA for recovery of aeromonads after 24 h of cultivation at 30°C (53). Environment Protection Agency (EPA) standards under the Safe Drinking Water Act employ either direct plate count methods or membrane filtration techniques (54) in combination with selective and differential media such as ADA with vancomycin.

As a genus, *Aeromonas* is easily distinguished from other Gram-negative, facultative anaerobes (*Enterobacteriaceae*, *Plesiomonas*, and *Vibrio*) by a few simple phenotypic tests (Fig 15.3). Presumptive identification on selective and differential media is routinely followed by biochemical tests for species identification. Conventional tests, as well as miniaturized identification kits (API 20NE and 50E, Biolog, and MicroScan), are commonly used, although misidentification at the species level can occur (48). This is partially due to the increased number of new *Aeromonas* species and the lack of precisely determined physiologic traits among all species to ensure comparable results between different laboratories (7, 48).

Of the analytic, chemotaxonomic methods, fatty acid analysis (FAME) has been successfully used for *Aeromonas* identification from food (53). Another chemotaxonomic approach, matrix-assisted laser desorption ionization–time of flight mass spectrometry, successfully identified species with accuracy greater than 90% (55) and is currently one of the most rapid and accurate identification methods in routine laboratory use. However, only identification of biochemically typical strains has high accuracy (56).

The evolution of molecular methods (e.g., multiplex PCR, restriction fragment length polymorphism analysis-PCR, AFLP, quantitative PCR [qPCR], ribotyping, and the use of species-specific probes and primers) to identify either *Aeromonas* spp. or their virulence factors has

decreased the time for analysis; however, their accuracy, discriminatory power, and reproducibility differ substantially, and application of these approaches is more common for taxonomic purposes than for routine identification.

TOLERANCE TO ENVIRONMENTAL FACTORS ASSOCIATED WITH FOOD PROCESSING AND PRESERVATION

Bacterial contamination of food products can occur in multiple locations within a food processing plant and can have profound effects, including causing food spoilage as well as food-borne illnesses. A variety of measures affecting environmental conditions have been implemented within food processing and storage facilities to help minimize bacterial growth and biofilm formation.

Temperature, Osmotic Pressure, and pH

One of the easiest methods to control microbial contaminants in foods is heating and chilling of food, although *Aeromonas* spp. have demonstrated resilience, especially at cold temperatures. The ideal temperature for growth of the mesophilic species is ca. 25°C (57), and heat can kill *Aeromonas* spp. in culture media at 45°C and above. However, *A. hydrophila*'s thermal resistance in food, such as raw liquid eggs, is substantially greater than that of laboratory strains in culture media (58). Being resilient to colder temperatures, *A. hydrophila* retained viability for 14 days in milk, yogurt, and cheese at 4°C, even when cocultured with probiotics (59). This cold environment had minimal effects on expression of adhesion properties (HEp-2 cells) and virulence factors (e.g., cytotoxins, enterotoxins, and hemolysin) by *Aeromonas* isolates from various foods (e.g., chicken, lamb, and milk) (60). Although bacteria like vibrios may not survive freezing, *A. hydrophila*, *A. caviae*, and *A. veronii* have repeatedly been obtained from frozen foods, including 2 to 6% of beef (61), 10% of sausages (62), and 2 to 6% of fish (63), with *A. hydrophila* surviving in frozen tilapia for one year (64). Another treatment that can affect bacterial viability is providing a starvationlike state by methods such as washing bacterial cells with minimal nutrients. This stressful environment rendered *A. hydrophila* less susceptible to the effects of exposure to 10 to 15% ethanol and the bactericidal effects of prompt temperature fluctuations after being starved for 50 days in sterilized distilled water (65).

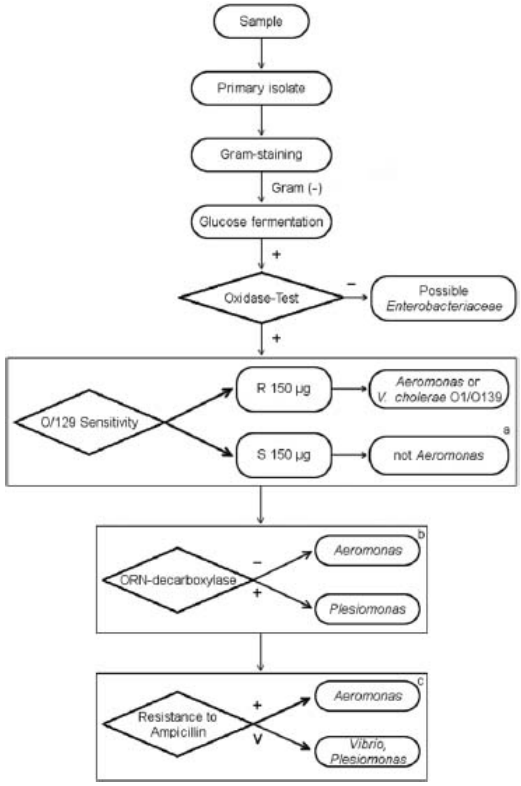

Figure 15.3 Preliminary identification scheme for *Aeromonas*. This flow chart can be used for rapid preliminary identification of aeromonads. Aeromonads are Gram-negative, facultative anaerobes, ferment glucose, and are positive for oxidase, which differentiates them from oxidase-negative *Enterobacteriaceae*. Distinguishing *Aeromonas* spp. from other oxidase-positive Gram-negative bacilli (i.e., *Vibrio* and *Plesiomonas*) is possible with the following test results: resistant to vibriostatic compound O/129 (150 µg 2,4-diamino-6,7-diisopropylpteridine), negative for ornithine decarboxylase (ORN-decarboxylase), and resistant to ampicillin (10 µg). +, positive reaction; –, negative reaction; v, variable result. a, some strains are sensitive to O/129 (150 µg) (161); b, except for rare ornithine decarboxylase-positive strains (162); c, except for *A. trota* (22).

Elevated NaCl concentrations can subject microbes to osmotic stress, with bactericidal effects. For aeromonads, up to 6% NaCl at 4°C is bacteriostatic, with lytic effects occurring as the temperature increases (66). NaCl at 2% impedes biofilm formation of aeromonads (67). Mesophilic *Aeromonas* spp. are sensitive to pH levels less than 6 or greater than 10 (68) and are even more sensitive to pH changes in the presence of sodium nitrite (69).

UV Light, Gamma Irradiation, Cold Plasma, and Hydrostatic Pressure

One of the limitations of typical PCR is differentiating viable from nonviable microorganisms when nucleic acid is amplified. However, new PCR modifications have resulted in viability PCR, which uses propidium monoazide to prevent PCR amplification from any free DNA or accessible DNA through damaged membranes. Another alternative molecular viability technique utilizes bacterial rRNA precursors to test viability through reverse transcription-qPCR (RT-qPCR), enabling species specificity and high sensitivity. Results obtained with RT-qPCR agree with those of culture techniques, demonstrating that 41 mJ/cm^2 of UV light (254 nm) resulted in complete inactivation at 30 seconds of an *A. hydrophila* culture of 1×10^8 CFU/ml (70).

A major challenge in the food processing industry is minimizing bacterial contamination that causes food spoilage. One potential treatment postpackaging is gamma irradiation, which is highly

bactericidal to both planktonic and biofilm growth of *A. hydrophila*, with decimal reduction values observed with application of less than 0.5 kGy (71). This treatment provided a 5-log reduction of aeromonads in mixed sprouts, chicken, fish (72), and frozen shrimp (receiving 3 kGy), supporting its efficacy postprocessing (73). Cold plasma technology can be used as a disinfectant, as a 15-second exposure reduced the population of planktonic *A. hydrophila* by 5 logs and a 15-min exposure inactivated *Aeromonas* biofilms on lettuce (74). Aeromonads are also quite sensitive to high hydrostatic pressure (i.e., 100 MPa) compared to other common foodborne pathogens (e.g., *Escherichia coli*, *Shigella*, *Listeria*, and *Salmonella*) (75).

Halogens, Ozone, and Modified Atmosphere

The World Health Organization has determined that most chlorinated drinking water contains free-chlorine levels between 0.2 and 1.0 mg/liter, with a maximum residual disinfectant safety level of up to 4 mg/liter (4 ppm) according to the EPA. Within U.S. public water systems, aeromonads were detected in 2.6% of 5,042 water samples, with *A. salmonicida* (28.2%) and *A. hydrophila* (24.6%) being the most prevalent species (76). *Aeromonas*-positive samples were more significantly associated with lower free-chlorine concentrations (0.02 mg/liter), whereas *Aeromonas*-negative samples correlated with higher free-chlorine levels (0.4 mg/liter) (76), further supporting the use of chlorine as a disinfectant in drinking water systems if adequate concentrations are maintained. Compared to *E. coli*, *Aeromonas* was more resilient to free chlorine (0.25 mg/liter), especially at 20°C, where there was more than 50% viability after 90 minutes of exposure, although lower temperatures (4°C) did increase sensitivity (77).

Ozone remains an effective treatment for treating both recirculating water from aquaculture ponds and wastewater as well as for preservation of food products. *A. salmonicida* populations in both lake water and seawater were reduced by 4 logs within 60 seconds by a treatment of 0.2 mg of ozone per liter (78). However, its use directly in aquaculture ponds may present a health risk to fish through oxidative stress (79); hence, its application would predominantly be restricted to water recycling and food processing. Packaging atmospheres of foods, especially fresh meat and poultry, can affect the level and diversity of microbial populations and thereby also affect the shelf life of food. Considering the ubiquitous nature of aeromonads and their proteolytic activities on foods (80), optimizing the packaging atmosphere to minimize their growth is critical, although the meat source, temperature, and presence of other microbial populations need to be considered.

RESERVOIRS AND LINKS TO WATER-AND FOODBORNE ILLNESS

With an estimated 48 million foodborne illnesses and 3,000 deaths per year (81), it is important to address the association of *Aeromonas* spp. with foodborne outbreaks. Considering its widespread nature, it is not surprising that *Aeromonas* spp. have been isolated from most types of foods, as well as drinking water.

Drinking Water

The primary reservoir for aeromonads is aquatic environments, including rivers, ponds, groundwater, lakes, estuaries, and seawater. Many aquatic aeromonads are psychrophiles, typically associated with poikilothermic animals. However, aquatic mesophilic aeromonads have been associated with cytotoxicity and clinical infections (82), thereby posing a risk to humans through aquatic recreational activities as well as drinking water. Associations with aquatic recreational activities involve near drowning events, with subsequent pneumonia caused by *Aeromonas* spp. (37, 38), as well as subclinical pediatric diarrhea and skin diseases. With regard to U.S. public water systems, *Aeromonas* spp. remain on the EPA's Contaminant Candidate List. When more than 3,000 human fecal specimens associated with gastroenteritis were analyzed for

pathogens, *Aeromonas* spp. were the most frequently recovered enteropathogen, with ingestion of treated and untreated water being the most probable source (83). As mentioned above, aeromonads are more resilient to free chlorine than most other aquatic enteropathogens (84). One of the challenges in controlling aeromonads is their ability to adhere to pipes and produce biofilms (85–87), making them more resistant to disinfectants, with the presence of the organic material of the biofilm reducing the disinfectant's efficacy. Biofilm formation within the water system presents an additional risk, namely, the exchange of antibiotic resistance genes via horizontal gene transfer (88), which creates increased challenges in clinical cases. Ma et al. determined that there were 84% more antibiotic-resistant genes in drinking water samples than in environmental samples (89). However, wastewater treatment plants harbor the highest prevalence of antibiotic resistance genes (89, 90), contributing to a growing global threat. Chlorinated effluent is rich in antibiotic-resistant isolates as well as aeromonads, with more than 25% of microbial isolates from effluent being resistant to five or more antibiotics (91). Considering that horizontal gene transfer between genera of *Enterobacteriaceae* and *Aeromonas* has already been demonstrated, aeromonads may serve as reservoirs of antibiotic resistance genes (92). Wastewater effluents are returned back to natural bodies of water, thereby allowing the resistant bacteria to colonize aquatic species as their next host (Fig 15.4).

Seafood

China, the United States, and Japan remain the leading consumers of seafood in the world, with the United States consuming 14.4 to 15.8 pounds per person per year from 2010 to 2015, of which 74% was fresh or frozen fish (93). As the world population increased 1.6% annually over the past 50 years, the rate of fish consumption doubled to 3.2%, leading to 31.4% of fish stocks being at biologically unsustainable levels. These trends have driven aquaculture to production of 73.8 million tons of fish and seafood in 2014, and the rate is growing at 5.8% annually (94).

One of the greatest risks for acquiring *Aeromonas* gastroenteritis comes from the consumption of raw and ready-to-eat seafood products. *Aeromonas* contamination of seafood most likely results from intestinal colonization while fish and shellfish reside in aeromonad-infested waters, which could lead to cross-contamination within food processing facilities. At seafood markets, *A. hydrophila* was isolated from 28 of 33 different table fish and 34% of 536 fish, which was a higher rate than the rate of isolation from shrimp (17%) (95). The predominant species, *A. salmonicida* (not a typical human pathogen), was isolated from 74% of sushi (74%), with *A. hydrophila*, *A. caviae*, and *A. dhakensis* each contaminating 2 to 5% of sushi. Most of these *Aeromonas* isolates encoded at least four of the five virulence factors associated with gastroenteritis (i.e., Act, Alt, Ast, HlyA, and AerA) (96). *Aeromonas* spp. pose a risk not only with finfish but also with oysters, crabs, and shrimp, where they reside in biofilms that create a greater safety hazard for consumption because of the difficulty in removing the aeromonads from the seafood (97).

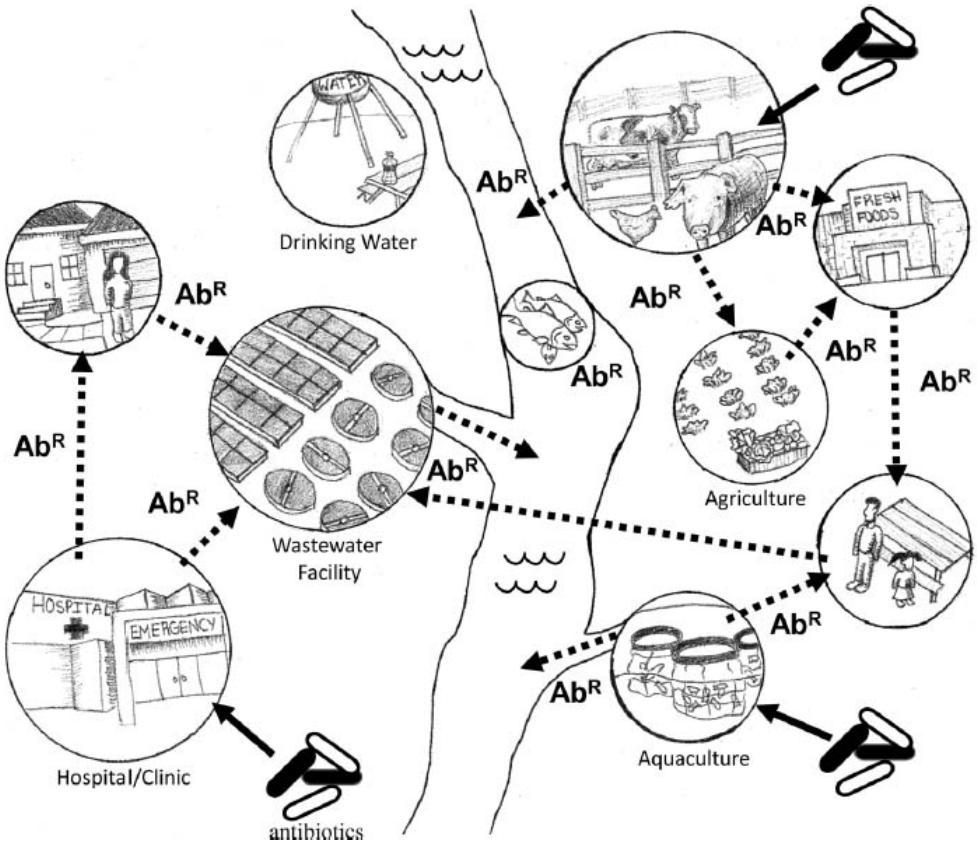

Figure 15.4 Cycle of antibiotic resistance within aeromonad reservoirs. The widespread occurrence of aeromonads contributes to their ability to colonize cold-and warm-blooded animals, both aquatic and terrestrial. The use of antibiotics prophylactically and clinically provides environments with subinhibitory concentrations of antibiotics, creating stress that can lead to resistance. Solid arrows represent the entrance of antibiotics, and dashed arrows represent pathways of transmission of antimicrobial resistance (Ab^R). Illustration by Andrew Albers and T. Skwor.

The innate immune response of teleosts is more elaborate and effective than that of mammals; however, stresses predispose fish to bacterial diseases. Considering that *Aeromonas*-associated fish diseases are opportunistic infections, it is critical to minimize changes in water temperatures and pH and concentrations of ammonia and organic matter, as well as overcrowding. *A. salmonicida* subsp. *salmonicida* is the most prominent species associated with furunculosis, which predominantly affects salmonids, although the disease also presents in nonsalmonids such as Atlantic cod, eel, halibut, carp, and goldfish (98). Infection initiates through colonization of the gills, the dorsal and pectoral fins, and possibly the oral and nasal cavities, with subsequent spreading in the internal organs (99). For more than 100 years, this species has been recognized as a cause of furunculosis, and it has plagued fish farms since the 1950s. Even though protective vaccines are available, the absence of their widespread use and varying degrees of efficacy for different fish strains render them problematic. Instead, aquaculture utilizes antibiotics as a prophylactic treatment, leading to increased levels of antibiotic resistance. In fish farms, 10% of *A. salmonicida*-associated furunculosis isolates were resistant to the antibiotics trimethoprim and sulfonamide, which are used clinically in humans to treat furunculosis (100). The resistance genes from freshwater farm aeromonads are already evident in recipient bay seawater farms, highlighting the risks associated with antibiotic use in aquaculture. Furthermore, these resistant strains have been identified in fish sold in fish markets, revealing their link to the human gut

microbiome (101) (Fig 15.4). Acquisition of antibiotic resistance genes escalates when aeromonads thrive in subinhibitory concentrations of antibiotics. Oxytetracycline, the most common drug utilized in aquaculture, is sensitive to prompt photodegradation, with only a 25-min half-life (102, 103), thus potentially exposing aeromonads and other fish gut microflora to subinhibitory concentrations. Food processing poses yet another environmental risk for the transmission of antibiotic resistance genes. Kruse et al. determined that *E. coli* on a cutting board underwent transconjugation with an R-plasmid-containing *A. salmonicida* strain from an infected salmon after processing (104). Some alternative treatments in lieu of prophylactic antibiotic treatment to protect fish stocks in farms include biofiltration utilizing oysters (105), use of probiotics (106), immunostimulation and vaccination (107), and phage therapy (108).

Meat

There are three risks associated with *Aeromonas* spp. and land animal meat: (i) the potential of contaminated food to cause gastroenteritis, (ii) the possibility of increased food spoilage, and (iii) the creation of a reservoir for antibiotic resistance genes. Animals carry *Aeromonas* spp. as part of their intestinal flora; hence, good sanitation during meat processing as well as food preparation is important. Frequently, contamination is introduced by *Aeromonas*-contaminated water that is used for carcass washing, although in developed countries, inadequate sanitation of household cutting boards predominates (109). *Aeromonas* spp. commonly occur on retail meats, including beef, chicken, lamb, duck, buffalo, sheep, pigs, and sausage (61, 109, 110). Bacterial contamination can play a role in meat spoilage, including producing foul odors and proteolytic and lipolytic activities. Wang et al. identified *A. salmonicida* and *A. hydrophila* as contaminants on chicken breast meat, contributing to sarcoplasmic and myofibrillar proteolytic degradation (80) as well as producing lipolytic activity, which adversely affected the organoleptic properties of meat (111). Overall, *A. hydrophila* is the predominant aeromonad contaminant associated with meat and meat products (109).

Aeromonads as part of the microflora in animals are at risk for the acquisition of antibiotic resistance. In the 1950s, it was discovered that antibiotics can serve as growth promoters of livestock, initiating an era of overuse and increasing antibiotic-resistant bacterial populations within livestock (109), including some that are resistant to last-resort antibiotics (e.g., colistin) (110). Using metagenomics, Ma et al. identified antibiotic resistance gene arrangements shared between pig, chicken, and human fecal isolates (112), revealing an interplay between agriculture and humans (Fig 15.4). Direct interactions with animals, consumption of contaminated meat, and exposure through other environmental factors indirectly mediate the link between these two groups.

Milk and Dairy Products

Raw milk continues to be analyzed for coliform numbers to evaluate safety measures, as *A. hydrophila* and *A. caviae* are frequent contaminants (113), and their lipase production accelerates spoilage (114). Melas et al. detected *Aeromonas* spp. in 41% of raw cow and 35% of ewe's milk samples, as well as in 10% of cheese samples, with the predominant species being *A. hydrophila*. Importantly, pasteurization did eliminate the *Aeromonas* contamination (113). All dairy products can potentially be contaminated, including yogurt (59) and ice cream (115), from which *A. hydrophila* and *A. caviae* have been isolated, respectively.

Most *Aeromonas*-associated dairy contamination is with cow's milk. The association of *Aeromonas* spp. with human breast milk is rarely studied. Considering that breast milk is recommended as the sole nutritional source for infants subsequent to birth, the microbial communities in breast tissue and milk are important in preventing dysbiosis. More than 20% of women are at risk of acquiring mastitis, supporting the importance of identifying microbial

populations associated with acute and subacute infections. Using culture-independent techniques, Patel et al. (116) detected elevated *Aeromonas* spp. in breast milk from women suffering from acute mastitis (16% of sequences obtained) compared to levels in healthy lactating women. The species in mastitic samples included the human pathogenic species *A. veronii*, *A. hydrophila*, and *A. caviae*, whereas *Acinetobacter baumannii* predominated in the milk from healthy women (116). The risk of disease in infants of mothers producing mastitic milk was not determined in this study; however, Qamar et al. (117) conducted a casecontrol study that revealed that 18.7% of diarrheal stool samples from infants (0 to 11 months) were positive for *Aeromonas* spp., which was significantly higher than the rate in healthy controls. This study also determined that infantile *Aeromonas*-associated diarrhea was inversely proportional to breastfeeding (odds ratio, 0.4), further supporting the importance of infants' receiving healthy breast milk (117).

Fruits and Vegetables

Many factors during pre-and postharvest periods contribute to the risks of microbial contamination of fruits and vegetables. During the preharvest period, spray irrigation with nonpotable water can present major risks of bacterial contamination (118). Additionally, abrasions of fruits and vegetables after harvest or during processing increases the sites for bacterial colonization and the potential formation of biofilms; hence the emphasis on postharvest washings. To minimize microbial contamination, washing with chlorine is a common practice. Produce that has been determined to be contaminated by *Aeromonas* spp. includes alfalfa sprouts, asparagus, celery, broccoli, peppers, redand green-leaf lettuce, and spinach (118). Most of these isolates were *A. hydrophila* and *A. caviae*, with 100% of the *A. hydrophila* strains being cytotoxic. These isolates grew between 5 and 35°C (119), highlighting the importance of properly cleaning produce before it is shipped to restaurants and grocery stores.

VIRULENCE FACTORS

Microbial pathogenesis depends not only on being genetically equipped but also on the expression of virulence factors during the host-pathogen interaction. While some virulence factors are present constitutively (e.g., lipopolysaccharide), others are induced only under certain biological conditions (e.g., specific temperatures, tissues, and nutrient concentrations), often resulting in specific pathogenic processes (diarrhea, septicemia, wound infection, etc.). *Aeromonas* spp. are equipped with many virulence factors that have various roles in their pathogenesis (Fig 15.1 and 15.2)

Flagella and Pili

Pathogenic bacteria typically use flagella to promote colonization and invasion of the host tissue. Mesophilic aeromonads possess genes for both polar and lateral flagellar systems, whereas psychrophilic aeromonads are frequently nonflagellated. Motility through liquid is accomplished by a single polar flagellum, whereas an inducible flagellar system with multiple lateral flagella is essential for swarming over surfaces (120). Both systems are essential for enterocyte adherence and biofilm formation (120).

Another filamentous structure, the pilus, serves as a potential colonizing factor, enhancing adherence to host tissues, and is involved in bacterial conjugation, enabling horizontal gene transfer. *Aeromonas* pili have two morphotypes. The predominant form is short and rigid and is involved in autoaggregation between bacteria (121). The other morphotype is a thin, long, and flexible pilus, which mediates adherence to enterocytes; this feature is common among all clinically relevant *Aeromonas* strains associated with diarrheal infections (122).

Degradative Enzymes

Most aeromonads elaborate a variety of extracellular enzymes, such as proteases, lipases, collagenase, nucleases, amylases, chitinases, and elastase. These degradative enzymes may contribute to overall virulence; however, their specific roles in pathogenesis have yet to be determined.

Aeromonads secrete a wide range of proteases that are associated with tissue damage, enhanced invasivity, complement inactivation, and nutrient recycling (123, 124). They include heat-labile serine protease, heatstable metalloprotease, EDTA-sensitive and -insensitive metalloproteases, and fibrinolytic protease (123). Additionally, aminopeptidases can degrade exogenous peptides, activate cytotoxic enterotoxin (Act) and aerolysin (AerA), cleave the terminal methionine from newly synthesized peptides, and stabilize plasmids (123, 125). Serine protease (68 kDa; caseinolytic) and metalloprotease (60, 44, and 31 kDa; elastolytic and caseinolytic) are secreted predominantly during the late stationary phase and are lethal for fish (126). Nitta et al. successfully purified and characterized serine protease from *A. veronii* (65 kDa; proteolytic) (127). Its bioactivity produced α-thrombin from prothrombin, which converts fibrinogen to insoluble fibrin, thus establishing direct involvement in septic shock by promoting disseminated intravascular coagulation. Additionally, it induces vascular leakage, thereby lowering blood pressure with subsequent edema and septic shock (128).

In addition to proteases, aeromonads produce various lipases. These lipolytic enzymes provide bacteria with nutrients, destroy leukocyte membranes (Fig 15.2) and other eukaryotic cells, and generate free fatty acids affecting the immune system (124). Additionally, a glycerophospholipid-cholesterol acyltransferase isolated from *A. hydrophila* and *A. salmonicida* lyses red blood cells through membrane disruption (123, 129).

Collagenases enhance the invasivity of bacterial pathogens through the degradation of collagen. *A. hydrophila* and *A. veronii* both encode these enzymes, which play roles in their pathogenesis (130). Another important virulence factor of *A. hydrophila* is elastase, which hydrolyzes elastin and casein (131). Insertional inactivation of the elastase gene *ahpB* increased by a hundred times the 50% lethal dose for rainbow trout compared to wild-type controls. Deleting the nuclease gene *ahn* from strains of *A. hydrophila* attenuated their pathogenicity in both fish and mice. The biological effects of the *ahn* protein include nucleic acid recycling, protection against foreign exogenous DNA (i.e., bacteriophage) (123), and immunologic evasion, supporting an involvement in systemic dissemination (132).

Hemolysins and Aerolysin

Hemolysins are a group of multifunctional enzymes contributing to pathogenicity (123). Aeromonads possess several hemolysins (AerA, HlyA, Ahh1, and Asa1) that are divided into two classes, α-and β-hemolysins. The α-hemolysins cause incomplete or reversible lysis of erythrocytes, whereas the β-hemolysins (such as aerolysin) are pore formers in cell membranes and lead to complete erythrocyte lysis (Fig 15.2) (123). The most abundant aeromonad hemolysin is a heat-labile hemolysin (encoded by *ahh1*) which has increased hemolytic activity when coexisting with aerolysin A (encoded by *aerA*) (133).

Aerolysin, identified in the early 1970s, is one of the best-characterized aeromonad virulence factors (134). It is initially produced as an inactive preproaerolysin form with a protein signal sequence that is subsequently eliminated upon translocation through the inner cytoplasmic membrane. Proaerolysin (52 kDa), the form without the signal sequence, is secreted as an inactive soluble monomeric or dimeric form (134). Subsequent removal of the C-terminal peptide (135) produces a mature form which binds to a glycosylphosphatidylinositol-anchored protein receptor on red blood cells or enterocytes (136). Once it is bound, aerolysin heptamers form aqueous β-

barrel channels into cell membranes, leading inevitably to cell death (137). In mice, *aerA* mutations in strains of *A. hydrophila* significantly impaired pathogenicity, resulting in >100-fold-higher lethal doses (138). Mechanisms of action can be attributed to its apoptotic induction in murine T cells, aiding in immune evasion (139), to endoplasmic reticulum calcium release within granulocytes through the G-protein signaling pathway (140), or to severe vacuolation of endoplasmic reticulum in enterocytes (141). Together, these observations indicate that aerolysin seems to be required for establishment as well as subsequent maintenance of systemic infections (141).

Enterotoxins

Aeromonads encode three major enterotoxins, namely, cytotoxic enterotoxin (Act), heat-labile cytotonic enterotoxin (Alt) and heat-stable cytotonic enterotoxin (Ast). Although numerous *Aeromonas* spp. carry these genes, their production is limited due to regulation dependent on growth conditions. Cytotoxic enterotoxin (Act) is a single-chain, cholesterol-binding, pore-forming 52-kDa toxin exhibiting cytotoxicity in red blood cells and intestinal epithelial cells (121, 142). As is typical for enteric pathogens, Act evoked a secretory fluid response in a rabbit ligated intestinal loop model and induced lethality in mice (143). Act production is growth condition dependent, with calcium elevating promoter activity, while glucose and iron induce attenuation (130).

Cytotonic enterotoxins primarily act on intestinal epithelium in a cholera toxin-like fashion, increasing cyclic AMP (cAMP) levels and prostaglandins (124). *Aeromonas* spp. contain a variety of cytotonic enterotoxins, including Alt and Ast, although these toxins differ in their cross-reactivity with cholera antitoxins (144). The heatstable enterotoxin of *A. veronii* and Ast of *A. dhakensis* cross-react with cholera antitoxin, whereas *A. hydrophila* heat-stable (15-to 20-kDa) and heat-labile (40-to 44-kDa) Alt enterotoxins lack this interaction. Immunization with heat-labile Alt (56°C for 10 min) reduced fluid secretion after *A. hydrophila* infection in a mouse ligated ileal-loop model (144). Clinically, 23 of 31 aeromonad isolates from a foodborne outbreak after consumption of raw, fermented fish encoded Alt (145). Similar to Alt, the heat-stable (100°C for 30 min) cytotonic enterotoxin Ast increased cAMP levels (146). Together, these two toxins act synergistically, strongly impacting the overall virulence of aeromonad-induced gastroenteritis (147).

Shiga-like toxins (encoded by s*tx1* and *stx2*), which were analyzed in only a few studies, have been identified in over 60% of clinical strains of aeromonads, with 64 of 66 strains carrying at least one *stx* gene. Coculturing cell-free aeromonad supernatants with neutralizing STX1 or STX2 antibodies reduced or completely inhibited cytotoxic phenotypes in Vero cells, thereby establishing their pathogenic role (148). However, other studies revealed a substantially lower prevalence of *stx* genes among *Aeromonas* isolates (149), suggesting that additional studies are needed.

Biofilms

Biofilms are a major problem in the food industry because of their resilience to disinfectants. Their development consists of three steps: (i) irreversible microbial adhesion to a surface or substrate; (ii) proliferation with extracellular polysaccharide production and subsequent genomic regulation, progressing to three-dimensional biofilm maturation; and (iii) dispersal of biofilm. Foodrelated environmental stresses can influence biofilm formation: *A. hydrophila*, *A. caviae*, and *A. veronii* produce substantially more biofilms in colder (10°C compared to 37°C) and more acidic (pH ~5) environments. Food preservatives, such as 0.4% potassium sorbate, significantly increase biofilm formation as well (67). Once a mature biofilm is formed, it becomes more resilient to desiccation, starvation, and disinfectants. The ability to form a biofilm on stainless steel in a food processing facility may threaten the entire food stock associated with the factory. *Aeromonas* spp. have been isolated from a slaughterhouse and a cheese-making factory, where they synthesized

biofilms on stainless steel disks (150), both at room temperature (20°C) and at 4°C, with *A. caviae* having the greatest resistance to treatment with amphoteric surfactants and diamines (86).

When a rabbit ileal-loop method was used, human diarrheal isolates of *A. caviae* were shown to produce thick biofilms within the ileal and colonic mucosa. Initial adherence was mediated via lateral flagella, with subsequent bacterial aggregation leading to biofilm formation, which strengthens tissue adherence, traps more nutrients, accumulates more bacteria, attenuates phagocytic activation and migration by masking pathogenassociated molecular patterns, and alters virulence gene regulation through quorum sensing.

Secretion Systems

Due to the difficulty of crossing two phospholipid bilayers in Gram-negative bacteria, some bacteria have evolved multiple secretion systems that transport virulence factors outside the cell. These proteins are involved in a diverse array of activities, including host immune evasion, invading mammalian cells (potentially resulting in tissue damage), injecting proteins into other bacteria or eukaryotic cells, and adapting to and acquiring nutrients from the environment. *Aeromonas* spp. possess type II, type III, type IV, and type VI secretion systems (T2SS, T3SS, T4SS and T6SS), although there is species variation (151). These secretion systems are required for the release of many of the virulence factors mentioned in this chapter.

Proteins secreted via T2SS must first pass through a Sec or Tat secretion system in the inner membrane. Once in the periplasm, folded virulence factors are passed through the T2SS to its extracellular space (152). *Aeromonas* T2SS secrete aerolysin, the aerolysin-related cytotoxic enterotoxin Act, amylases, DNases, and proteases (151).

Unlike T2SS, T3SS has an injectisome that secrets proteinaceous substrates from the bacterial cytoplasm to the eukaryotic cytoplasm, making it possible for them to cross the inner and outer membranes of bacteria and the eukaryotic cell membrane. There is a high prevalence of T3SS among clinical *Aeromonas* isolates (153), although T3SS is regulated by environmental factors such as the host cell, temperature, and quorum sensing. Mutations within T3SS subunits result in attenuated pathogenic phenotypes. Virulence factors secreted through T3SS include the ADP-ribosylating toxin AexT, the actin disrupter and apoptosis inducer AopO, the inflammatory suppressors AopN and AopP, and the pore formers AopB and AopD (154). Other T3SS-secreted proteins of unknown virulence status include the putative tyrosine phosphatase AopH, inositol polyphosphate 5-phosphatase (Ati2), the putative serine/threonine kinase AopO, and the regulator of T3SS genes ExsE (154). ExsE upregulates lateral flagella; thus, it is involved in host cell adhesion (155).

Similar to T3SS, the T4SS apparatus can transfer molecules through bacterial and eukaryotic cell membranes; however, it is ancestrally related to bacterial conjugation and thus is capable of transferring plasmid DNA containing antibiotic resistance and virulence genes as well as protein. T4SS are unique secreting proteins that remodel host cells to aid in bacterial survival and replication, as well as uptake or transfer of DNA in a contact-dependent or -independent manner (152). They have been identified only in *A. veronii* and *A. caviae*, with the latter having been obtained from hospital effluent (98).

T6SS nanostructures, like T3SS, are more evident in clinical strains than environmental isolates, suggesting a role in virulence (153); however, similar to all of the secretion systems discussed above, they are not obligatory for disease. Additionally, many strains do not carry all 13 subunits needed for a functional T6SS apparatus. Their effector proteins target a range of different molecules, including peptidoglycan on other bacteria, lipases, amidases, glycoside hydrolases, pore-forming toxins, and proteins aiding metal ion uptake. T6SS aids cell-cell communication, therefore playing a role in biofilm formation and responsiveness to quorum sensing (156).

The critical role of secretion systems in disease highlights them as potential targets for new alternative treatments inhibiting them, such as curcumin (157).

Other Virulence Factors

Unique to Gram-negative bacteria, lipopolysaccharide consists of a core lipid A structure and O-specific polysaccharide. The lipid A portion acts as an endotoxin, eliciting local inflammation, which can lead to sepsis (124), whereas O antigen is an important colonizing factor and the basis for *Aeromonas* sp. serotyping (151). Some strains of *A. hydrophila* (e.g., serovars O:11 and O:34) and *A. salmonicida* are capable of capsule production, but only under certain conditions, such as glucose enrichment (158, 159). These capsules serve as virulence factors due to their complement resistance, ability to aid in adherence and biofilm formation, and ability to mask potential cell wall receptor ligands, thereby promoting antiphagocytic activity (158). Additionally, psychrophilic as well as mesophilic aeromonads produce a surface protein layer (S-layer) augmenting similar virulence phenotypes (124).

Iron acquisition is essential for both the host and pathogen. Inside the host organism, most iron is sequestered intracellularly and is bound within iron-carrying proteins or in metal-protein complexes. To overcome iron starvation, mesophilic *Aeromonas* spp. produce two types of low-molecular-weight peptides called siderophores to acquire free iron within the host organisms. These are enterobactin (also produced by other Gramnegative bacteria) and amonabactin (found only in aeromonads) (124). Psychrophilic strains, in contrast, utilize iron-specific outer membrane receptors in a siderophore-independent manner (160).

CONCLUSIONS

Aeromonas as a genus represents many challenges for food and medical microbiologists, diagnostic laboratories, and clinicians. Their ubiquitous nature, adaptation to stressful environmental conditions, ease of acquiring antibiotic resistance, and possession of various virulence factors make *Aeromonas* spp. important contaminants and opportunistic pathogens. Although there has been some debate in the past as to whether *Aeromonas* spp. are true enteropathogens, this chapter provides support for this role by noting many gastroenteritis outbreaks from water and a variety of foods, as well as describing many virulence factors that have been characterized through animal models. Food and water are the two major sources of contamination that pose a risk of acquiring gastrointestinal infections.

Pathogenic strains of *Aeromonas* have been obtained from many foods, including milk, chicken, and seafood. Their contamination is not only a public health concern, because of the potential for acquiring a gastrointestinal infection, but also a food spoilage concern, because of their production of lipases and proteases, which substantially shorten food shelf life. The persistence of aeromonads on refrigerated and frozen foods challenges this type of food preservation. Additionally, this microbe's ability to form biofilms provides an additional level of resistance to disinfectants, desiccation, and starvation. Within food processing environments, aeromonad biofilms that develop on surfaces can also serve as sources of recontamination.

The natural habitat of *Aeromonas* spp. is the aquatic environment, including freshwater, seawater, and brackish waters. Contaminated drinking water, especially when untreated, is the most direct source of infection. However, the resilience of aeromonads to low levels of chlorine and their ability to form biofilms within water treatment systems pose challenges to maintaining safe drinking water. Their ubiquitous presence in rivers, lakes, and seawater has an indirect effect on foods, where psychrophilic species can cause disease in fish in aquaculture or their native environment, thus adversely affecting food economics.

Whether the organisms are present in food or water or in human microflora, the antibiotic resistance acquired by aeromonads merits special attention. An example is when members of the genus *Aeromonas* acquired chromosomal β-lactamase genes, resulting in resistance to the broadspectrum antibiotic ampicillin, now used as a selective agent. The widespread occurrence of aeromonads establishes them in environments (e.g., wastewater treatment facilities, aquaculture, and mammalian gut microbiota) containing subinhibitory antibiotic concentrations, providing ideal conditions for horizontal gene transfer, including intergenus transfer. Prophylactic and clinical overuse of antibiotics in aquaculture, agriculture, and human medicine has led to *Aeromonas* strains becoming resistant to antibiotics of last resort, such as colistin (110).

For all of these reasons, more research is needed to further elucidate the pathogenicity and foodborne-illness potential of *Aeromonas* spp. More effective practices for treating food and water to reduce aeromonad contamination and proper identification from sources of infection and their corresponding clinical samples are examples of future research needs.

Yersinia enterocolitica

Yersinia enterocolitica is a Gram-negative, non-sporeforming, non-toxin-producing, facultatively anaerobic, rod-shaped bacterium. Its growth temperature ranges from −2 to 42°C, and it is classified in the family *Enterobacteriaceae*. Only three *Yersinia* species (*Yersinia pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica*) are pathogenic for humans, and the distribution of *Y. enterocolitica* in the environment is diverse (Fig 16.1). Foodborne *Yersinia* species are transmitted to humans by the oral route and can cause intestinal symptoms, such as abdominal pain, diarrhea, and fever. They are found worldwide, with a higher prevalence in countries with temperate and cold climates (1).

CELL METABOLISM

Y. enterocolitica is motile at 25°C but loses its motility at 37°C. It is a facultative anaerobe that anaerobically uses glucose as an energy source through fermentation:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2 + 2ATP$$

Most strains also reduce nitrates. When they are artificially cultured in laboratory settings, lactose fermentation is inhibited by the addition of bile salts in some growth media. When cultured in triple sugar iron medium, *Y. enterocolitica* produces urease but loses its ability to produce hydrogen sulfide (2). Coenzyme B12 is needed to break down 1,2-propanediol for carbon and energy utilization, and it is produced only anaerobically (3). *Y. enterocolitica* uses iron as a growth factor without producing a chelator, which is usually

necessary for the process. Most prokaryotic microorganisms acquire iron through an iron chelator known as a siderophore. *Y. enterocolitica*, however, uses siderophores from other bacteria for its iron uptake process. For example, it uses deferoxamine that is produced by *Streptomyces pilosus*. The pathogenicity of *Y. enterocolitica* is positively correlated with iron utilization. The need for iron varies among different strains of *Y. enterocolitica*, which affects their degree of virulence (2).

GENOME STRUCTURE

Y. enterocolitica strain 8081 has been sequenced and determined to have a circular DNA chromosome of 4,615,899 bp. The number of coding sequences is 4,037, with 7 rRNA operons and 81 tRNAs. The GC content of the chromosome is 47.27%. The average gene size is 968 bp, and the chromosome contains 60 insertion sequence elements and 4 prophage regions. In addition to the chromosome, *Y. enterocolitica* has four plasmids, i.e., pYVe8081, p29807, pYVa127/90, and pYVe227, which are 67,721, 2,682, 66,591, and 69,673 nucleotides, respectively, in length (3). *Y. enterocolitica* needs both the chromosome and a plasmid to be pathogenic, because the chromosome and the pYV pathogenic plasmid contain genes necessary for virulence. The virulent strains contain plasmids that carry genes for the low-Ca21 response, which is needed for pathogenicity (4). The unique features that distinguish the *Y. enterocolitica* genome from genomes of all other *Yersinia* species are the coenzyme B12 biosynthetic (*cbi*) and 1,2-propanediol degradation (*pdu*) genes. These gene clusters are located on a genomic island that is about 40 kb in size.

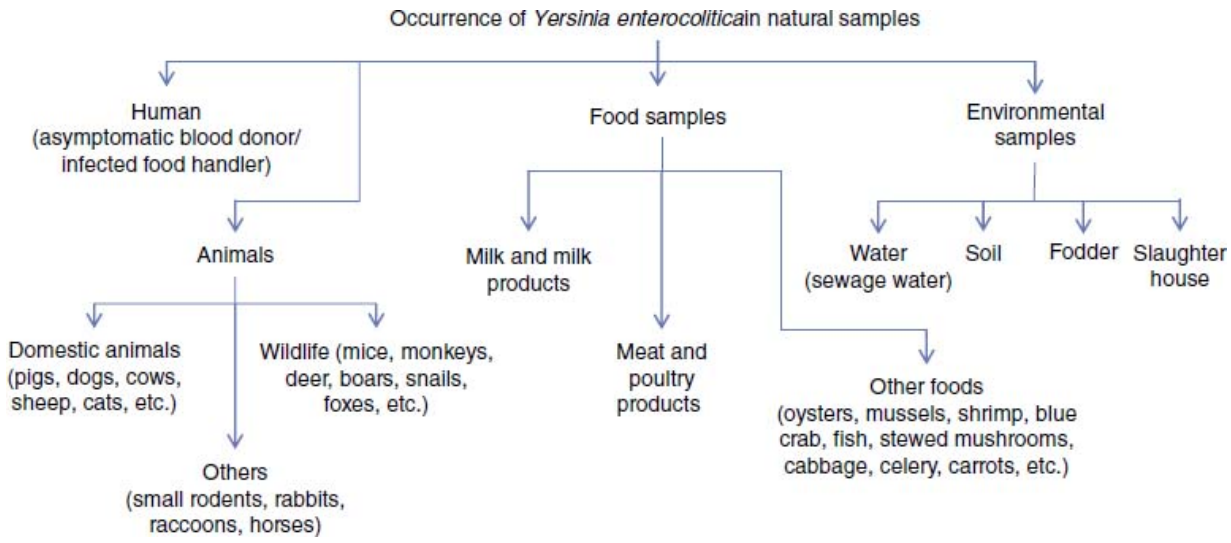

Figure 16.1 Sources of *Yersinia enterocolitica*. Adapted with permission from reference 23.

ASSOCIATION OF *Y. ENTEROCOLITICA* WITH FOODS

Food is a known source of *Y. enterocolitica* infection, although pathogenic isolates have seldom been obtained from food samples, with the exception of raw pork products. The low rates of isolation of pathogenic *Y. enterocolitica* from food samples are due to the limited sensitivity of culture methods, which have been largely used to obtain yersiniae from foods (5). PCR methods, which have not been used in many studies, have higher rates of *Y. enterocolitica* detection in raw pork products than culture methods (5). However, the isolation of pathogenic bioserotypes of *Y. enterocolitica* from raw pork is not common, except for edible pig offal, with the most common isolate being bioserotype 4/O:3 (Table 16.1.). Most studies addressing the detection and isolation of *Y. enterocolitica* in foods have focused on pig meat products (Table 16.1.). More studies are needed to determine the association of *Y. enterocolitica* with produce, because produce is grown in soil, and *Y. enterocolitica* can survive in soil (Fig 16.1). Soil, insects, animals, and humans can frequently come into contact with fruits and vegetables during their

growing, harvesting, and processing stages. Hence, their surfaces can be contaminated with soil-borne microbes such as *Y. enterocolitica*.

YadA is a collagen-binding outer membrane protein adhesin factor of *Y. enterocolitica*. Fredriksson-Ahomaa and Korkeala (6) determined the prevalence of *yadA*positive *Y. enterocolitica* in food in Finland, finding the highest prevalence in pig offal, including pig tongues (83%), livers (73%), hearts (71%), and kidneys (67%). Interestingly, the rate of detection in minced meat was greater with the PCR method than with the culture method (Table 16.1.). Ail is also an outer membrane protein adhesin factor of yersiniae. Thisted Lambertz and Danielsson-Tham (7) detected *ail*-positive *Y. enterocolitica* in 10% (9/91) of raw pork samples (loin, fillet, chop, ham, and minced meat) and in one of 27 ready-to-eat pork products. Vishnubhatla et al. (8) detected a high prevalence of *yst* (heat-stable enterotoxin)-positive *Y. enterocolitica* in ground beef. In the same study, *yst*-positive *Y. enterocolitica* was also detected in tofu by real-time PCR. These PCR results reveal that the rate of contamination of *Y. enterocolitica* in pork and other processed meats and foods is underestimated by culture methods. No pathogenic *Y. enterocolitica* was detected in fish or chicken samples in Finland but was detected in three (3%) lettuce samples. In Korea, Lee et al. (9) isolated one *ail*-positive *Y. enterocolitica* strain of bioserotype 3/O:3 from 673 ready-to-eat vegetables, revealing that vegetables may be a source of human infection. Sakai et al. (10) described a *Y. enterocolitica* O:8 outbreak in Japan in which the isolates from patients and salad had a similar pulsed-field gel electrophoresis pattern. Interestingly, Favier et al. (11) isolated *Y. enterocolitica* 2/O:9 from chicken eggshell surfaces in Argentina. The XbaI patterns from pulsed-field gel electrophoresis analysis of these isolates revealed genomic heterogeneity among the strains, suggesting that contamination came from different sources. Contamination of the egg surface might have occurred from direct or indirect contact with feces of other *Y. enterocolitica*-contaminated farm animals, such as pigs,

during collection of the eggs on farms, during transportation, or via handling in retail shops.

Table 16.1 Detection of pathogenic *Y. enterocolitica* in naturally contaminated samples using PCR and culture methods[a]

		No. (%) of samples

[d] Liver, heart, and kidney.

[e] Except pig offal and tongues.

FACTORS INFLUENCING SURVIVAL AND GROWTH

Y. enterocolitica is a facultatively anaerobic bacterium, having the ability to multiply under both aerobic and anaerobic conditions. The bacterium can survive in water at 4°C for up to 64 weeks and at freezing temperatures (12).

Temperature

The ability of *Y. enterocolitica* to multiply at low temperatures is a food safety concern. Its growth temperature range is from −2 to 42°C, with an optimum growth temperature of 28 ± 1°C (12). *Y. enterocolitica* can multiply at refrigeration temperature considerably more rapidly than *Listeria monocytogenes* (12). For example, in a food at neutral pH held at 5°C, *Y. enterocolitica* populations can increase from 10 CFU/ml to 2.8×10^7 CFU/ml in 5 days. Examples of thermal inactivation rates (D_T, where D is time and T is temperature) for *Y. enterocolitica* are as follows: $D_{55°C}$ = ~2 min, $D_{60°C}$ = ~0.5 min, and $D_{65°C}$ = ~2 s.

pH

The minimum pH for growth of *Y. enterocolitica* is 4.2 ± 0.2 at 22°C (12). The presence of organic acids reduces the ability of *Y. enterocolitica* to grow at low pH, and certain organic acids can completely inhibit growth at a low pH at which other less restrictive acids allow growth to occur. For example, acetic acid is more inhibitory than lactic and citric acids per gram-mole at a given pH, and the order of bactericidal activity of these acids is as follows: acetic acid > lactic acid > citric acid > sulfuric acid.

Water Activity

The minimum water activity (a_w) at which *Y. enterocolitica* can grow is 0.96. Salt (NaCl) can limit or prevent growth or inactivate

the bacterium. For example, *Y. enterocolitica* can grow in 5% salt but not in 7% salt, depending on the incubation temperature. At <3°C, 7% NaCl is bactericidal to the pathogen, and at 25°C it is bactericidal or bacteriostatic. The pathogen is inactivated in 9% NaCl at 25°C (12).

Preservatives and Growth Inhibitors

Potassium sorbate at pH 6.5 inhibits the growth of *Y. enterocolitica* in a dose-dependent manner up to 5,000 ppm, and concentrations of >1000 ppm at pH 5.5 completely inactivate yersiniae. Sodium nitrite at 150 ppm inhibits growth of *Y. enterocolitica* on bologna. Modifiedatmosphere packaging with 100% N_2 and a combination of gases (e.g., CO_2-N_2) inhibits yersiniae growth during storage at refrigeration temperature (12).

Y. enterocolitica can grow in vacuum-packed foods during refrigerated storage. However, it does not survive pasteurization or normal cooking, including boiling, baking, and frying temperatures. Several studies have revealed that *Y. enterocolitica* can multiply in foods held at refrigeration temperature and can compete well with the natural microflora of foods (1). For example, *Y. enterocolitica* at 10^4 CFU/g grew in the presence of 10^4 to 10^5 CFU/g of lactic acid bacteria at 8°C in vacuumpackaged cooked ham and sausage, whereas these lactic acid bacteria inhibited the growth of *L. monocytogenes* and *Escherichia coli* in the same experimental studies. Interestingly, growth of *Y. enterocolitica* O:9 was greater under anaerobic than aerobic conditions at 4°C in the presence of 1% lactic acid at pH 3.9 to 5.8 (12).

Pig carcasses are often chilled in rooms for 2 to 4 days after slaughter and prior to cutting. In addition, prepackaged raw meat products may remain in retail chilling cabinets for more than a week, depending on the product, packaging, package atmosphere, and rate of turnover. Pathogenic variants of *Y. enterocolitica* can propagate during this relatively long storage period. The growth of *Y. enterocolitica* is influenced by the package atmosphere. Under

anaerobic conditions, *Y. enterocolitica* is unable to grow in beef at pH 5.4 to 5.8, whereas growth can occur anaerobically at pH 6.0 (12). In 100% CO_2, *Y. enterocolitica* growth is inhibited. In vacuum-packed meat, *Y. enterocolitica* grew at all storage temperatures more rapidly than the spoilage microflora. In CO_2 packs, the bacteria could grow at both 5 and 10°C but not at lower temperatures. Growth of *Y. enterocolitica* was inhibited at both 4 and 10°C in a 60% CO_2–0.4% CO mixture, whereas the numbers of yersiniae in samples packed in a high-O_2 mixture (70% O_2–30% CO_2) increased from ca. 5×10^2 CFU/g at day 0 to 10^4 CFU/g at day 5 at 4°C and to 10^5 CFU/g during storage at 10°C. Growth in chub packs (stuffed in plastic castings) was even greater. Yersiniae inoculated into pasteurized milk at 10 or 1,000 CFU/ml grew to levels of 5.0 to 7.0 log CFU/ml after 7 days (12) at refrigeration temperature (13).

YERSINIOSIS

Yersiniosis is an infection largely associated with eating raw or undercooked pork contaminated with *Y. enterocolitica*. In the United States, *Y. enterocolitica* is estimated to cause approximately 117,000 illnesses, 640 hospitalizations, and 35 deaths annually (14). *Y. enterocolitica* infections have been observed on all continents, but they appear to be most prevalent in Europe (68). Foodborne outbreaks of yersiniosis are rare, and most occur sporadically withoutan apparent source (15). Cases of yersiniosis are sometimes severe, leading to prolonged acute infections, pseudoappendicitis, and long-term sequelae, such as reactive arthritis (ReA) and erythema nodosum. Secondary immunologically induced sequelae, such as ReA, are common, especially in HLA-B27-positive individuals. The prevalence of *Y. enterocolitica* O:3/O:9-specific antibodies in healthy blood donors is relatively high in Finland (31%) and Germany (43%), as determined by an immunoblotting technique (16, 17), suggesting a high rate of subclinical yersiniosis in healthy populations. Gastrointestinal symptoms of yersiniosis range from mild self-limiting diarrhea to acute mesenteric

lymphadenitis, which can lead to appendicitis (18, 19). Gastroenteritis caused by *Y. enterocolitica* is the most frequent form of yersiniosis, typically affecting infants and young children. The clinical manifestations of infection depend to some extent on the age and physical state of the patient, including the presence of underlying medical conditions and the biotype or pathotype of the organism. In older children, acute yersiniosis can manifest as a pseudoappendicular syndrome and is frequently confused with appendicitis. Sometimes it is followed by long-term sequelae, including ReA, erythema nodosum, uveitis, glomerulonephritis, and myocarditis. Sepsis is a rare complication of *Y. enterocolitica* infection and usually occurs during blood transfusions, especially in patients with predisposing underlying disease, as seen mostly in an iron-overloaded state (20).

Foodborne Yersiniosis

Foodborne yersiniosis is primarily a zoonotic gastrointestinal disease, like campylobacteriosis and salmonellosis, but is not as frequently reported (21). In Europe, outbreaks of yersiniosis are rare, but sporadic cases attributed to *Y. enterocolitica* are often reported (22). In England and Wales, the number of reported cases of yersiniosis in humans is lower than in other European countries (23). In 2005, fewer than 0.1 case of yersiniosis per 100,000 individuals was reported in the United Kingdom, compared to 12.2 cases in Finland and 6.8 cases in Germany (21). A higher prevalence of gastrointestinal illness, including fatal cases of yersiniosis, has been reported in developing countries, suggesting the need for further investigation of this bacterium as a food safety issue worldwide (24, 25).

Although pathogenic strains of *Y. enterocolitica* have infrequently been isolated from foods, foodborne outbreaks of yersiniosis have occurred (26). An important property of this bacterium is its ability to multiply at temperatures near 0°C, which allows it to survive and grow in many chilled foods. Sabina et al. (27) reported that different serotypes predominate in different countries. For example, in

China, serotype O:3 is primarily associated with infections, followed by O:9 and O:8, whereas the predominant serotype in Australia, Europe, and Canada is O:3, that in Japan is O:8, and that in Scandinavia and the Netherlands is O:9.

Epidemiologic Studies, Outbreaks, and Transmission

Indirect evidence suggests that swine are an important reservoir of *Y. enterocolitica* and the principal source of human infections. In case-control studies, a correlation between the consumption of raw or undercooked pork and the prevalence of yersiniosis has been reported (12, 15, 23, 28, 29). Serotyping methods have been used to subtype *Y. enterocolitica* strains to identify sources of infections and transmission vehicles (Table 16.2.).

In addition, several methods have been used to detect and obtain *Y. enterocolitica* from the environment (Fig 16.2). Conventional and molecular detection methods are the two most widely reported for epidemiologic studies. However, the most commonly used methods have been conventional methods, which are dependent on culture-based procedures and biochemical and serological identification. The efficacy of these methods depends on certain substrates in the assay media which can influence survival and growth, isolation, and identification (Fig 16.2). Thus, many factors related to the epidemiology of yersiniosis, such as sources and transmission routes, need further elucidation using more robust methods. Although animals, especially swine, have been identified as reservoirs for *Y. enterocolitica* and, hence, have been reported as principal sources of human infections (15, 23), most of the strains isolated from many animal sources differ both biochemically and serologically from strains isolated from humans with yersiniosis. *Y. enterocolitica* strains that belong to bioserotypes associated with human disease have frequently been isolated from the tonsils and fecal samples from slaughtered pigs. In several countries, *Y. enterocolitica* bioserotype 4/O:3, a pathogenic bioserotype, is the predominant bioserotype in asymptomatic pigs. Occasionally, bioserotype 4/O:3 has been isolated from dogs and cats (30), and

dogs harbor and excrete this *Y. enterocolitica* bioserotype in their feces for weeks after infection, suggesting that dogs and cats may be sources of human infections. *Y. enterocolitica* strains of biotypes 2 and 3 and serotypes O:5, 27, and O:9 have sporadically been isolated from slaughtered pigs, cows, sheep, and goats; however, the reservoir of these bioserotypes is not definitively established (31–33). In addition, wild rodents and pigs have been shown to be reservoirs for *Y. enterocolitica* O:8 strains in Japan (34).

Table 16.2 Epidemiologic studies of human infection with *Y. enterocolitica*[a]

Year(s)	Country	Description	Reference
1981–1990	Republic of Georgia	Report of 84 clinical isolates of *Y. enterocolitica*; the most frequently reported serotypes were O:5, O:10,46, and O:6,30.	92
1982–1991	The Netherlands	Analysis of clinical information from 261 Dutch patients with gastrointestinal infections caused by *Y. enterocolitica* serotypes O:3 and O:9	93
1982[b]	Canada	Outbreak of gastroenteritis among hospitalized patients associated with *Y. enterocolitica* serotype O:5	94
1982–1985	Canada	Examination of 125 isolates of *Y. enterocolitica*; serotypes O:7,8, O:5, and O:6,30 were frequently obtained from symptomatic patients.	95
1983	Finland	Report of 46 fecal isolates of *Y. enterocolitica*, including two serotypes (O:7 and O:6) associated with occurrence	77
1984[b]	Bangladesh	Case report of a fatal diarrheal illness associated with serotypes O:7 and O:8	96
1984[b]	Hong Kong	Report of *Y. enterocolitica*-associated septicemia in four patients regarding serotypes O:17	97
1984–1985	United Kingdom	Report of two nosocomial outbreaks of *Y. enterocolitica*	98

		serotype O:10 and O:6 infections in hospitalized children	
1986[b]	United Kingdom	Case report of nosocomial transmission of serotype O:6,30 associated with gastroenteritis	99
1986–1992	Canada	Report of 79 symptomatic children with culture-proven infection, including serotypes O:5, O:6,30, and O:7,8	100
1987	United Kingdom	Report of 77 *Y. enterocolitica* strains from patients, including serotypes O:6,30 and O:7	101
1987–1988	Australia	Report of 11 cases of *Y. enterocolitica* enteritis, including most frequently serotype O:6,30	102
1987–1989	Chile	Prospective case-control study of infants with diarrhea in Chile, showing a significant rate of reported serotypes O:6, O:7,8, O:7, and O:10	103
1988–1991	Nigeria	Of nine strains of *Y. enterocolitica* obtained from stool samples of children with diarrhea, six belonged to biotype four, serotype O:3.	104
1988–1993	New Zealand	Of 918 isolates of *Y. enterocolitica* from symptomatic patients, 98% were recognized human pathogens, with biotype 4, serotype O:3 being the most frequently recovered.	105
1968–2000	Brazil	Of 106 strains, 71 were bioserotype 4/O:3, isolated from human and animal clinical material, and 35	106

		were biotype 1A or 2, isolated from food.	
2002	Iran	Report of 8 cases of *Y. enterocolitica* infection out of 300 children with acute diarrhea aged 0–12 years who were attending a pediatric hospital in Tehran	107
2002–2004	Nigeria	Detection of *Y. enterocolitica* belonging to bioserotype 2/O:9 in investigating 500 human samples	24
2004	Japan	Report of food poisoning due to *Y. enterocolitica*	
2005–2006	Norway	Investigation of an outbreak involving 11 persons infected with *Y. enterocolitica* O:9	89
2001–2008	Germany	Almost 90% of *Y. enterocolitica* strains were diagnosed as serotype O:3.	108
2009[b]	Iraq	Identification of three children with diarrhea caused by *Y. enterocolitica* infection	25
2009	Australia	Report of 3 outbreaks due to consumption of roast pork contaminated with *Y. enterocolitica*	109

[b] Year(s) of publication.

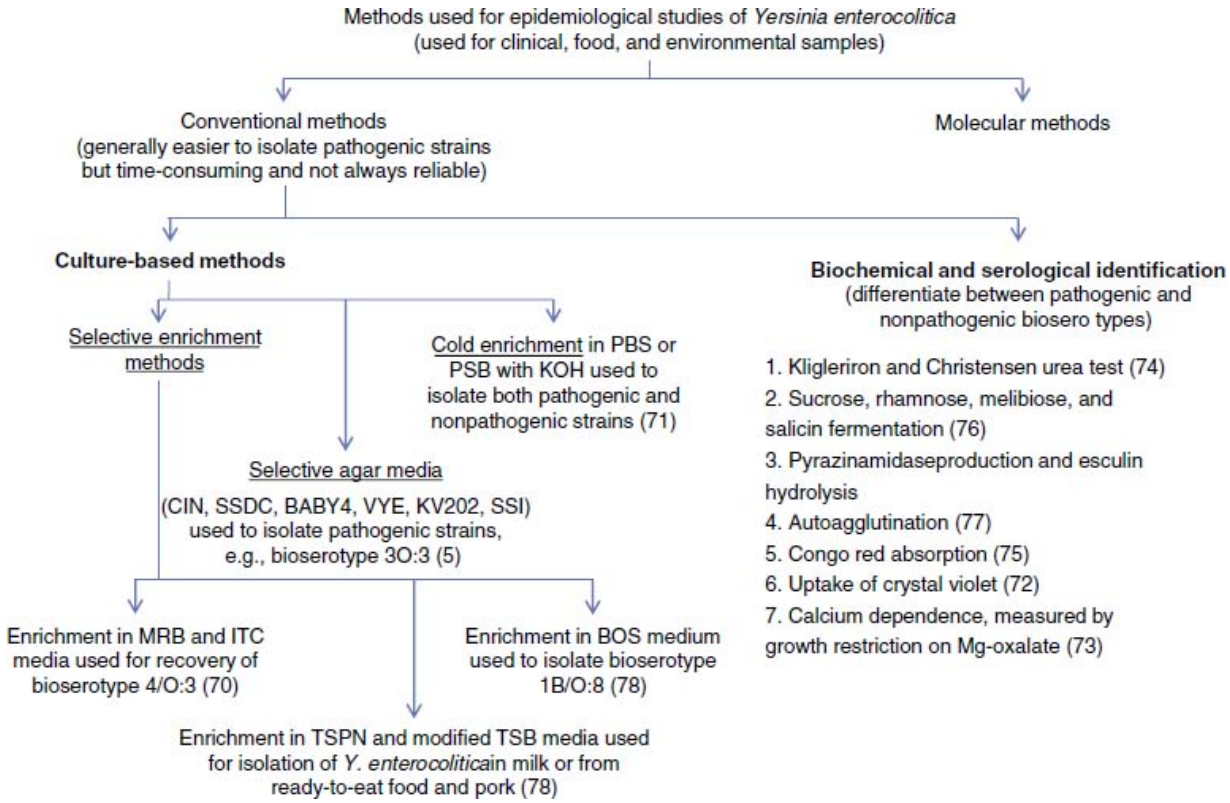

Figure 16.2 Methods used for epidemiological studies of *Y. enterocolitica* 1. Numbers in parentheses are reference numbers. Selective enrichment methods (70), selective agar media (5), a cold enrichment method (71), and biochemical and serological identification methods (71–78) are listed. BOS, bile-oxalate-sorbose medium; CIN, cefsulodin-irgasan-novobiocin; ITC, modified Rappaport base supplemented with irgasan, ticarcillin, and potassium chlorate; MRB, modified Rappaport broth containing magnesium chloride, malachite green, and carbenicillin; PBS, phosphate-buffered saline; PSB, phosphate-buffered saline with sorbitol and bile salts; SSDC, *Salmonella-Shigella* deoxycholate calcium chloride; SSI, Statens Serum Institut (Copenhagen, Denmark) enteric medium; TSB, tryptic soy broth; TSPN, TSB with polymyxin and novobiocin; VYE, virulent *Y. enterocolitica*. Adapted with permission from reference 23.

Strains of very rare bioserotypes, such as bioserotype 5/O:2,3, were isolated from sheep, hares, and goats, and bioserotype 3/O:1,2a,3 has been isolated from chinchillas (35). All of the environmental

isolates except one had a NotI profile identical to that of an isolate recovered from pig feces from the same farm. This suggests that the environment also represents a vehicle of *Y. enterocolitica* contamination from pigs. However, the prevalence of pathogenic *Y. enterocolitica* in the environment was lower than that in pigs. Several studies using different typing methods have been conducted to compare human strains with animal, mostly swine, isolates. Most of the results reveal that pigs are the main source of human *Y. enterocolitica* infections (31, 33).

VIRULENCE FACTORS

Y. pestis and *Y. pseudotuberculosis* have nearly identical chromosomal DNA sequences and are distantly related to pathogenic *Y. enterocolitica* (36, 37). Among the 11 species that make up the genus *Yersinia*, only *Y. pestis*, *Y. enterocolitica*, and *Y. pseudotuberculosis* are pathogenic for humans. These three species cause quite diverse diseases (37). *Y. enterocolitica* and *Y. pseudotuberculosis* induce gastroenteritis when consumed in contaminated food and have been isolated from patients with diarrhea. *Y. pestis* is the agent of bubonic plague and can cause oropharyngeal plague as a result of the consumption of inadequately cooked infected goat and camel meat or handling of meat from infected animals (15, 38, 39). The risk, morbidity, and mortality of contracting plague through consumption of food deliberately contaminated with *Y. pestis* are currently unknown but potentially real.

Y. pestis, *Y. enterocolitica*, and *Y. pseudotuberculosis* possess a range of virulence factors that aid attachment to host cells or tissues, causing dysfunction of host cells. Several researchers have reported that three plasmids are involved in the virulence of *Y. pestis*: pYV (virulence plasmid, 70 kb; Yops, or type III secretion system [T3SS]), pFra/pMT1 (96.2 kb; murine toxin, phospholipase, or F1 capsule-like antigen), and pCP1/pPst/pPla (9.6 kb; plasminogen activator) (40, 41). Among these plasmids' products,

the pYV-encoded T3SS (Yops) promotes cytotoxicity, leading to the common symptoms of plague, whereas the pYV plasmids of all three species are of the same size and genetically highly conserved (41). Once injected into the host cell cytoplasm, YopE, -H, -P, and -T cooperatively disrupt the cytoskeleton of epithelial cells, macrophages, and dendritic cells, thereby decreasing their capacity to engulf the invading bacteria. YopP/J can also facilitate evasion of adaptive immune responses by inhibiting the ability of dendritic cells to present antigens to $CD8^+$ T cells (42), either directly or possibly by decreasing the population of dendritic cells via induction of apoptosis (43–45). A similar strategy is employed by *Y. pseudotuberculosis* using the GTPase-activating protein YopE to circumvent phagocytosis by dendritic cells (42, 46). In addition to the *Yersinia* injectisome and effector proteins, at least three adaptor proteins—YopB, YopD, and VirF/LcrV (low-calcium-response V antigen)—are required for T3SS activity. VirF/LcrV (also called V antigen) is a multiple adaptational response family member that regulates the T3SS at the level of transcription and, when secreted into the extracellular host environment, contributes to virulence by downregulating inflammation (47).

Yersinia infections are biphasic and are initiated by a “quiet” 36-to 48-hour period of bacterial replication without a measurable host response. This initial quiet phase is followed by an influx of activated phagocytes into infected tissues and lymph nodes, which induces an acute inflammatory response characterized by cytokine production and tissue necrosis (48–51). The T3SS Yop effectors are likely responsible for the initial inhibition of phagocytic functions, but the mechanisms affecting such a sudden, bipolar “off-on” inflammatory response are presently not fully understood. The T3SS is absolutely required for effective colonization of systemic organs, and T3SS inactivation leads to rapid clearance of the bacteria by the host (52). As a result, yersiniae lacking a functional T3SS are avirulent and can function as live attenuated vaccine strains in mice (52–54).

T3SSs are not the sole secretion systems identified in the yersiniae that promote bacterial virulence. A type VI secretion system (T6SS) was recently identified in *Y. pseudotuberculosis*, which harbors four copies, one of which is regulated by temperature, growth phase, and the *N*-acyl homoserine lactone (AHL)-dependent quorum-sensing system, including the type IV pilus gene cluster, which contributes to pathogenicity (55). However, more studies are needed to elucidate the period of bacterial replication in a host cell leading to the disease state.

The Yops are *Yersinia* outer proteins that provide yersiniae the ability to target lymph tissues during infection and have genetic determinants responsible for infection and overcoming host defense mechanisms (36, 41). YopH, a protein tyrosine phosphatase, disrupts T-cell and Bcell activation by interfering with phosphorylation signaling events, resulting in decreased expression of the costimulatory molecules B7.2 and CD69, as well as the leukocyte mitogen interleukin 2 (IL-2) (56). Very little is known about YopM, but its deletion results in a dramatic decrease in virulence (57). YopM appears to be injected into host cells along with other T3SS effector proteins, but there is also evidence that YopM can bind to the extracellular acute phase protein α 1-antitrypsin (58).

All human-pathogenic *Yersinia* species harbor an approximately 70-kb virulence plasmid, which carries a set of genes whose transcription is activated at 37°C in the presence of millimolar concentrations of calcium (59). Virulence factors found on the surface of *Y. pseudotuberculosis*, *Y. enterocolitica*, and *Y. pestis* are shown in Fig 16.3. All three pathogens share Ail, YadB, and YadC, which are important to adhesion. However, only Pla is unique to *Y. pestis*, whereas YadA and invasin are important adhesins in *Y. pseudotuberculosis* and are also invariably expressed by *Y. pestis*.

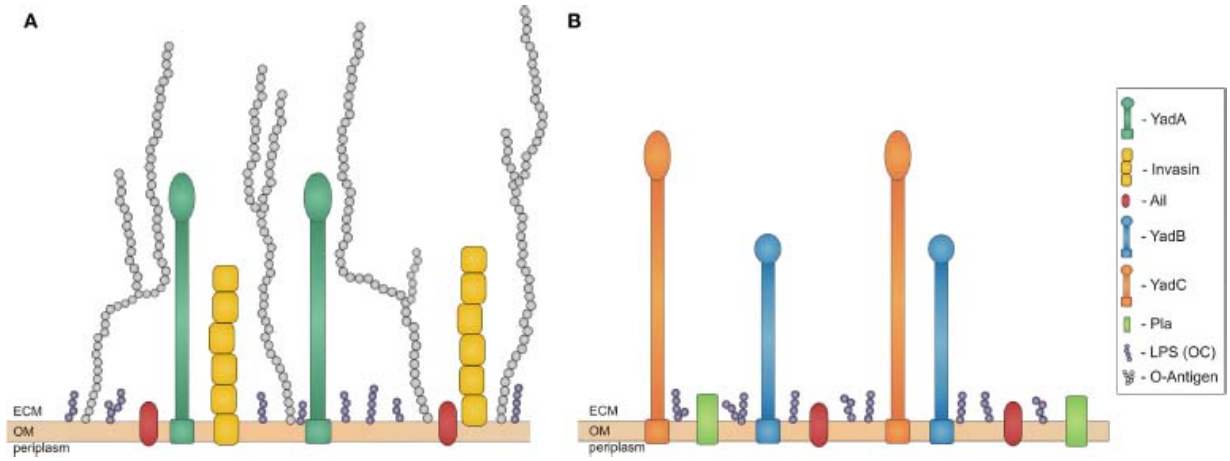

Figure 16.3 Virulence factors on the surface of *Y. pseudotuberculosis*, *Y. enterocolitica* (A), and *Y. pestis* (B). Invasin, YadA, Ail, and O antigen are shared by *Y. enterocolitica* and *Y. pseudotuberculosis* (YadB and YadC are absent from panel A for clarity), whereas Pla is unique to *Y. pestis*. YadA and invasin are important adhesins in *Y. pseudotuberculosis* and *Y. enterocolitica* but are not expressed by *Y. pestis*. Reprinted from reference 79.

Yersinia virulence determinants vary, but the most studied are those secreted via a T3SS. For yersiniae to efficiently deliver Yops into the host, it is essential that they adhere to the host cell surface and remain in close association during the delivery process. Apart from the T3SS virulence plasmid, two other plasmids that are unique to *Y. pestis*, pPCP and pMT (sometimes referred to as pFra), possess additional virulence factors. pPCP encodes the plasminogen activator Pla protease/adhesin (Fig 16.3). Pla converts plasminogen to plasmin (60), which then degrades extracellular matrices and confers on *Y. pestis* the ability to rapidly invade the host and migrate to lymphatic tissues (61). To ensure that this is possible, the yersiniae produce other virulence factors in addition to the T3SS. An active T3SS can deliver effector proteins into the host cell cytosol only if the bacterial cells make direct contact with, and bind tightly to, the host cell surface. Over the last 30 years, several chromosomally encoded or plasmid-encoded protein virulence factors have been identified that play a variety of roles in host cell attachment prior to effector protein injection. In each case,

attachment is not the exclusive function, and not all are present or active in all three human-pathogenic *Yersinia* species. However, a combination of these proteins confers the ability to adhere to and invade host cells or bind sufficiently to ensure successful T3SS delivery of Yops.

Invasin is a chromosomally encoded protein that mediates attachment to and entry into host cells by *Y. pseudotuberculosis* and *Y. enterocolitica*, although in *Y. pestis*, it is a pseudogene and therefore inactive (59). Invasin also promotes internalization in small intestine epithelial cells by binding to host cell target receptors known as β1-integrins that are present on the host cell surface. The integrins form clusters, resulting in the rearrangement of the host cell cytoskeleton, which promotes phagocytosis, ultimately leading to the internalization of the bacteria in the epithelial cells. Invasin has a greater (up to 100 times) affinity for some integrins than its natural ligand, fibronectin (59). The authors also reported that such strong associations are believed to be the major contributing factors influencing how internalization occurs and how Yop is delivered into host cells. Also, pYV is responsible for the calcium-dependent growth phenotype at 37°C. When pYV-bearing cells are cultivated in low-calcium or calcium-deficient media, they elicit a Mg^{2+}-dependent low-calcium response, resulting in the production of pYV-encoded virulence-associated antigens (LcrV and LcrW), including release of a series of proteins (Yops) (62). The low-calcium response is expressed phenotypically on solid media by the formation of pinpoint colonies (36, 41, 62). The pYVassociated virulence determinants include colony morphology and size, the low-calcium response, crystal violet binding, Congo red uptake, autoagglutination, hydrophobicity, mannose-resistant hemagglutination, expression of surface fibrils, and serum resistance (36, 41, 62). However, the expression of these physiological traits at 37°C also leads to the loss of pYV and the concomitant disappearance of the associated phenotypes.

MODE OF TRANSMISSION

The most common route for transmission of pathogenic *Y. enterocolitica* is fecal to oral via contaminated food. Direct person-to-person contact is not commonly recognized, but Lee et al. (63) reported *Y. enterocolitica* O:3 infections in infants who were likely exposed to infection by their caregivers. This may happen when basic hygiene and handwashing practices are inadequate. Indirect person-to-person transmission has been reported and occurs largely by transfusions of contaminated blood (20). However, transmission to a person having direct contact with pigs, a common risk factor for pig farmers and slaughterhouse workers, has also occurred. The main known sources of human infection are the consumption of contaminated pork and pork products. It has been established that pathogenic *Y. enterocolitica* can be transmitted from slaughterhouses to meat processing plants and then to the retail environment through contaminated pig carcasses and offal (64, 65). Cross-contamination of offal and pork can occur directly or indirectly via equipment and air and food handlers in slaughterhouses (66), retail shops (65), and residential kitchens.

The detection rate of pathogenic *Y. enterocolitica* in raw pork products is comparatively high, but because consumption of raw pork is not common in most developed countries, it is not likely a major direct source of yersiniosis. However, in Germany, raw minced pork with pepper and onion is considered a delicacy that can be purchased as a ready-to-eat product at butcher shops (86). This could be a source of infection if the product is contaminated. This is reinforced by a study in which the predominant genotype of *Y. enterocolitica* recovered from pig heart, liver, kidney, tongue, and ear samples was also found in a cat whose diet consisted mostly of raw pig hearts and kidneys (12). In addition, a dog which was fed raw minced pork excreted the genotype found in the minced meat (12). These findings further substantiate the idea that raw pork contaminated with *Y. enterocolitica* is a food safety concern.

CURRENT RESEARCH FINDINGS

Studies are under way to determine the effect of IL-12p40 on ReA, a chronic condition resulting from an infection with *Y. enterocolitica* (67, 68). IL-12 is a cytokine with two subunits, p40 being one of them. Mice with an IL-12p40 deficiency generally have defective immune systems. This research addressed the involvement of *Y. enterocolitica* antigens and Toll-like receptor (TLR) expression in causing ReA. TLR binds to portions of yersiniae that elicit arthritis. Understanding the mechanism of ReA development may enable the discovery of a treatment for this condition. It was determined that the Peyer's patches of IL-12p40-deficient mice were infected with substantially more yersiniae and contained higher levels of TLR than those of *Y. enterocolitica*-infected wild-type mice. These findings suggest that the absence of IL-12p40 contributes to ReA due to the inability of the host to remove *Y. enterocolitica* effectively (67, 68). The incomplete removal of bacteria triggers TLR expression, which leads to articular inflammatory response (69).

Another study attempted to determine if there was a relationship between the presence of food and the production of AHL, a quorum-sensing signal molecule, by *Y. enterocolitica*. Results revealed that AHLs are preferentially produced by *Y. enterocolitica* in fish and meat but inhibited in vegetables, suggesting that quorum sensing enables *Y. enterocolitica* to take up nutrients and to possibly reside in specific environments (69).

CONCLUSIONS

Y. enterocolitica is a zoonotic pathogen that can cause yersiniosis in humans and animals. Pigs are a main source of human yersiniosis. There have been challenges with associating *Y. enterocolitica* from clinical specimens with food and environmental samples. For example, because of the weak discriminating power of bioserotyping methods, which typically identify within a bioserotype a high degree of similarity between *Y. enterocolitica* isolates and the predominant

genotypes of *Y. enterocolitica*, such methods have limited usefulness in epidemiologic studies. Furthermore, conventional culture-dependent methods for isolating yersiniae from foods have several limitations, such as low sensitivity, long incubation times, and a lack of discrimination between pathogenic and nonpathogenic strains. With PCR-based assays, pathogenic *Y. enterocolitica* can be detected in natural samples relatively rapidly and with a high degree of specificity. Recently, several real-time PCR assays for qualitative detection of *Y. enterocolitica* in clinical, food, and environmental samples have been developed. However, to date, a PCR-based method has been applied in only a few reported epidemiologic studies.

Y. enterocolitica is the major cause of yersiniosis in humans, although *Y. pseudotuberculosis*-associated disease is likely underreported due to lack of surveillance and differences in the isolation strategies applied. Extreme heterogeneity among strains of *Y. enterocolitica* and *Y. pseudotuberculosis* further complicates efforts to link illnesses to the source and monitor human disease in a systematic manner comparable to that used for other, more thoroughly studied foodborne pathogens (e.g., *Salmonella*). In healthy individuals, the resulting illness can manifest as mild, self-limiting diarrhea, but in young children and immunocompromised individuals, yersiniosis can represent a significant source of morbidity and mortality. Additionally, chronic diseases, such as ReA, and secondary (or nosocomially derived) complications, such as sepsis, can develop in immunocompromised persons. Very little is known about yersinia-associated autoimmune disease and other chronic conditions. Two pathogenic strains (1B/O:8 and 3/O:9) of *Y. enterocolitica* have been sequenced, and their DNA sequences have been compared (3, 17) to gain insight into virulence mechanisms required to initiate infection and cause acute symptoms or chronic conditions in patients. Yersiniosis surveillance efforts concentrate almost exclusively on *Y. enterocolitica*, making attempts to accurately estimate the incidence of *Y. pseudotuberculosis*-associated gastroenteritis difficult. Presently, enteropathogenic

yersiniae cases are likely underestimated. Implementing a more robust global surveillance system would improve our understanding of yersiniosis trends and help identify which agricultural, hygienic, and clinical controls are most effective in reducing the incidence of yersiniosis.

Listeria monocytogenes

Listeriosis has emerged as a major foodborne disease during the past 40 years, after a 1981 outbreak of listeriosis in Nova Scotia, Canada, was traced to contaminated coleslaw (1). However, the discovery of the causative agent of listeriosis, *Listeria monocytogenes*, dates back to the mid-1920s, when E. G. D. Murray and James Pirie independently reported detailed descriptions of listeriosis in small animals (2). A fascinating account of the discovery of *L. monocytogenes* has been compiled by Jim McLauchlin (3). The first documented retrospective case of human listeriosis involved a soldier who suffered from meningitis at the end of World War I, and there is a suggestion in the literature that listeriosis may have been the cause of Queen Anne's 17 unsuccessful pregnancies (4).

Between 1930 and 1950, only a few human listeriosis cases were reported. Today, the estimated incidence of listeriosis in most developed countries is 2 to 5 cases per 1,000,000 population, with nearly 1,600 cases estimated to occur annually in the United States (5). The emergence of listeriosis during the past 50 years is the result of complex interactions between various factors reflecting changes in social patterns. These factors include the following:

- improvements in medicine, public health, sanitation, and nutrition that have resulted in increased life expectancy, particularly in developed countries
- the greatly increased population of immunocompromised individuals at increased risk of listeriosis and other diseases as a result of the increased use of immunosuppressive medications for the treatment of malignancies, management of organ transplantations, and autoimmune diseases, as well as the ongoing epidemic of AIDS
- changes toward centralized and more consolidated food production and processing, the ever-expanding national and international distribution of foods, and increased use of refrigeration as a primary means of food preservation
- changes in food habits, including increased consumer demand for preservative-free, fresh-tasting convenience foods that can be purchased ready to eat (RTE), refrigerated, and rapidly prepared with minimal or no cooking before consumption
- expanded use of antacids and gastric-acid-suppressive medications
- improved diagnostic methods and enhanced public health surveillance

Listeriosis is an atypical foodborne illness of major public health concern because of the severity of the disease (meningitis, septicemia, and spontaneous abortion), the high case fatality rate (approximately 20 to 30%), the long incubation time (up to 70 days), and a predilection for individuals who have an underlying condition that leads to impairment of T-cell-mediated immunity. Control of *L. monocytogenes* in foods represents a significantly greater challenge than that of most foodborne pathogens in that it is widely distributed in the environment, is resistant to diverse environmental conditions, including low pH and high NaCl concentrations, and is facultatively anaerobic and psychrotrophic. The various ways in which *L. monocytogenes* can enter food processing plants, its capacity for prolonged survival in the environment (soil, plants, and water), on foods, and in food processing plants, and its ability to grow at low temperatures (2 to 4°C) and to survive in biofilms or on/in foods and food contact surfaces for prolonged periods under adverse conditions have made this bacterium a major concern of the agrifood industry for more than 35 years.

The significance of *L. monocytogenes* as a foodborne pathogen is complex. The severity and case fatality rate of the disease require appropriate preventive measures, but the characteristics of the microorganism are such that it is unrealistic to expect all food to be *Listeria* free. This dilemma has generated an ongoing debate concerning both the various strategies for prevention of listeriosis and the regulation of *L. monocytogenes* in foods. Since 1985, considerable research has been conducted to identify the routes of contamination, the behavior of this pathogen in a wide range of foods, and various microbial intervention strategies, including the use of *Listeria* growth inhibitors, thermal and nonthermal processing, and postpackaging pasteurization. Epidemiologic investigations of outbreaks have helped identify the vehicles of transmission and have led to an expanding list of RTE foods that have been associated with outbreaks. Basic research on the genetics, molecular biology, and immunologic responses of animals and humans to *L. monocytogenes* has provided detailed insights into the virulence characteristics of this fascinating pathogen.

CHARACTERISTICS OF THE ORGANISM

Classification—The Genus *Listeria*

Listeria is a member of the phylum *Firmicutes*, and while it was previously placed in the order *Bacillales*, genomic data support its placement in the *Lactobacillales* together with genera like *Staphylococcus*, *Streptococcus*, and *Lactobacillus* (6). Traditionally, *Listeria* is placed in the *Listeriaceae* together with the genus *Brochothrix*, although recent genomic analysis suggests that *Brochothrix* may be placed in a separate family in the future (6).

The genus *Listeria* currently contains 19 species. *L. monocytogenes* is one of six closely related species forming a group that also includes *Listeria ivanovii*, *L. innocua*, *L. seeligeri*, *L. welshimeri*, and *L. marthii* (7–9). This group is sometimes referred to as *Listeria sensu stricto* (9). The remaining 13 species are more phylogenetically distant from *Listeria sensu stricto* and can be subdivided into three distinct phylogenetic clades based on genomic data: (i) a clade containing *Listeria grayi*, (ii) a clade containing *Listeria fleischmannii*, *L. floridensis*, *L. aquatica*, *L. costaricensis*, *L. goaensis*, and *L. thailandensis*, and (iii) a clade containing *Listeria rocourtiae*, *L. weihenstephanensis*, *L. cornellensis*, *L. grandensis*, *L. newyorkensis*, *L. riparia*, and *L. booriae* (10). Within the genus *Listeria*, only *L. monocytogenes* and *L. ivanovii* are considered pathogenic, as evidenced by their 50% lethal doses (LD_{50}) in mice and their ability to grow in mouse spleen and liver. *L. monocytogenes* is the only human-pathogenic *Listeria* species of major public health concern, and *L. ivanovii* infections are primarily confined to animals.

The methods used for isolating *L. monocytogenes* from food and clinical samples have been reviewed and described elsewhere (11). Identification of *Listeria* to species level is based on a limited number of biochemical markers, among which hemolysin production has been traditionally used to differentiate between *L. monocytogenes* and frequently encountered nonpathogenic *Listeria* species, such as *L. innocua* (12). Other biochemical tests used to discriminate between species include acid production from various sugars. A wide range of miniaturized biochemical test kits are commercially available for species confirmation in addition to more rapid methods that utilize enzyme-linked immunosorbent assays and DNA probes for specific genes.

Further Characterization and Subtyping of *L. monocytogenes*

L. monocytogenes isolates are often characterized below the species level for the purposes of public health surveillance and to assist in outbreak investigations. Serotyping has proven its value over many years. There are 13 serotypes of *L. monocytogenes* that can cause disease, but more than 90% of human isolates belong to three serotypes: 1/2a, 1/2b, and 4b (13). Because of the low discriminatory power of this method, phage-typing systems were developed, and prior to the introduction of molecular typing methods, they were a primary means of distinguishing between strains of the same serotype.

Since 1989, various molecular typing methods have been applied to *L. monocytogenes*, including multilocus enzyme electrophoresis, ribotyping, DNA microrestriction (DNA fragments generated with

high-frequency-cutting enzymes and separated by conventional agarose gel electrophoresis) and macrorestriction (large DNA fragments generated with infrequently cutting enzymes and separated by pulsed-field gel electrophoresis [PFGE]), and random amplification of polymorphic DNA (14). Due to their ability to type all strains and the high discriminatory power of some of them, these methods have become standard tools for epidemiologic investigations. In addition, unlike serotyping and phage typing, which require specialized reagents (typing sera and bacteriophages) available to only a few reference laboratories, these molecular methods can be performed in any reasonably well-equipped laboratory. This includes the routine subtyping and reporting of *Listeria* isolates by public health and regulatory laboratories in the United States and other countries via the Centers for Disease Control and Prevention's (CDC) PulseNet. This international network of laboratories uses highly standardized subtyping protocols (i.e., PFGE) to detect foodborne disease clusters that may have a common source. *L. monocytogenes* was added to PulseNet in 1999, and a standardized PFGE protocol is available (15). Whole-genome sequencing (WGS) technologies are now largely replacing PFGE for *L. monocytogenes* surveillance both in the United States and in parts of the European Union (16, 17). Laboratories using WGS surveillance use a combination of core genome multilocus sequence typing and single-nucleotide-variant methods to detect outbreak clusters (18).

Both early Sanger sequencing-based research and WGS data have revealed that most *Listeria* isolates are part of groups of genetically highly similar strains, called clonal complexes (CCs). While genetic variability within these CCs is limited, genomic divergence between closely related CCs is usually high (19). Some of these CCs were recognized before the introduction of sequence-based methods and were found to be often involved in outbreaks and are called epidemic clones (ECs). Evans et al. (20) examined several outbreak strains of *L. monocytogenes* 4b and classified them as ECI and ECII. The ECI isolates were involved in outbreaks prior to 1998, whereas ECII isolates were involved in multistate outbreaks in the United States in 1998 and 2002. ECII isolates have diverged in the serotype-specific region of the genome compared with other serotype 4b strains. Maury et al. (21) found that some CCs are more likely to be associated with human central nervous system or maternal-neonatal listeriosis than with foodborne illness and that they were hypervirulent in a humanized mouse model of listeriosis. Some of these hypervirulent CCs overlap with previously recognized ECs, such as ECI, while others have not been recognized as ECs previously (e.g., CC6).

Susceptibility to Physical and Chemical Agents

L. monocytogenes can grow at 0 to 45°C, with growth occurring more slowly at lower temperatures. The average generation times for 39 *L. monocytogenes* strains were 43, 6.6, and 1.1 h at 4, 10, and 37°C, respectively, and the associated lag times were 151, 48, and 7.3 h (22). Temperatures below 0°C preserve or moderately inactivate the bacterium. Survival and injury during frozen storage depend on the substrate and the rate of freezing. Among foodborne pathogens, *L. monocytogenes* is considered one of the most resistant to freeze injury. *L. monocytogenes* is inactivated by exposure to temperatures above 50°C.

Zheng and Kathariou (23) identified three genes (*ltrA*, *ltrB*, and *ltrC*) in *L. monocytogenes* that are essential for low-temperature growth. When *ltrB* was used as a probe, it hybridized only with outbreak-associated ECI serotype 4b strains of *L. monocytogenes*.

The pH range for the growth of *L. monocytogenes* was thought to be 5.6 to 9.6, although the bacterium can initiate growth in laboratory media at pH values as low as 4.4. Growth at low pH values is influenced by the incubation temperature and the type of acid. At pH values below 4.3, listeriae may survive but do not multiply. Experimentally, the presence of up to 0.1% acetic, citric, and lactic acid in tryptose broth inhibits the growth of *L. monocytogenes*, with inhibition increasing as the incubation temperature decreases. The antilisterial activity of these acids is related to their degree of dissociation, with citric and lactic acids being less detrimental than acetic acid at an equivalent pH.

L. monocytogenes grows optimally at a water activity (a_w) of 0.97. For most strains, the minimum a_w for growth is 0.93, but some strains may grow at a_w values as low as 0.90. Further, the bacterium may survive for long periods at a_w values as low as 0.83 (24). An inverse relationship exists between the

thermal resistance of *L. monocytogenes* and the a_w of the medium in which it is suspended (25), which must be addressed by manufacturers who rely on low a_w and thermal treatment for food preservation.

L. monocytogenes can grow in the presence of 10 to 12% sodium chloride and can grow to high populations at moderate salt concentrations (6.5%). The bacterium survives for long periods at high salt concentrations, with survival in such environments being significantly increased at lower temperatures.

The inoculum level of *L. monocytogenes* affects its ability to grow under adverse environmental conditions (temperature, pH, and a_w). For example, at 25°C and an a_w of 0.997, growth can be initiated at pH 4.45 by fewer than 10 CFU/ml, whereas growth can be observed at pH 3.9 when the cell concentration exceeds 6×10^6 CFU/ml (26). Multiple predictive microbiology models based on data obtained from studies using microbiological media and various foods describe the effects and interactions of temperature, pH, a_w, sodium chloride content, organic acid concentration, and sodium nitrite concentration on both growth and survival of *L. monocytogenes*.

LISTERIOSIS AND RTE FOODS

Certain RTE processed foods that support the growth of *L. monocytogenes* are high-risk vehicles for transmitting listeriosis to susceptible populations, as determined by active surveillance for sporadic listeriosis and epidemiologic investigation of listeriosis outbreaks. These foods are usually preserved by refrigeration and offer an appropriate environment for the multiplication of *L. monocytogenes* during manufacture, aging, transportation, and storage. The risk is likely to be increased if the RTE foods are exposed to marginal abuse temperatures (8 to 15°C) or have extended refrigerated shelf lives. Foods in this category include unpasteurized milk and dairy products prepared from unpasteurized milk, such as soft unripened and surface-ripened cheeses, frankfurters that were not reheated before consumption, delicatessen meats, and smoked fish, as well as some seafood and certain fresh-cut fruits and vegetables.

In Canada, the regulatory policy directs inspection and compliance action on RTE foods that can support the growth of *L. monocytogenes*. The highest priority is given to foods that have previously caused listeriosis and those that have more than 10 days of shelf life (27). The need to establish effective, risk-based food safety controls has resulted in *L. monocytogenes* being the focus of a large number of qualitative and quantitative microbiological risk assessments in various RTE foods (28–35). The most comprehensive of these assessments was conducted by the U.S. Food and Drug Administration (FDA), in collaboration with the U.S. Department of Agriculture (USDA) Food Safety and Inspection Service and the CDC. The assessment was undertaken to predict the potential relative risk of listeriosis from eating certain RTE foods among three age-based groups of people: perinatal (16 weeks after fertilization to 30 days after birth), elderly (60 years of age and older), and intermediate age (general population, less than 60 years of age). This assessment evaluated foods within 23 categories considered to be principal potential sources of *Listeria* (Table 17.1.) and found that RTE meats, including deli meats and frankfurters, posed the greatest risk. Subsequent risk assessments have examined in detail a variety of RTE foods and various sectors of the food chain (36).

From the exposure models and “what-if” scenarios used in the risk assessment, it was determined that the following five factors affected consumer exposure to *L. monocytogenes* at the time of food consumption: (i) amount and frequency of the food consumed, (ii) prevalence and levels of *L. monocytogenes* in the food, (iii) likelihood of *L. monocytogenes* growth in the food during refrigerated storage, (iv) refrigerated-storage temperature, and (v) duration of refrigerated storage of the food before consumption. The risk assessment model was used to estimate the likely impact of control strategies by changing one or two input parameters and measuring the change in the model outputs. For example, one “what-if” scenario determined that the predicted number of listeriosis cases would be reduced by 69% if all home refrigerators were consistently operating at or below 7.2°C. Another scenario determined that reducing the maximum storage time of deli meats from 28 to 14 days would reduce the median number of cases in the elderly population by 13.6%.

Fluid Milk Products

Raw milk is a well-documented source of *L. monocytogenes*. The first major outbreak of foodborne listeriosis was traced to California-produced Mexican-style cheese in 1985 (37), followed by an outbreak in North Carolina in 2000, both of which were likely caused by the use or partial use of unpasteurized milk for cheese making (38). The prevalence of *L. monocytogenes* in bulk tank raw milk varies from 1 to 13%, while its prevalence in milk processing plants ranges from 7 to 28% (39). Therefore, raw milk and food products made from raw milk are potential sources of *L. monocytogenes*. Based on numerous surveys, about 2.5, 3.6, and 5.2% of the raw milk samples tested in North America, Europe, and elsewhere, respectively, were positive for *L. monocytogenes* (40). However, the ability of *L. monocytogenes* to survive and proliferate in raw dairy products stored at refrigeration temperatures makes this bacterium a particular concern for the dairy industry. Contamination levels that are initially low (e.g., <1 CFU/25 g) may increase to high cell numbers that could pose a human health hazard if milk and certain cheeses are subjected to long-term refrigerated storage (40).

Most thermal-inactivation studies have shown that cells of *L. monocytogenes* suspended in milk were effectively inactivated by high-temperature short-time (HTST) pasteurization (71°C for 15 s or equivalent) (40, 41). One multistate survey showed a very low frequency of isolation (1 of 5,519 samples) for *L. monocytogenes* in commercial pasteurized fluid milk products sold in the United States (42), with the same being true for dairy products prepared from pasteurized milk (40). Differences were observed when thermal inactivation of freely suspended *L. monocytogenes* cells was compared with that of cells that were internalized within phagocytic leukocytes (43). The physiological state (actively growing cells versus cells in stationary phase) and growth of *Listeria* at elevated temperatures (e.g., in infected cows that may have developed fever) before pasteurization are some of the potential factors that may have caused these cells to become more heat resistant. Lado and Yousef (44) state that the following factors should be considered in evaluating the effect of pasteurization on *L. monocytogenes*: (i) the safety margin of pasteurization for inactivation of the bacterium may be lower than previously thought; (ii) the level of contamination in pooled milk is lower than that used in most inoculation studies; (iii) homogenization of milk destroys the integrity of phagocytic cells in milk, thus removing any protection offered to bacterial cells; and (iv) thermoduric spoilage microorganisms surviving HTST pasteurization are likely to outcompete *L. monocytogenes*. Hence, there is general agreement with the observations of the WHO informal study group, which concluded that "pasteurization is a safe process which reduces the number of *L. monocytogenes* in raw milk to levels that do not pose an appreciable risk to human health" (276). Recognizing the small margin of safety offered by HTST pasteurization, most milk processors have adopted processes that employ temperatures well above the minimum legal requirements for pasteurized milk. *L. monocytogenes* grows in pasteurized milk, with the numbers increasing 10-fold in 7 days at 4°C. Further, listeriae grow more rapidly in pasteurized milk than in raw milk when incubated at 7°C. Therefore, fluid milk that is contaminated after pasteurization and stored under refrigeration may attain very high populations of *L. monocytogenes* after 1 week. Temperature abuse may further enhance growth rates, as was evidenced in pasteurized-milk-associated outbreaks in Illinois (45) and Massachusetts (46).

Table 17.1 Relative risk ranking and predicted number of cases of listeriosis for the total U.S. population on a per-serving and per-annum basis[a]

		Predicted median no. of cases of listeriosis for 23 food categories				
		Per-serving basis[b]			Per-annum basis[c]	
Relative risk ranking	Risk category	Food	No. of cases	Risk category	Food	No. of cases
1	High	Deli meats	7.7×10^{-8}	Very high	Deli meats	1,598.7
2		Frankfurters, not reheated	6.5×10^{-8}	High	Pasteurized fluid milk	90.8
3		Pâté and meat spreads	3.2×10^{-8}		High-fat and other dairy products	56.4
4		Unpasteurized fluid milk	7.1×10^{-9}		Frankfurters, not reheated	30.5
5		Smoked seafood	6.2×10^{-9}	Moderate	Soft unripened cheese	7.7
6		Cooked RTE crustaceans	5.1×10^{-9}		Pâté and meat spreads	3.8
7	Moderate	High-fat and other dairy products	2.7×10^{-9}		Unpasteurized fluid milk	3.1
8		Soft unripened cheese	1.8×10^{-9}		Cooked RTE crustaceans	2.8
9		Pasteurized fluid milk	1.0×10^{-9}		Smoked seafood	1.3
10	Low	Fresh soft cheese	1.7×10^{-10}	Low	Fruits	0.9
11		Frankfurters, reheated	6.3×10^{-11}		Frankfurters, reheated	0.4
12		Preserved fish	2.3×10^{-11}		Vegetables	0.2
13		Raw seafood	2.0×10^{-11}		Dry/semidry fermented sausages	<0.1
14		Fruits	1.9×10^{-11}		Fresh soft cheese	<0.1
15		Dry/semidry fermented sausages	1.7×10^{-11}		Semisoft cheese	<0.1
16		Semisoft cheese	6.5×10^{-12}		Soft ripened cheese	<0.1
17		Soft ripened cheese	5.1×10^{-12}		Deli-type salads	<0.1
18		Vegetables	2.8×10^{-12}		Raw seafood	<0.1
19		Deli-type salads	5.6×10^{-13}		Preserved fish	<0.1

20		Ice cream and other frozen dairy products	4.9×10^{-14}		Ice cream and other frozen dairy products	<0.1
21		Processed cheese	4.2×10^{-14}		Processed cheese	<0.1
22		Cultured milk products	3.2×10^{-14}		Cultured milk products	<0.1
23		Hard cheese	4.5×10^{-15}		Hard cheese	<0.1

[a] Adapted from reference 6.

[b] Foods were classified as high risk (>5 cases per billion servings), moderate risk (≤5 but ≥1 case per billion servings), and low risk (<1 case per billion servings).

[c] Foods were classified as very high risk (>100 cases per annum), high risk (>10 to 100 cases per annum), moderate risk (>1 to 10 cases per annum), and low risk (<1 case per annum).

Cheeses

L. monocytogenes can survive the cheese manufacturing and ripening process because of its relative hardiness to temperature and pH fluctuations, its ability to multiply at refrigeration temperature, and its salt tolerance. Growth in cheese milk is retarded but not completely inhibited by lactic starter cultures. During cheese making, *L. monocytogenes* is concentrated about 10-fold in the curd, with the remaining cells appearing in the whey. The behavior of listeriae in the curd is influenced by the type of cheese, ranging from growth in feta cheese to significant inactivation during cottage cheese manufacture. During cheese ripening, the *L. monocytogenes* population may increase (Camembert), decrease gradually (Cheddar or Colby), or decrease rapidly during early ripening and then stabilize (blue cheese). Consumption of soft Mexican-style cheeses (e.g., queso fresco or queso blanco) and surface-ripened cheeses (e.g., Brie or Camembert) by susceptible persons is an important risk factor for sporadic and epidemic listeriosis in North America and Europe. Over 3 decades ago, 49% of the sporadic listeriosis cases in France were attributed to consumption of soft cheese. Prevention efforts have reduced this incidence by 68% between 1987 and 1997 (47, 48). The first documented foodborne listeriosis outbreak in Japan resulted in 86 cases of infection (mainly gastroenteritis) and was traced to *L. monocytogenes* serotype 1/2a contamination in washed-type cheese (49).

Meat and Poultry Products

The growth potential for *L. monocytogenes* in meat and poultry products depends on the meat variety, pH, and type and number of competing microorganisms. A 2006 survey in the United States revealed that 3.5% of commercial ground beef samples were positive for *L. monocytogenes* (50). Poultry supports the growth of *L. monocytogenes* better than other meats, whereas properly fermented sausage does not permit *Listeria* growth. Contamination typically occurs via symptomatic or asymptomatic carriage of *L. monocytogenes* by the animal before slaughter, followed by contamination of the carcass during or after slaughter. Because *L. monocytogenes* tends to concentrate and multiply in the kidneys, mesenteric and mammary lymph nodes, livers, and spleens of infected animals, organ meats may be more hazardous to consume than muscle tissue (51). Regardless of the contamination route, *L. monocytogenes* strongly attaches to the surface of raw meats and is difficult to remove or inactivate. *L. monocytogenes* multiplies readily in meat products, including vacuumpackaged beef, at pH values near 6.0, whereas little or no multiplication occurs at pH 5.0 (51). RTE meat products that have received a heat treatment followed by cooling in brine before packaging may provide an environment that is particularly conducive to multiplication of *L. monocytogenes* because of the reduction in competitive microbiota and the high salt tolerance of the bacterium.

Based on the USDA monitoring program for *L. monocytogenes*, the prevalence of this pathogen in cooked RTE meat and poultry products decreased from 4.61% in 1990 to 0.19% in 2017 (52), with much of this decrease being due to the adoption of mandatory hazard analysis and critical control point

programs for the industry beginning in 1998. Since 2004, producers of such products in the United States must also use one of the three USDA alternatives for control of *Listeria*, namely, (i) use of a postlethality treatment (e.g., postpackaging pasteurization) and use of an antimicrobial agent (e.g., lactate or diacetate) or process (e.g., freezing) that suppresses or limits the growth of the organism, (ii) use of either a postlethality treatment or an antimicrobial agent or process that suppresses or limits growth of the organism, or (iii) use of only sanitation to control the organism (53). Surveys of both meat and poultry processing facilities have identified both transient and persistent strains of *L. monocytogenes*, with the pathogen in some cases persisting at the same location for months or years (54–57).

Cooked, RTE meat and poultry products have been frequent sources of sporadic and outbreak-associated listeriosis in both North America and Europe. Consumption of unreheated frankfurters and undercooked chicken was first identified as a risk factor for sporadic cases of listeriosis in the United States (58) after a contaminated turkey frankfurter product was linked to a sporadic *L. monocytogenes* infection in a cancer patient in 1989 (59). Nationwide outbreaks of listeriosis were traced to contaminated frankfurters or deli meat in the United States in 1998, 2000, and 2002 (54–56) and in Canada in 2008 (60). In 2017 and 2018, the largest outbreak of listeriosis recorded to date affected over 1,000 people and caused 204 deaths in South Africa. The source was polony, a processed deli meat, contaminated with *L. monocytogenes* sequence type 6. The total cost of the outbreak has been estimated at $250 million (61).

Cross-contamination of RTE meat and poultry products with *L. monocytogenes* can occur during both production and retail sale (62). In a large U.S. survey of RTE foods obtained from different retail markets, in-storepackaged deli meats were about seven times more likely to harbor *L. monocytogenes* (2.7% positive) than manufacturer-packaged products (0.4% positive) (63). Using more recent retail contamination rates (34) and consumer purchasing habits (64), approximately 80% of all listeriosis cases and deaths involving deli meat can be attributed to products sliced at retail with mechanical delicatessen slicers now recognized as the major source of *Listeria* cross-contamination (34, 65, 66).

Seafood

The role of seafood in human listeriosis was reviewed in 2000 (67). The same year, Huss et al. (68) classified the following seafood as potential high-risk foods for listeriosis: (i) mollusks, including fresh and frozen mussels, clams, and oysters (in shell or shucked); (ii) raw fish; (iii) lightly preserved fish products, including salted, marinated, fermented, cold-smoked, and gravad fish; and (iv) mildly heat-processed fish products and crustaceans. Smoked seafood and cooked RTE crustaceans were identified as moderate-to high-risk foods in the FDA 2003 risk assessment. Shrimp, smoked mussels, and imitation crabmeat have been implicated as sources of human listeriosis. Gravad rainbow trout and cold-smoked rainbow trout were responsible for two outbreaks in Sweden and Finland, respectively (69, 70).

In the United States, *L. monocytogenes* has been isolated from both domestic and imported fresh, frozen, and processed seafood products, including crustaceans, molluscan shellfish, and finfish (71). An FDA survey of domestic and imported refrigerated or frozen cooked crab meat in 1987 and 1988 determined contamination levels of 4.1% for domestic products and 8.3% for imported products (72). Crab and smoked fish samples analyzed by the FDA between 1991 and 1996 yielded *L. monocytogenes* contamination rates of 7.5% and 13.6%, respectively. From 1999 to 2003, 2.9% and 14.9% of the hot-and cold-smoked, respectively, seafood samples (primarily fish) tested positive for *L. monocytogenes* (71) with 3.6% of RTE crustaceans (primarily crab and shrimp) also being positive during the same period. However, consumption of smoked seafood in the United States is still much less than that of meats and cheeses, and the much smaller scale of production of these products helps to explain the general lack of large-scale outbreaks in the United States. Cold-smoked fish continues to be the focus of efforts to develop new control measures and systems for *L. monocytogenes* (73).

As was true for meat processing plants, *L. monocytogenes* is also frequently found in facilities producing raw and RTE seafood. When Hoffman et al. (74) compared the ribotypes of *L.*

monocytogenes strains isolated from smoked fish processing environments and raw fish, various unique ribotypes were recovered from raw fish samples, indicating that the raw fish was possibly contaminated from a source other than the processing environment.

Products of Plant Origin

Compared to dairy, meat, poultry, fish, and seafood products, *L. monocytogenes* has until recently received only limited attention regarding its prevalence and growth in products of plant origin. At the time when the previously discussed *Listeria* risk assessment was published, in 2003, *L. monocytogenes* was recognized as an infrequent contaminant of vegetables (e.g., broccoli, cabbage, celery, cucumbers, green beans, lettuce, mushrooms, onions, potatoes, radishes, spinach, sprouts, tomatoes, and yams) and fruits (e.g., apples, blueberries, cantaloupe, melons, pears, pineapple, and watermelon) (75). More recent surveys, including many conducted outside North America, have yielded similar findings (76). Vegetables and fruits are prone to both pre-and postharvest contamination. Strawn et al. (77) recovered *L. monocytogenes* from 17.5% of 263 field and 30% of 74 water samples collected over a 5-week period from 21 produce farms in New York State.

Risk factors associated with increased isolation included manure application, presence of wildlife, soil cultivation, and field worker activity. During subsequent postharvest processing, fresh produce is prone to contamination during slicing, dicing, and washing (78). While chemical sanitizers are typically added to flume water to minimize cross-contamination during washing, their effectiveness typically decreases over time as the levels of soil and organic material increase in the water during continued processing. While the prevalence of *L. monocytogenes* in fresh produce is presumed to be quite low (<5%), reliable data for specific vegetables and fruits are still lacking due to limited collection and sampling.

Fruits and vegetables differ in their ability to support the growth of *L. monocytogenes* (79), with the manner of product handling during postharvest processing having an impact on maximum attainable populations. Many types of fresh produce to be further processed undergo one or more washing steps in which a chemical sanitizer is added to the water to minimize cross-contamination through the wash water. However, given the increasing number of *Listeria* recalls involving fresh-cut produce, washing alone cannot completely ensure end product safety. Further processing steps, such as slicing, dicing, and shredding, can spread *Listeria* to previously uncontaminated product, as has been shown for celery (80) and onions (81). Listeriae can reportedly grow in such products, including diced celery (82), diced onions (82), and shredded lettuce (83), with the extent of growth being dependent on the degree of temperature abuse and the type of packaging. Caramel apples are also capable of supporting growth if *Listeria* enters the center of the apple via the stick (84). However, recent studies indicate that *L. monocytogenes* is far less thermally resistant than *Salmonella* in low-moisture foods (e.g., nuts, spices, and powders), with the latter organism being the primary pathogen of concern (85).

Involvement of fruits and vegetables in human listeriosis dates back at least to a 1981 Canadian outbreak in which coleslaw prepared from *Listeria*-contaminated cabbage was responsible for 7 adult and 34 perinatal cases of listeriosis (1). Fertilization of the cabbage with manure from *Listeria*-infected sheep was cited as the most probable route of contamination. More than 25 years then passed without any major reports of systemic listeriosis from consumption of produce, which supported the low ranking of fresh fruits and vegetables in the 2003 *Listeria* risk assessment. However, in 2008, fresh produce once again emerged as a vehicle for listeriosis, with a multistate outbreak in the United States involving sprouts being linked to 20 cases of illness during 2008 and 2009. Subsequent outbreaks in the United States have been traced to consumption of diced celery in 2010 (10 cases, 5 deaths) (86), cantaloupe in 2011 (147 cases, 33 deaths) (87), nectarines and peaches in 2014 (2 cases, 1 death) (88), mung bean sprouts (5 cases, 2 deaths) (89), and commercially prepared caramel apples (35 cases, 7 deaths) (90), all of which have been reviewed by Garner and Kathariou (91). Leafy greens also have been implicated in two multistate outbreaks, one originating in Colorado in 2011 (99 cases, 515 deaths) (92) and the other in Ohio in 2016 (19 cases, 1 death) (93), in addition to frozen vegetables from Washington State in 2016 (9 cases, 3 deaths) (94).

EFFECTS OF NEWER METHODS OF FOOD PRESERVATION

New trends in food preservation have recently been developed, including the use of bacteriocins as biopreservatives, as well as vacuum and modified-atmosphere packaging, all of which have been reviewed by Lado and Yousef (44). Nisin, produced by certain strains of *Lactococcus lactis* subsp. *lactis*, is by far the most widely recognized bacteriocin. The antagonistic effect of nisin on *L. monocytogenes*, which is well documented, is strongly dependent on the pH and chemical composition of the food to which it is added. Pediocins (from *Pediococcus pentosaceus* and *Pediococcus acidilactici*) and bavaracin A (95) (from *Lactobacillus bavaricus*) transiently affect *L. monocytogenes* growth and survival in various beef systems, especially at low temperature. Meat-borne lactic acid bacteria can effectively inhibit the growth of *L. monocytogenes* by rapid production of lactic acid and bacteriocins and can be used as potential biopreservatives in cooked meat products (96). A similar effect was observed with the bacteriocin carnocin from *Carnobacterium piscicola* in broth and skimmed milk (97). However, the emergence of resistant mutants can be a drawback to the use of bacteriocins, as has been observed with bavaracin A and nisin (95, 98).

In vitro studies have also demonstrated antilisterial activity of essential oils that function by partitioning the lipids of the cell membrane and mitochondria, resulting in increased membrane permeability and cell leakage. Examples of essential oils include carvacrol, thymol, eugenol, perillaldehyde, cinnamaldehyde, and cinnamic acid, which have MICs of 0.05 to 5 μl/ml *in vitro* (54). However, these essential oils must be carefully paired with particular food so as to not impart undesirable flavor characteristics.

A survey of vacuum-packaged processed meat in retail stores in the early 1990s revealed that 53% of the samples tested were contaminated with *L. monocytogenes* and that 4% contained more than 1,000 CFU/g (99). This observation corroborates experimental evidence that the growth of *L. monocytogenes* (a facultative anaerobe) is not significantly affected by vacuum packaging. There has been considerable interest in modified-atmosphere packaging of meat products (low oxygen and high carbon dioxide concentrations) in recent years because of the increasing demand for refrigerated convenience foods with extended shelf lives. Studies with meat juice, raw chicken, and precooked chicken nuggets revealed that such atmospheres do not significantly affect the growth of *L. monocytogenes*.

L. monocytogenes is sensitive to low doses of irradiation. Sublethal heating, freezing, sanitizer exposure, and exposure to various nonthermal processing methods, including high-intensity pulsed light, high pressure, irradiation, and pulsed electric fields, can injure a substantial portion of surviving cells (100). Heat-stressed *L. monocyte genes* may be considerably less pathogenic than nonstressed cells. While injured cells can repair the damage induced by stress and grow on nonselective agar, the additional stress encountered when cells are grown on selective agar leads to variable recovery. Hence, when present in foods, sublethally damaged cells may go undetected.

RESERVOIRS

The role of improperly fermented silage in the transmission of animal listeriosis, first referred to as “circling disease” in 1929, to ruminants is now well known. This pathogen is geographically widespread in both rural and urban environments (101) and can survive and/or grow in improperly fermented silage, pasture grass, decaying vegetation, soil, sewage, and various aquatic environments, including surface water of canals, lakes, ditches, and freshwater tributaries (102). Alfalfa and other crops grown on soil treated with sewage sludge can be contaminated with *Listeria*. In one study, half of the radish samples grown in *L. monocytogenes*-inoculated soil were confirmed positive 3 months later (103). The wide spread presence of *L. monocytogenes* in soil is likely due to contamination by decaying plant and fecal material, with the soil providing a cool, moist environment and the decaying material providing the nutrients (104).

L. monocytogenes has been isolated from the feces of many healthy animals and birds; listeriosis in many animal species has been recorded. Humans exhibiting symptoms of listeriosis and asymptomatic carriers shed the organism in their feces. Figure 17.1 illustrates the many ways in which *L.*

monocytogenes can be spread from the environment to animals and humans and back to the environment.

Food Processing Facilities

Entry of *L. monocytogenes* into food processing facilities can occur through soil on workers' shoes and clothing, transport equipment, animals that excrete the bacterium or have contaminated hides or surfaces, raw plant tissue, raw food of animal origin, and possibly healthy human carriers. Growth of *Listeria* is favored by high humidity and the presence of nutrients. *L. monocytogenes* is most often recovered from moist areas such as floor drains, condensate, stagnant water, floors, and residues on processing equipment (105). *L. monocytogenes* can attach to various types of surfaces, including stainless steel, glass, plastic, and rubber, and form biofilms, as has been described for meat and dairy processing environments (106). *Listeria* spp. can survive on fingers after hand washing and in aerosols. The presence of *L. monocytogenes* in the food chain is evidenced by the widespread distribution of the listeriae in processed products. Contaminated effluents from food processing plants increase the spread of *L. monocytogenes* in the environment. Sources of *L. monocytogenes* in dairy processing plants include the environment (floors and floor drains, especially in areas in and around coolers or places subject to outside contamination) and raw milk. Efforts to ensure that milk is safe from *L. monocytogenes* contamination should focus on promoting appropriate methods of pasteurization and on identifying and eliminating sources of postpasteurization contamination (40). Strict adherence to the guidance in the Pasteurized Milk Ordinance (http://ncims.org/wp-content/uploads/2018/06/2017-PMO-FINAL.pdf) helps minimize *Listeria* contamination in dairy processing environments and better ensure the safety and quality of the final product.

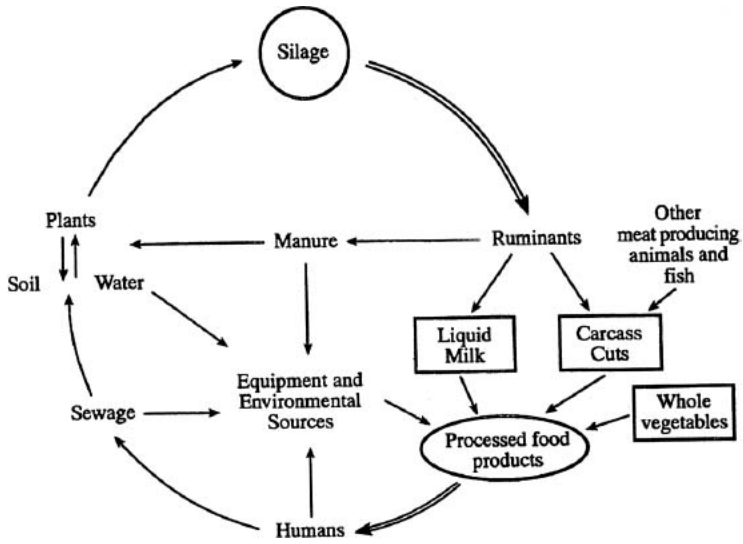

Figure 17.1 Potential routes of transmission of *L. monocytogenes*. Circles or ovals indicate areas of greatest risk of *L. monocytogenes* multiplication. Boxes indicate where direct consumption of minimally processed products (whole fresh vegetables, cooked carcass cuts of meat and fish, and effectively pasteurized milk) presents a low risk. Double arrows indicate consumer risk. Adapted from reference 117.

The presence of *L. monocytogenes* on carcasses is usually attributed to contamination by fecal matter during slaughter, evisceration, and fabrication. A high percentage (11 to 52%) of healthy animals are fecal carriers. Up to 45% of pigs can harbor *L. monocytogenes* in their tonsils, and 24% of cattle have contaminated internal retropharyngeal nodes (107, 108). *L. monocytogenes* has been recovered from both unclean and clean zones (especially workers' hands) in slaughterhouses, with the most heavily contaminated work areas involving cow dehiding and pig stunning and hoisting. Surveys conducted at both turkey and broiler slaughterhouses failed to recover *L. monocytogenes* from feathers, scald tank water overflow, neck skin, livers, hearts, ceca, or large intestines. In contrast, *L. monocytogenes* was

isolated from feather plucker drip water, chilling water overflow, recycling water for cleaning gutters, and mechanically deboned meat. These findings demonstrate the importance of the defeathering machine, chillers, and recycled water in product cross-contamination (109).

Contamination of processed RTE foods with *L. monocytogenes* occurs primarily after processing. To date, there is no evidence to indicate that *L. monocytogenes* can survive validated heat processing protocols used to render foods safe. Having the propensity to adhere to food contact surfaces and form biofilms, *L. monocytogenes* is particularly difficult to eliminate from the food processing environment even when well-designed sanitation programs are used (110). For example, *L. monocytogenes* can persistently survive on stainless steel food contact surfaces, such as those found on dicing machines, and repeatedly contaminate RTE meats (54).

Because *L. monocytogenes* is a frequent contaminant of raw foods and ingredients, ample opportunity exists for the reintroduction of *Listeria* into food processing facilities. Extensive information on the problem of *L. monocytogenes* in various food processing environments and approaches for control has been provided by Kornacki and Gurtler (110). Tompkin (111) outlined a six-step *Listeria* control program for food processing environments that includes (i) prevention of the establishment and growth of *Listeria* species in niches or other sites that can lead to contamination of RTE foods, (ii) implementation of a sampling program to assess how well the control program is working, (iii) rapid and effective response when the sampling program yields positive results for *Listeria* species, (iv) verification by follow-up sampling to ensure that the source of contamination has been identified and corrected, (v) short-term assessment of the last four to eight samplings to facilitate early detection of problems and trends, and (vi) long-term assessment at appropriate intervals (quarterly, annually, etc.) to identify widely scattered contamination events and to measure overall progress towards continuous improvement. Longitudinal studies based on various molecular subtyping analyses can assist in identifying *L. monocytogenes* contamination patterns in food processing plants and validating intervention strategies (54, 55, 74, 112, 113). The design of the environmental sampling program and response to positive findings will determine the overall effectiveness of the *Listeria* control program in food processing environments (111).

Surveys of Foods for Prevalence of *L. monocytogenes* and Regulatory Status in Different Countries

Numerous surveys that have been reviewed and summarized elsewhere confirm that *L. monocytogenes* contamination of fermented (114) and unfermented (40) dairy products, meat (51), poultry and eggs (115), fish and seafood (71), and fresh produce (116) is widespread in many parts of the world. One large-scale qualitative/quantitative survey of retail RTE foods was conducted by investigators at the National Food Processors Association in the United States (117). Product categories examined included luncheon meats, deli salads, Mexican-style cheeses, packaged salads, blue-veined and soft-ripened cheeses, smoked seafood, and seafood salads. Of 31,705 samples examined, 1.82% (the range by sample category varied from 0.17% to 4.7%) were positive for *L. monocytogenes*. Pathogen levels in positive samples ranged from <0.3 CFU/g to 1.5×10^5 CFU/g. A dose-response model was developed by combining the food survey data with concurrent data on illness in the population that consumed the foods surveyed. Based on this model, control strategies focused on foods that yielded higher cell numbers of *L. monocytogenes* are likely to have greater positive public health impact than the current zero-tolerance policy (28, 118).

In a survey conducted in Denmark during 1994 to 1995, *L. monocytogenes* was isolated from 14.2% and 30.9% of raw fish and raw meats, respectively (71). Preserved, non-heat-treated fish and meat products were more frequently contaminated (10.8% and 23.5%, respectively) than heat-treated meat products (5%). *L. monocytogenes* was present at levels exceeding 100 CFU/g in 1.3% of the preserved (non-heat-treated and heat-treated) fish and meat products that were packed under vacuum or modified atmosphere for extended shelf life. In contrast, another survey covering the same product types that were not packed under vacuum or modified atmospheres revealed significantly lower contamination levels (0.3 to 0.6%) (119). In a Japanese survey of retail foods, *L. monocytogenes* was isolated from 12,

20, 37, and 25% of minced beef, pork, chicken, and pork-beef mixture, respectively, with only five chicken samples having populations greater than 100 CFU/g. *L. monocytogenes* was isolated from 5.4% of smoked salmon samples and 3.3% of RTE uncooked seafood (120).

A survey conducted in Spain revealed *L. monocytogenes* contamination in 9.3% of RTE foods and 2.9% of foods intended to be cooked before consumption (121). In another investigation, *L. monocytogenes* was isolated from 22% of retail smoked fish samples (122). *L. monocytogenes* has been isolated from many vegetables, including bean sprouts, cabbage, cucumbers, leafy vegetables, potatoes, prepackaged salads, radishes, salad vegetables, and tomatoes in North America, Europe, and Asia, with coleslaw, chopped celery, cantaloupe, apples, and most recently lettuce having been linked to major outbreaks of listeriosis.

Because of the frequent occurrence of *L. monocytogenes* in foods and the persistence of this pathogen in food processing environments, food regulatory agencies in many countries have established tolerance levels other than "zero" (i.e., absence in the sample tested) for *L. monocytogenes*. Following a nationwide outbreak of listeriosis in Canada in 2008 that was traced to RTE deli meats, the Canadian government revised its policy on *L. monocytogenes* in RTE foods to include new end product compliance criteria in addition to environmental monitoring and the use of postlethality treatments and/or *Listeria* growth inhibitors for RTE meat products. Foods are divided into two risk categories, with category 1 foods (those that support *L. monocytogenes* growth to 100 or more CFU/g) being regulated more stringently than foods in categories 2a (those that support *L. monocytogenes* growth to 100 CFU/g or less throughout shelf life) and 2b (those that do not support *L. monocytogenes* growth during the expected product shelf life) (123). In the European Union, according to European Food Safety Authority regulation 2073/2005, RTE foods are divided into three groups as follows: (i) RTE food for populations "at risk," where absence in 25 g is required; (ii) RTE foods able to support the growth of *L. monocytogenes*, where absence in 25 g is also required while the food is under the control of the food producer; and (iii) RTE foods which cannot support the growth of *L. monocytogenes*, where up to 100 CFU/g is permitted.

In contrast, the United States, while acknowledging the widespread distribution of *L. monocytogenes* in the food supply and the difficulties in producing *L. monocytogenes*-free foods, has decided not to adopt tolerance levels for *L. monocytogenes* in RTE foods. It is argued that establishing "acceptable" levels for *L. monocytogenes* would require knowledge of the number of listeriae unlikely to cause human infection. While progress is continually being made to establish such tolerance levels through various risk assessments, the United States has thus far maintained its "zero-tolerance" policy for *L. monocytogenes* in RTE foods (43), particularly in view of a recent outbreak that involved extremely low levels of *L. monocytogenes* in ice cream (124, 125).

Human Carriage

Asymptomatic fecal carriage of *L. monocytogenes* has been studied in various human populations, including healthy people, pregnant women, outpatients with gastroenteritis, slaughterhouse workers, laboratory workers handling *Listeria*, food handlers, and patients undergoing renal transplantation or hemodialysis (126). *L. monocytogenes* can be found in 2 to 6% of fecal samples from healthy people, and listeriosis patients often excrete high numbers. In one study, stool specimens from 21% of patients contained 10^4 or more *L. monocytogenes* CFU/g, and 18% of household contacts of patients with listeriosis fecally shed the same serotype and multilocus enzyme type of *L. monocytogenes* as the index case patient (127, 128). Among household contacts of 18 pregnant women with listeriosis, 8.3% asymptomatically shed *L. monocytogenes*, whereas no listeriae were isolated from 30 household contacts of age-, sex-, and hospital-matched controls (63). Results from a 1985 outbreak investigation in California showed that community-acquired outbreaks might be amplified through secondary transmission by fecal carriers. The very low prevalence of *L. monocytogenes* in human stools and the short duration of fecal shedding argue against routine stool screening of persons with possible work-related exposure to the pathogen (e.g., dairy workers) as a tool for prevention of listeriosis (129). *L. monocytogenes* isolated from asymptomatic carriers may carry the full complement of virulence genes or may be attenuated by truncated virulence-associated genes such as *inlA* and *actA* (130).

L. monocytogenes has not been isolated from oropharyngeal samples of healthy people, and the presence of listeriae in cervicovaginal specimens may be associated with pregnancy-related listeriosis. The role of healthy carriers in the epidemiology of listeriosis is unclear.

FOODBORNE OUTBREAKS

Foodborne transmission of listeriosis, although suggested in the early medical literature, was not definitively documented until 1981, when a case-control study was simultaneously used with strain typing investigation in an outbreak in Canada (1). Since 1981, epidemiologic investigations have repeatedly revealed that consumption of contaminated food is the primary mode of transmission of listeriosis. Since 1981, more than 10 major (>30 cases) outbreaks of listeriosis have been traced to various foods, including soft cheeses, delicatessen meats, cantaloupe, caramel apples, frozen corn, and the deli meat polony.

An outbreak of listeriosis in Massachusetts in 1979 may have been caused by raw produce, but the food source was not positively identified. Twenty patients with *L. monocytogenes* serotype 4b infection were hospitalized during a 2-month period; only nine cases had been detected in the previous 26 months. Ten of the patients were immunosuppressed adults, and 5 out of the total 20 patients died. Fifteen patients are thought to have acquired the infection in the hospital. Consumption of tuna fish, chicken salad, or cheese was associated with illness, but no specific brand was implicated. It was postulated that the raw celery and lettuce, served as a garnish with the three foods, may have been contaminated with *L. monocytogenes* (131). Although the source of infection was not definitively identified in this outbreak, consumption of cimetidine or antacids was implicated as a risk factor for listeriosis, a factor that has been identified in several case-control studies. Decreased gastric acidity might have increased the survival of *L. monocytogenes* cells as they passed through the stomach.

The first confirmed foodborne outbreak of listeriosis occurred in 1981 in Nova Scotia, Canada. Thirty-four pregnancy-associated cases and seven cases in nonpregnant adults were reported during a 6-month period. A case-control study implicated locally prepared coleslaw as the vehicle, and the epidemic strain was subsequently isolated from an unopened package of the product. Cabbage fertilized with manure from sheep suspected of having *Listeria* meningitis was the probable source. Harvested cabbage was stored over the winter and spring in an unheated shed, which provided a definite growth advantage for this psychrotrophic pathogen (1).

Pasteurized milk was identified as the most likely source of infection in another large outbreak of listeriosis, in Boston, MA, in 1983 (132). Forty-nine cases occurred during a 2-month period, 42 in immunosuppressed adults and 7 in pregnant women; the overall case fatality rate was 29% (119). A case-control study implicated pasteurized milk with 2% fat as the vehicle. Multiple serotypes of *L. monocytogenes* were isolated from raw milk at the implicated dairy, but none belonged to the outbreak strain. No deviations from approved pasteurization processes were noted at the dairy, suggesting that the contamination occurred after pasteurization.

In 1985, the first outbreak of listeriosis to attract widespread attention occurred in Los Angeles County, CA, when contaminated soft Mexican-style cheese was linked to 142 cases over an 8-month period (37). Pregnant women accounted for 93 cases. The remaining 49 cases were in nonpregnant adults; 48 of 49 nonpregnant adults had a predisposing condition for listeriosis. Among pregnancy-associated cases, 87% occurred in Hispanic women. The case fatality rates were 32% for perinatal cases and 32% for nonpregnant adults. Inadequate pasteurization and mixing of raw milk with pasteurized milk likely resulted in the contaminated cheese.

L. monocytogenes-contaminated Vacherin Mont d'Or cheese (a soft surface-ripened variety) was responsible for a 4-year-long (1983 to 1987) outbreak in Switzerland involving 122 cases (J. Bille, presented at the Foodborne Listeriosis Symposium, Wiesbaden, Germany, 7 September 1988). Contaminated pâté was epidemiologically linked to 300 cases of listeriosis in the United Kingdom during 1989 to 1990 (133). Contaminated pork tongue in aspic marketed in France was the principal vehicle for 279 cases of listeriosis reported during a 10-month period in 1992 (134). Potted pork

("rillettes") was associated with 39 cases in 1993, and soft cheese was the vehicle for 33 cases in 1995 (135). Recalling the implicated food, advising the general population through the mass media to avoid consuming the implicated product, and taking appropriate action to prevent further *L. monocytogenes* contamination during manufacture and handling terminated these large outbreaks.

A large multistate outbreak of listeriosis occurred in the United States between August 1998 and March 1999. A total of 101 outbreak-associated cases (including 15 perinatal cases) were identified in 22 states. Fifteen adult deaths and six miscarriages or stillbirths were associated with this outbreak. A case-control study implicated turkey franks from a major manufacturer produced at one facility. *L. monocytogenes* serotype 4b of the epidemic PFGE subtype was isolated from opened and unopened packages of frankfurters from the implicated factory (136, 137).

Between December 1998 and February 1999, an increase in listeriosis cases due to *L. monocytogenes* serotype 3a was recognized in Finland. A total of 25 cases, most of which occurred in hematological or organ transplant patients, were identified as part of the outbreak; six patients died from *Listeria* infection. Butter served at a tertiary-care hospital was implicated as the source of infection. The epidemic strain was isolated from all 13 butter samples obtained from the hospital kitchen and from several lots from the dairy and wholesale store. One sample contained 11,000 *L. monocytogenes* CFU/g, with the others having lower counts (5 to 60 CFU/g) (27). Another outbreak of listeriosis associated with butter occurred in 2003 in the United Kingdom.

Between May and November of 2000, a listeriosis outbreak in the United States impacted 11 states. When subtyped, the *L. monocytogenes* isolates from these cases were all serotype 1/2a and were indistinguishable from each other by PFGE. Eight perinatal and 21 nonperinatal cases were reported. Among the 21 nonperinatal case patients, the median age was 65 years (range, 29 to 92 years); 13 (62%) were female. This outbreak resulted in four deaths and three miscarriages or stillbirths. A casecontrol study implicated sliced processed turkey meat from a delicatessen. A traceback investigation identified a single food processing plant as the source of this outbreak and led to the recall of 16 million pounds of processed turkey meat. The same plant had been identified in a *Listeria* contamination event that had occurred a decade previously (138).

An outbreak of listeriosis, identified in North Carolina in 2000, affected 13 people, of whom 12 were 18-to 34-year-old Hispanic females. This outbreak, which resulted in five stillbirths, was traced to Mexican-style cheese produced from contaminated raw milk at a local dairy (38). Another listeriosis outbreak in Texas was associated with legally imported but illegally distributed cheese prepared in Mexico. Five of six case patients reported eating the implicated cheese. These outbreaks underscore the need for educating Hispanic women about food safety considerations during pregnancy and enforcing existing laws that regulate the illegal sale and importation of certain cheeses that have been prepared from raw milk.

During October 2002, another multistate outbreak of listeriosis was recognized in Pennsylvania and eight other states in the United States (139). This outbreak of 54 cases included eight deaths and three fetal deaths. Case-control studies implicated delicatessen turkey meat as the source of the outbreak. In traceback studies, the outbreak strain, which was related to the 1998-1999 outbreak strain according to PFGE, was found in the environment of one turkey processing plant and in turkey products produced by another plant. Together, the two plants recalled more than 30 million pounds of turkey meat products (Table 17.2.). This outbreak, together with the outbreak in 2000 that was traced to delicatessen turkey, led to the three previously discussed alternatives for control of *Listeria* in RTE meats, with no additional large-scale RTE meat-related outbreaks having been identified in the United States since 2002. However, in 2008, a nationwide outbreak in Canada that included 57 cases of illness and 23 fatalities was traced to various delicatessen meats that became contaminated during packaging at a larger manufacturing facility in the province of Ontario. The *L. monocytogenes* isolates from this outbreak belonged to serotype 1/2a but were of two distinct PFGE patterns (140). This outbreak led to the adoption of additional preventive measures in Canada, as described above.

Since the initial link between consumption of coleslaw and listeriosis in 1981 that confirmed *L. monocytogenes* as a foodborne pathogen, fresh produce was thought to play a minor role in invasive

illness. However, in 2010 consumption of commercially diced celery was linked to 10 cases of listeriosis, including 5 fatalities in the state of Texas (141). In 2011, a much larger outbreak of listeriosis in the United States was traced to cantaloupes that were grown and packed in Colorado, with a total of 146 cases of illness, including 30 deaths, being reported across 28 states from July 31 to October 27. The victims ranged in age from <1 to 96 years with a median age of 77 years (87). An unusual feature of this outbreak was the involvement of four different *L. monocytogenes* strains, belonging to serotypes 1/2a and 1/2b, that exhibited widely divergent PFGE patterns and genome sequences (142). Three of these four strains were recovered from the processing line or packing area, suggesting multiple incoming sources of contamination. In subsequent years, several other listeriosis outbreaks in the United States have been linked to produce, including outbreaks linked to mung bean sprouts in 2014 (5 cases, including 2 deaths) (89), prepackaged caramel apples in 2014 to 2015 (35 cases, including 7 deaths) (90), packaged salads in 2016 (19 cases, including 1 death) (93), and frozen vegetables in 2016 (9 cases, including 3 deaths) (94).

Table 17.2 Selected invasive listeriosis outbreaks, 1990 to 2018

Yr(s)	Geographic location	No. of persons affected	No. of deaths or fetal deaths	Vehicle	Serotype[a]	Reference(s)
1989–90	Denmark	26	6	Blue mold cheese or hard cheese	4b	266

[b] Inferred from multilocus sequence typing (19).

The *L. monocytogenes* strains responsible for the major outbreaks from 1981 to 1992 (Canada, 1981; California, 1985; Switzerland, 1983 to 1987; France, 1992) were all serotype 4b and belonged to a small number of closely related clones, as evidenced by ribotyping, multilocus enzyme electrophoresis, and DNA macrorestriction pattern analysis (143). This group of closely related, epidemic-associated strains was designated ECI. The 1998–1999 and 2002 multistate outbreaks in the United States were caused by strains of a novel epidemicassociated lineage, ECII (20).

During the past decades, several outbreaks of febrile gastroenteritis caused by *L. monocytogenes* have been documented (Table 17.3.). These gastroenteritis outbreaks differ in several respects from the invasive outbreaks just described. They affect persons with no known predisposing risk factors for listeriosis. The infectious dose appears to be much higher (1.9×10^5 to 1.6×10^9 CFU/g or CFU/ml) than that for typical invasive listeriosis in the susceptible population. Finally, the symptoms of gastrointestinal listeriosis appear within a day or less (typically in 18 to 27 h) of exposure (similar to other bacterial enteric infections), in contrast to the several weeks or more of incubation observed for invasive listeriosis.

Table 17.3 Outbreaks of gastrointestinal manifestation of listeriosis in humans with no known predisposing condition[a]

Yr(s)	Geographic location	Incubation time (h)	No. of persons affected	Symptoms	Vehicle Vehicle	Serotype	Contamination level (CFU/g or ml)	Ref
1986–87	Pennsylvania	Unknown	Unknown	Fever, vomiting, and diarrhea in the week before positive culture	Unknown	Multiple serotypes	NA	273

CHARACTERISTICS OF DISEASE

Human disease caused by *L. monocytogenes* predominantly occurs in certain well-defined high-risk groups that include pregnant women, neonates, immunocompromised adults, and the elderly but has also been documented in individuals with no predisposing underlying conditions. In nonpregnant adults, *L. monocytogenes* primarily causes septicemia, meningitis, and meningoencephalitis, with a mortality rate of 20 to 30%. Other infrequent manifestations of listeriosis in this population include endocarditis in persons with underlying cardiac lesions (including prosthetic or porcine valves) and various types of focal infections, including endo-ophthalmitis, septic arthritis, osteomyelitis, pleural infection, and peritonitis (102). Clinical conditions known to predispose persons to the serious manifestations of listeriosis include malignancy, organ transplants, immunosuppressive therapy, HIV infection, and advanced age. Although pregnant women, particularly in the third trimester of pregnancy, may experience only mild flu-like symptoms (fever and myalgias with or without diarrhea) from exposure to *L. monocytogenes*, the infection has serious consequences for the fetus, leading to stillbirth or abortion. In neonates who are less than 7 days old, sepsis and pneumonia are the predominant syndromes, whereas in older neonates, the infection manifests as meningitis and sepsis.

Several investigations of listeriosis outbreaks show that *L. monocytogenes* can also cause febrile gastroenteritis in otherwise healthy hosts (Table 17.3.). Interestingly, Murray and Pirie clearly stated in their original descriptions of cases from the 1920s that diarrhea was a common feature of listeriosis in small animals (3). The most compelling evidence for the gastrointestinal manifestation of *L. monocytogenes* infections comes from outbreak investigations by Dalton et al. (45) and Aureli et al. (144). Fever and diarrhea are the most consistent symptoms in gastrointestinal listeriosis. Also, the incubation time for the enteric form is rather short, usually in the range of 18 to 27 hours. However, the incubation time varied between 24 and 144 hours in a 2001 Japanese outbreak involving cheese, possibly because of wide-ranging contamination levels (Table 17.3.). In the five investigations in which attempts were made to quantify the numbers of *L. monocytogenes* cells in the implicated foods, contamination levels were very high (range, 1.9×10^5 to 1.6×10^9 CFU). From the data available thus far for gastrointestinal listeriosis, it appears that infection requires a high dose of *L. monocytogenes*. It is not known whether the strains involved in the gastrointestinal forms of listeriosis possess additional virulence factors similar to those of common enteric pathogens.

While listeriosis outbreaks attract the most attention, most cases of human listeriosis occur sporadically. However, some of these sporadic cases may be unrecognized common-source clusters. The source and route of infection of most of these cases remain unknown, although foodborne transmission has been either demonstrated or suspected in most instances. Many cases have not been associated with food because of the difficulties associated with prospective investigations. Long incubation times (up to 10 weeks) make accurate food histories difficult if not impossible to obtain, and incriminated foodstuffs almost always have been consumed or discarded.

Understanding the epidemiology of sporadic cases is critical to the development of effective control strategies. An active surveillance program for listeriosis in the United States from 1989 to 1991 based on a population of 19 million people yielded an estimated incidence of 7.9 cases per million. A case-control study of dietary risk factors conducted during the same period indicated that foodborne transmission was responsible for about one-third of cases and that patients with listeriosis were more likely than controls to have eaten soft cheeses or foods purchased from delicatessen counters (145, 146). By 1993, the incidence of sporadic cases of listeriosis in the active surveillance sites had declined to 4.4 cases per million (147), with this decrease being attributed to enhanced efforts by the food industry and regulatory agencies to prevent contamination of processed foods. The 2010 data from CDC's foodborne diseases active surveillance program (FoodNet) indicate that the incidence of listeriosis in the United States had declined to 2.4 cases per million population (148), with an estimated 1,600 cases occurring annually, including 255 fatalities (5).

Although exposure to *L. monocytogenes* is common, invasive listeriosis is rare. It is unclear whether this is due to early acquired protection, to intrinsic resistance of the average healthy host, or to most strains being only weakly virulent. Despite improvements in the emerging picture concerning the key

events affecting the relative susceptibility of humans to this pathogen (149), there remain gaps in our understanding of the onset of disease (see below). Between 2 and 6% of healthy individuals are asymptomatic fecal carriers of *L. monocytogenes*. The risk of clinical disease in intestinal carriers of *L. monocytogenes* is unknown but must be very low, given the rarity of diagnosis. Endogenous infections by *L. monocytogenes* in the gut are plausible, especially in patients receiving immunosuppressive therapy, which can impair resistance to infection and alter the intestinal defense mechanisms to favor listerial invasion. Nevertheless, asymptomatic fecal carriage has been observed in pregnant women who proceed to normal birth at term, and women who have given birth to infected infants do not necessarily suffer the same problem in later pregnancies. Similarly, recent transplant recipients may harbor *L. monocytogenes* in the gut without developing the disease.

Epidemiologic studies since 1981 have focused on the role of contaminated food in transmission of listeriosis. However, two unusual transmission routes have been described. Hospital-acquired listeriosis is sporadically observed, mainly in nurseries, with equipment serving as the vehicle. During intrauterine infections, amniotic fluid can contain up to 10^8 *L. monocytogenes* CFU/ml (150). Mineral oil was also implicated in one outbreak of neonatal listeriosis (151). Primary cutaneous infections without systemic involvement have been observed as an occupational disease in veterinarians and farmers, with most cases being caused by manipulation of presumably infected bovine fetuses or cows.

INFECTIOUS DOSE AND SUSCEPTIBLE POPULATIONS

Infectious Dose

The infectious dose of *L. monocytogenes* depends on many factors, including the immunological status of the host, the type of food consumed, the degree of virulence of the particular strain, and the numbers ingested, as seen from the previously discussed outbreaks (152). The severity of the disease is such that tests with human volunteers are impossible. Studies involving monkeys and other animals suggest that reducing levels of exposure will reduce clinical disease (153). However, these experiments do not help to determine the minimal infective dose for humans. Further, the current assumption is that for infectious and toxicoinfectious agents, a single cell has a small but finite probability of causing disease. In the case of *L. monocytogenes*, a risk assessment by the WHO and the Food and Agriculture Organization of the United Nations estimated that the median probability for a single cell causing listeriosis is in the range of 10^{-12} to 10^{-14} (154) based on exposure data and annual disease statistics. When exposed to *L. monocytogenes* at the beginning of the third trimester, pregnant rhesus monkeys showed an increased risk of delivering a stillborn infant with pathology similar to that of humans, including acute inflammation, placentitis, fetal liver necrosis, and isolation of *Listeria* from the placental and fetal tissues (155).

The populations of *L. monocytogenes* in contaminated food responsible for epidemic and sporadic foodborne cases usually contained more than 100 CFU/g. The frankfurters implicated in the 1998 listeriosis outbreak in the United States contained less than 0.3 CFU/g (124), while ice cream implicated in a 2014–2015 outbreak yielded *L. monocytogenes* at an average most probable number of 8/g (125). However, these results may not accurately reflect the numbers consumed, since *Listeria* populations in the food would be expected to change between the time of consumption and analysis. It is clear that the risk of foodborne listeriosis is overwhelmingly associated with RTE foods that support the growth of *L. monocytogenes* at refrigeration or marginal abuse temperatures. Hence, additional epidemiologic information is clearly needed to more accurately assess the infectious dose.

Susceptible Populations

Most human cases of listeriosis occur in individuals who have a predisposing disease that leads to impairment of their T-cell-mediated immunity (152). The percentage of patients suffering from a known underlying condition varies from 70 to 85% in some surveys to nearly 100% in others (156, 157). The most commonly affected populations include those at either age extreme (neonates and the elderly), pregnant women, and individuals who are immunosuppressed by medication (corticosteroids

or cytotoxic drugs), especially after organ transplantation or illness (hematologic malignancies, such as leukemia, lymphoma, and myeloma, as well as solid malignancies). Listeriosis is 300 times more frequent in people with AIDS than in the general population (158). In addition to impaired T-cell immunity, a small percentage of listeriosis patients suffer from chronic diseases not usually associated with immunosuppression, such as congestive heart failure, diabetes, cirrhosis, alcoholism, and systemic lupus erythematosus, alone or in association with known predisposing diseases. Mortality in listeriosis cases is almost exclusively associated with predisposing diseases and conditions (159), with recent transplant patients being the subpopulation at greatest risk, as they are ~2,500 times more susceptible than healthy adults under 65 years of age (154).

Concurrent infection can also influence susceptibility to listeriosis. This was exemplified by a cluster of cases in 1987 in Philadelphia that were caused by a number of different strains. Clinical and epidemiologic investigations suggested that individuals who were previously asymptomatic for listerial infection but whose gastrointestinal tract harbored *L. monocytogenes* became symptomatic, possibly because of a coinfecting agent (158). However, a single food vehicle could not be identified due to the diversity of strains.

VIRULENCE FACTORS AND MECHANISMS OF PATHOGENICITY

In the early 1980s, *L. monocytogenes* was an attractive model system to study both intracellular parasitism and the immunological response of humans and animals to infection. This was due to five main factors: (i) *L. monocytogenes* grows well in culture media, (ii) it can be genetically manipulated, (iii) it belongs to a genus that contains pathogenic and nonpathogenic species, (iv) it infects mammalian cells in tissue culture, and (v) several laboratory animals are susceptible to *Listeria* (160). The *L. monocytogenes* genome was first sequenced in 2001, paving the way for the discovery of a series of new virulence factors (102, 161, 162). Since that initial study, genome sequencing has become the tool of choice for outbreak investigations of *L. monocytogenes*. In addition, as genomic data can be used for taxonomic purposes, genome sequences for representatives of all *Listeria* species are available (10, 163).

Pathogenicity of *L. monocytogenes*

Many tests for addressing *L. monocytogenes* pathogenicity have been developed, including tissue culture assays and tests using laboratory animals, in particular immunocompetent and immunocompromised mice (164, 165). Animal models routinely involve intraperitoneal or intragastric infection, and virulence is evaluated either by comparing the LD_{50}s or by enumerating bacteria in infected target organs, in particular the spleen and liver. Heterogeneity in the virulence of *L. monocytogenes* has been observed in several *in vitro* and *in vivo* studies (LD_{50}s of *L. monocytogenes* strains range from 10^3 to 10^9 CFU) (153, 166, 167), depending on the animal or *in vitro* system being used and whether the immune system of the animal was suppressed prior to exposure. No clear correlation between the level of virulence and the origin (human, animal, category of food, or environment) or the strain characteristics (serotype, phage type, multilocus enzyme type, or DNA micro-or macrorestriction patterns) could be established. Diet may also play a role, as a recent study showed that even short-term exposure to a high-fat diet increased susceptibility of mice to *Listeria* infection (168).

However, only 3 of the 13 known serovars of *L. monocytogenes*, 1/2a, 1/2b, and 4b, account for more than 90% of human cases of listeriosis (158, 169). Among the listeriosis-associated serotypes, 4b strains cause a large proportion of listeriosis outbreak cases worldwide, serotypes 1/2a and 1/2b account for a significant portion of sporadic cases, and serotypes 1/2a, 1/2b, and 1/2c predominate in food isolates (67, 170–172). As discussed earlier, specific ECs of serotype 4b and 1/2a have been linked to specific single nucleotide polymorphisms. The relatively low percentage of cases caused by serotypes 1/2a, 1/2b, and 1/2c from foods appears to be strongly influenced by mutations leading to premature stop codons in *inlA*, which encodes internalin A. Although rare nonpathogenic or weakly pathogenic *L.*

monocytogenes isolates have been reported, all strains of *L. monocytogenes* are considered potentially capable of causing human disease.

There has been substantial debate over the appropriateness of various routes of administration and animal models for studying *L. monocytogenes* pathogenicity, particularly in regard to fetal infections. Since most listeriosis cases are associated with foodborne transmission, it is generally accepted that an oral route of administration is most suitable, particularly since there can be substantial differences in the ability of *L. monocytogenes* strains to cross the intestinal barrier. Crossing both the intestinal and placental barriers involves two proteins, internalin A (InlA) and internalin B (InlB), which mediate high-specificity attachment to specific epithelial cells and low-specificity attachment to a wide variety of cell types, respectively (173). The former attaches to the Ecadherin receptor, while the latter attaches to the hepatocyte growth factor (Met) receptor. E-cadherin receptors differ among mammalian species, with InlA from *L. monocytogenes* binding to the receptors on the intestinal epithelial cells of humans, guinea pigs, rabbits, and gerbils but not those of mice or rats, bringing into question the appropriateness of using mice to study orally transmitted listeriosis. Similarly, there are differences in host specificity related to the ability of *L. monocytogenes* to cross the placental barrier, with the pathogen invading the barrier in humans, rats, rabbits, and gerbils but not in mice or guinea pigs. High-efficiency invasion of the placental barrier requires receptors for both InlA and InlB (173, 174). There have been an increasing number of dose-response trials and related research that have focused on the use of rhesus monkeys, guinea pigs, gerbils, or "humanized" mice (155, 175–178).

Experimental Infection and Cell Biology of the Infectious Process

Much of the original work on the disease course of *L. monocytogenes* was performed with mice injected intravenously, with subsequent monitoring of bacterial growth kinetics in the spleen and liver. Within 10 minutes after intravenous injection, 90% of the inoculum is taken up by the liver and 5 to 10% by the spleen. During the first 6 hours, the number of viable *Listeria* cells in the liver decreases 10-fold, indicating rapid destruction of most of the bacteria. Surviving *Listeria* cells then multiply within susceptible macrophages and grow exponentially in the spleen and liver for the next 48 hours, peaking at day 2 or 3 postinfection (179). Rapid inactivation ensues during the next 3 to 4 days, indicating recovery of the host. Convalescent mice are resistant to challenge and have a delayed-type hypersensitivity characterized by swelling of the footpads injected with crude cell preparations of *L. monocytogenes*.

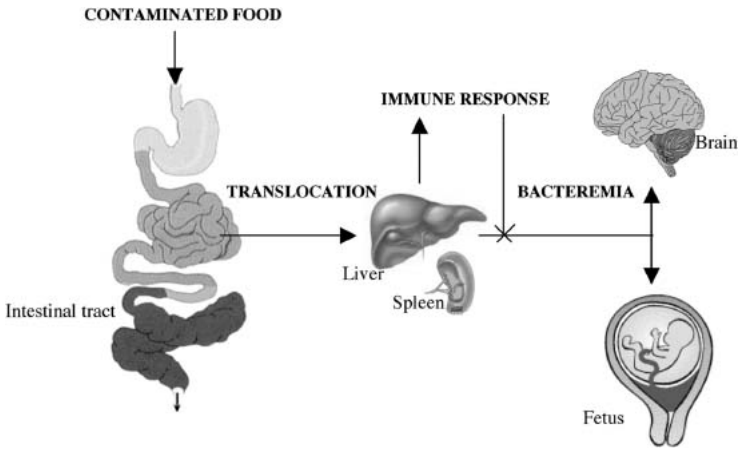

Figure 17.2 Schematic representation of the pathophysiology of *Listeria* infection.

However, as described above, the natural route of foodborne infections with *L. monocytogenes* in humans is via the gastrointestinal tract. *L. monocytogenes* infects intestinal epithelial cells in a process that requires the interaction of InlA, expressed at the bacterial surface, with epithelial E-cadherin, expressed at the surface of epithelial cells (180). Although *L. monocytogenes* has a relatively broad host range, the relative susceptibility of mammalian species to ingested *L. monocytogenes* varies based

in large part on the attachment to and invasion of the intestinal epithelium. As indicated above, this reflects differences in the epithelial receptors. For example, mice are relatively resistant to intestinal infection with *L. monocytogenes* because of a single amino acid difference between human and mouse E-cadherin (181). Recent studies using different *L. monocytogenes* strains report that, in contrast to strains from other serovars, serotype 4b epidemic strains appear to be able to cause systemic infection in mice infected orally. This suggests that there might be serovar-specific virulence factors playing a role in mouse susceptibility to orally acquired listeriosis (182). The probability that an oral infection will lead to perinatal infections has been related to the probability of specific "key events": (i) survival of the pathogen in the upper gastrointestinal tract, (ii) attachment to and uptake into the intestinal epithelial cells, (iii) survival and escape from phagosomes and transfer to phagocytes, (iv) transfer across the placenta, and (v) pathogen growth leading to fetal morbidity and mortality (149).

From the intestinal lumen, bacteria traverse the epithelial-cell layer and disseminate via the bloodstream to other organs, such as the spleen and liver, where they are internalized by splenic and hepatic macrophages in which they can survive and replicate (Fig 17.2). When the *Listeria* cells reach the liver and the spleen, most are rapidly killed. In the initial phase of infection, infected hepatocytes are the targets for neutrophils and later for mononuclear phagocytes that are responsible for control and resolution of infection. The bacterial cells are subsequently transported via the blood to regional lymph nodes. Depending on the level of T-cell response induced in the first days following initial infection, further dissemination may subsequently occur via the blood to the brain or, in the pregnant animal, the placenta.

L. monocytogenes possesses the ability to cross the maternofetal barrier and leads to placental abscesses, chorioamnionitis, and finally infection of the fetus. As the highest concentrations of *L. monocytogenes* are encountered in the gut and in the lung, it is thought that infection might be amplified through ingestion of contaminated amniotic fluid rather than solely as a consequence of the hematogenous transplacental route (183). Several animal models have been developed to study pregnancy-associated (15, 184–186) and pulmonary (186) *L. monocytogenes* infections.

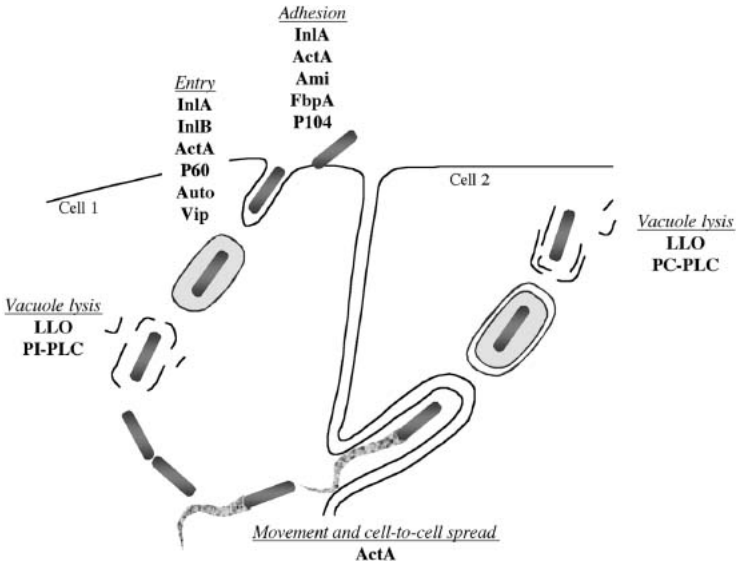

Figure 17.3 Schematic representation of the successive steps of the cell infection process. Factors implicated in the different steps are indicated.

L. monocytogenes has, in addition to its ability to cross initially the intestinal barrier and the maternofetal barrier, the capacity to cross the blood-brain barrier and reach the central nervous system (CNS) and cause meningitis, encephalitis, and brain abscesses. Invasion of brain cell endothelial cells seems a prerequisite for meningeal pathogens that penetrate the CNS. It has been proposed that *L. monocytogenes* utilizes penetration of human brain microvascular endothelial cells as a means of

crossing the blood-brain barrier. *L. monocytogenes* adheres to human brain microvascular endothelial cells through the microvilli and then infects them by an InlBdependent mechanism (187).

Once inside a susceptible host, *L. monocytogenes* has the potential to disseminate and multiply in a wide vari ety of cell types and tissues. *Listeria* is primarily found intracellularly due to its ability to induce its own phagocytosis into many cell lines (e.g., macrophages, fibroblasts, hepatocytes, and epithelial cells) that are normally nonphagocytic (188). Detailed analysis of infected-tissuecultured cells reveals a complex series of interactions between the bacteria and the cell (Fig 17.3). Host cell infection begins with the adhesion and internalization of the bacteria either by phagocytosis in the case of macrophages or by induced phagocytosis (invasion) in the case of normally nonphagocytic cells. It has been suggested that at the intestinal epithelium, InlA provides high-specificity adhesion while InlB activates the c-MET receptor, which in turn accelerates junctional endocytosis into the enterocytes (189), with goblet cells being the specific location of attachment (190). Bacterial invasion starts by a close contact with the plasma membrane that progressively enwraps the bacterium. This process is usually referred to as the "zipper" mechanism, in contrast to the "trigger" mechanism used by *Salmonella* or *Shigella* (191).

Following internalization, bacteria reside within membrane-bound vacuoles (phagosomes) for ~30 min. *L. monocytogenes* escapes the vacuoles by perforating the membrane by the combined action of listeriolysin O (LLO) and two phospholipases. Neumann et al. (192) concluded that *L. monocytogenes* could escape phagosomes independent of listeriolysin in interleukin-4-deactivated human macrophages. Once free in the cytosol, *L. monocytogenes* replicates and becomes covered with actin filaments. These filaments rearrange within 2 hours into long comet tails (up to 40 μm in length) left behind in the cytosol while the bacteria move ahead at a speed of ~0.3 μm/s (193, 194). When moving bacteria contact the plasma membrane, they induce the formation of bacterium-containing protrusions. Contact between these protrusions and neighboring cells results in the internalization of the protrusion (195). In the newly infected cell, the bacterium is surrounded by two plasma membranes that must be lysed to initiate a new cycle of multiplication and movement. Lysis of the two membrane vacuoles requires at least four virulence factors: LLO, the metalloprotease Mpl, and two phospholipases (see below). The entire cycle is completed in about 5 hours. This process allows *L. monocytogenes* to disseminate by direct cell-to-cell transfer, thereby avoiding humoral defenses such as antibodies. This accounts for the early observations that antibodies are not protective and that immunity to *Listeria* is T cell mediated (160).

Virulence Factors

The overall pathogenesis of *L. monocytogenes* and identification of individual virulence determinants have been studied extensively using a variety of genetic techniques. Conjugative transposons from the Tn*1545*-Tn*916* family or Tn*917* transposons were initially exploited to generate mutant libraries, allowing the identification of several *L. monocytogenes* virulence factors (196, 197). Additionally, Tn*1545*-and Tn*917*-derived tagged transposons were also used for signature-tagged mutagenesis (198, 199). As previously discussed, genome sequencing of multiple strains has allowed the direct comparison of pathogenic and nonpathogenic isolates for the identification of specific virulence determinants. Plasmid vectors originating from *Bacillus subtilis* and *Escherichia coli* are used for genetic studies in *L. monocytogenes*, including allelic exchange of chromosomal DNA, cloning, gene expression, or reporter gene fusion (200). For allelic exchange, inframe deletion, or site-specific mutagenesis, thermosensitive vectors such as pKSV7 (201) and pAUL-A (202) are used. A novel thermosensitive plasmid, pMAD, harboring the β -galactosidase gene, facilitates the screening and the generation of allelic exchanges (203). For complementation and gene expression, shuttle plasmids replicating in *E. coli* and *L. monocytogenes* are mostly used, such as pAT18, pMK4, and pAM401 (204–206).

Complementation of deletion mutants can now be achieved using a new integrative phage-derived plasmid, pPL2, that allows a single-copy integration at a specific location in the *L. monocytogenes* chromosome (207). Listeriae do not seem naturally competent; however, transformation with plasmid DNA can be obtained on protoplasts or by electroporation (208, 209). In addition to traditional

molecular methods, WGS and single-nucleotide-polymorphism analyses have been used extensively to study the evolution of *Listeria* virulence, *L. monocytogenes* population genetics, and genomic evolution.

These tools have led to the successive identification of multiple virulence determinants that are necessary to modulate the ability of *L. monocytogenes* to cause disease and determine the relative virulence ability of individual isolates. Gene expression analysis is providing an appreciation of the large number of genes (>70) that may be involved in *in vivo* infections and the complexity associated with the disease course and the ability of the microorganism to evade cellular defenses (210). Some of the well-defined virulence determinants are described in more detail below in relation to their role in *L. monocytogenes* pathogenesis.

Adhesion to Mammalian Cells

The first step in the disease course of foodborne listeriosis is the attachment of *L. monocytogenes* to the intestinal epithelium. In addition to its role as the first step in the internalization and passage through the intestinal epithelium, adhesion may promote colonization of the gastrointestinal tract, may direct the bacteria to appropriate target cells or tissues such as the CNS or the placenta, and may even facilitate cell invasion by activating cell signal transduction pathways or triggering the synthesis of a target cell receptor required for invasion.

Adherence involves a number of surface proteins, including InlA, ActA, Ami, p104, and FbpA. InlA is the first member of the internalin multigene family, a family characterized by the presence of a leucine-rich repeat (LRR) region (211). InlA promotes adherence and entry into cells expressing its receptor, the adhesion protein Ecadherin (180) (see above and below). ActA, the surface protein required for actin-based motility, may also promote attachment via host cell proteoglycans (212, 213). An ActA-deficient mutant is significantly impaired in attachment to and entry into IC-21 murine macrophages and Chinese hamster ovary epithelial cells. Ami is a bacterial surface amidase that presents an N-terminal domain similar to the amidase domain of the Atl autolysin of *Staphylococcus aureus* and a C-terminal, cell wallanchoring domain made up of eight GW dipeptide modules (214). Besides its lytic activity on *Listeria* cell walls (215), Ami is implicated in bacterial adhesion to target cells (216). Ami mutants are attenuated, indicating that Ami plays a role in the virulence of *L. monocytogenes*. Finally, FbpA is a fibronectin-binding protein shown to be required for intestinal and liver colonization after oral infection of transgenic mice expressing human Ecadherin. FbpA binds to immobilized human fibronectin and increases adherence of wild-type *L. monocytogenes* to HEp-2 cells. Despite the lack of conventional secretion and anchoring signals, FbpA is detected on the bacterial surface and was shown to be a substrate of the SecA2 pathway (199). In addition, FbpA behaves as a chaperone for two important virulence factors, LLO and InlB, probably preventing their degradation. The roles of surface proteins, including adhesion, have been reviewed by Bierne and Cossart (217).

Entry into Mammalian Cells

InlA and InlB were the first listerial factors identified as mediating bacterial invasion into different target cell types. As discussed above, their cellular receptors have also been identified. The molecular signaling cascades triggered during *Listeria* entry into host cells are being characterized in detail. InlA and InlB are just two of a family of internalins (e.g., InlC, InlD, InlH, and InlJ) that are characterized by the presence of LRRs (211). Some internalins are present in most lineages, whereas others are associated with specific lineages or serotypes (8). Some are associated with adhesion to enterocytes (InlA), whereas others may play a role in stimulating junction endocytosis (see above). Recent findings suggest that other molecules are also necessary for internalization (P60, ActA, Auto, and Vip), revealing a complex dialogue between *Listeria* and eukaryotic cells during the early phases of the infection cycle.

Internalins

InlA (800 amino acids) displays a classical signal sequence followed by an LRR region comprising 15 repeats of 22 amino acids. An interrepeat (IR) region separates the LRR region from a second repeat

region (called the B repeat region). The carboxy terminus displays a cell wall-sorting motif, LPTTG, which is the substrate for the enzyme sortase A and allows covalent linkage of the protein to the peptidoglycan. The LRR and IR regions are necessary and sufficient to promote *Listeria* entry into human epithelial cells (181). E-cadherin, the InlA receptor (180), belongs to the cadherin superfamily of cell adhesion molecules, which are transmembrane glycoproteins located at adherens junctions and allow cell-cell adhesion. The species-specific nature of the interaction between *L. monocytogenes* and animal hosts (see above) involves recogni tion of a proline at position 16 (Pro16) of the E-cadherin molecule (218). Also, as mentioned above, the truncation of InlA that occurs naturally in some strains associated with foods helps to explain the decreased incidence of listeriosis cases associated with 1/2a, 1/2b, and 1/2c from food sources, and a recent epidemiologic survey indicates that clinical strains express a full-length InlA far more frequently than do strains recovered from food products (219, 220), revealing that InlA is critical for the pathogenesis of human listeriosis.

InlB (630 amino acids) is another member of the internalin family involved in entry of *Listeria* into a broad range of cell lines, including hepatocytes and nonepithelial cells (221) (see above). It contains a signal peptide, seven LRR repeats, one IR region, and one B repeat. The C-terminal domain presents three tandem repeats (GW modules) that mediate attachment of InlB to the bacterial cell wall through noncovalent interaction with lipoteichoic acids (211). The LRR region of InlB is sufficient to confer invasiveness to noninvasive *L. innocua* or to latex beads (222). InlB directly binds to cellular glycosaminoglycans (GAGs) through its GW modules. InlB-dependent entry into epithelial cells is strongly affected by depletion of the cellular plasma membrane GAGs. It was proposed that interaction of InlB with GAGs through its GW modules leads to its detachment from the bacterial surface, allowing its clustering at the cellular surface through binding to Met by its LRR domain and favoring the local activation of the signaling pathway downstream of Met (223).

P60 Protein

For a long time, Δ*iap* (encoding invasion-associated protein) mutants could not be obtained, suggesting that the protein was essential for bacterial viability. Therefore, the role of P60 (encoded by *iap*) was first evaluated in spontaneous rough mutants expressing lower levels of P60 and forming long filamentous structures composed of bacterial chains (224). The rough mutants are less virulent and enter certain eukaryotic cells less efficiently, suggesting a role for P60 in bacterial invasion (225).

Ultimately, a viable Δ*iap* mutant was obtained, allowing more precise studies of the role of P60. Like rough mutants, these also had a defect in septum formation and in virulence after intravenous infection of mice. In addition, the Δ*iap* mutant is impaired in bacterial movement and spreading from cell to cell due to an improper localization of ActA at the surface of *L. monocytogenes* (226, 227). However, in contrast to studies using rough mutants, the invasiveness of the Δ*iap* mutant in mouse fibroblasts and human epithelial cells is only slightly diminished compared with that of wild-type bacteria (226, 227). P60 is an autolysin both secreted by and associated with the bacterial cell wall (224, 228). Secretion is mediated as for FbpA by the recently identified auxiliary secretion system SecA2, which mediates the secretion of at least 17 secreted and surface proteins of *L. monocytogenes* (226, 227). In addition, P60 plays an important role in the immune response against *L. monocytogenes* infection.

ActA Protein

ActA is a surface protein implicated in the attachment to cells (see above) and responsible for the actin-based motility of *Listeria* (see below). Moreover, expression of ActA in *L. innocua* is sufficient to promote bacterial entry in some epithelial cell lines (212).

Auto Protein

A novel autolysin-encoding gene, *aut*, has been identified (229). It is the only autolysin gene that is absent from the nonpathogenic species *L. innocua*. The *aut* gene encodes a surface protein, Auto, with an autolytic activity, as expected from the presence of a domain harboring homologies with autolysin-

encoding genes, especially *N*-acetylglucosaminidases. The protein Auto possesses a C-terminal cell wall-anchoring domain made up of four GW modules, similar to those observed in the other autolysin, Ami, and in InlB (230). The morphology of an *aut* deletion mutant is similar to that of the wild type, with no defect in septation and cell division, suggesting no role for Auto in these functions (229). Auto is required for entry of *L. monocytogenes* into different nonphagocytic eukaryotic cell lines. An *aut* deletion mutant has reduced virulence following intravenous inoculation of mice and oral infection of guinea pigs, which correlates with its low invasiveness. However, the autolytic activity of Auto by itself, rather than an invasive ability, might be critical for virulence. Indeed, Auto may control the general surface architecture exposed to the host by *L. monocytogenes* and/or the composition of the surface products released by the bacteria, hence affecting the host response to infection (229).

Vip Protein

The *vip* gene encodes an LPXTG surface protein absent from nonpathogenic *Listeria* species (231). *vip* is positively regulated by PrfA, the transcriptional activator of the major *Listeria* virulence factors. Vip is anchored to the *Listeria* cell wall by sortase A and is required for entry into some mammalian cells. Using a ligand overlay approach, a Vip cellular receptor was identified. It is the endoplasmic reticulum-resident protein Gp96, reported to also interact with Toll-like receptors (232). The Vip-Gp96 interaction is critical for bacterial entry into some cells. Comparative infection studies using oral and intravenous inoculation of nontransgenic and transgenic mice expressing human Ecadherin demonstrated a role for Vip in *Listeria* virulence not only at the intestine level but also in late stages of the infectious process. Vip thus appears to be a new virulence factor exploiting Gp96 as a receptor for cell invasion and/or signaling events that may interfere with the host immune response in the course of the infection (231).

Sortases

The genome of *L. monocytogenes* EGD-e contains 41 genes that encode LPXTG proteins, including InlA and Vip (230). LPXTG proteins are anchored to the peptidoglycan by transpeptidases named sortases (230). *srtA* encodes a sortase responsible for the anchoring of InlA, Vip, and at least 13 other proteins to the peptidoglycan (217). *L. monocytogenes* mutants lacking *srtA* are defective in internalizing into human enterocyte-like Caco-2 cells and hepatocytic HepG2 cells, as well as in colonizing the livers and spleens of mice infected orally. The *Listeria* genome encodes another sortase, SrtB, which has a limited number of substrates containing a C-terminal NXXTN sorting motif. SrtB is not required for the infectious process (233).

Escape from the Phagosome and Intracellular Growth

Once *L. monocytogenes* is internalized, the next key step in the disease course is to escape the vacuole or phagosome via the concerted action of LLO and two phospholipases C, each of which is considered a virulence determinant. Once in the target cell cytoplasm, *Listeria* then multiplies, acquiring nutrients from the cytosol.

Listeriolysin O

Nonhemolytic *L. monocytogenes* strains can be found in the environment but are avirulent in experimentally infected mice. Nonhemolytic mutants generated by conjugative transposons were found to be similarly avirulent in mice (234). Both wild-type and nonhemolytic strains entered mammalian cells but were unable to grow intracellularly due to an inability to escape from the phagocytic vacuole (235). Subsequent analysis indicated that the mutations resulted in disruption of *hly*, which encodes LLO. LLO is a pore-forming toxin that enables the bacterium to escape into the cytosol, where it replicates. LLO accomplishes this by binding to cholesterol and then oligomerizing into large complex pores. LLO is a 60-kDa secreted protein involved in *Listeria*'s escape from both primary and secondary vacuoles (236). LLO is a member of the pore-forming, cholesterol-dependent cytolysin family. These thiol-activated toxins are produced by several Gram-positive bacteria, including *Streptococcus*, *Clostridium*, and *Bacillus* species (236). They are active only on cholesterol-containing

membranes, with cholesterol likely acting as the receptor in the membrane. Unlike all other thiol-activated toxins, LLO has a maximal activity at pH 5 and is inactive at pH 7, and thus, its deleterious effect on cellular membranes is impaired when the bacterium is free in the cytosol. In addition, optimal pore formation by LLO occurs between pH 5.5 and 6.0 (the pH of the early phagosome). A second hemolysin, listeriolysin S, has been isolated from specific strains of lineage I *L. monocytogenes*, leading to the suggestion that this second hemolysin may account for the increased pathogenicity of this lineage (188).

Phospholipases

Two phospholipases are produced and secreted by *L. monocytogenes*: phosphoinositide-phospholipase C, encoded by the gene *plcA*, and a broad-range phospholipase, phosphatidylinositol-specific phospholipase C, encoded by *plcB* (237). The two phospholipases have membranedamaging activity and are involved in bacterial escape from primary and/or secondary phagosomes (237).

Once free in the cytosol, *L. monocytogenes* starts multiplying, with an approximate doubling time of 1 hour (238). A number of genes are upregulated as the microorganism grows within the host tissue (210). This includes several genes encoding virulence or metabolic determinants induced during the intracellular life of *L. monocytogenes*, including those involved in phagosomal lysis, actin-based motility, and cell-to-cell spreading. In contrast to most bacteria, *L. monocytogenes* replicates in the cytosol when it is directly microinjected into cells (239). The cytosol permissiveness for *L. monocytogenes* growth is likely due to the bacterium's ability to use a variety of cytosolic nutrients, as suggested by the fact that intracellular multiplication of several auxotrophic mutants is not affected (240). Intracytosolic growth of *L. monocytogenes* is highly dependent on the product of the *hpt* gene, which encodes a sugar uptake system (239), and is tightly regulated by PrfA (241).

Intracytoplasmic Movement and Cell-to-Cell Spreading

Induced phagocytosis, escape from the phagosome, and intracellular multiplication are essential steps for infection of individual cells but are not sufficient to achieve infection. *L. monocytogenes* must also efficiently infect tissues by direct cell-to-cell spreading. As described above, direct cell-to-cell spreading is the result of intracellular movement, protrusion formation, phagocytosis of the protrusion by a neighboring cell, formation of a doublemembrane-bound vacuole, and lysis of the two-membrane vacuole. Intracytoplasmic movement is strictly coupled to continuous actin assembly that provides the force for bacterial propulsion (Fig 17.4). Actin polymerization requires expression of the *actA* gene. *actA* mutants are invasive, escape from the phagosome, replicate, and form intracellular microcolonies but are not covered with actin, do not move intracellularly, and do not spread from cell to cell. ActA is a 639-amino-acid protein that presents a signal sequence at its amino-terminal domain and a transmembrane motif at its carboxyl-terminal domain that anchors the molecule to the bacterial surface (242). Immunolocalization of the ActA protein in infected cells has revealed that ActA is asymmetrically distributed on the bacterial surface, with an increasing concentration towards the opposite pole of the bacterial cell, which is the site of comet tail formation. The amino-terminal region of ActA alone can induce bacterial movement (243). Actin filaments in *Listeria* tails, as in *Shigella* tails, are branched, in contrast to those in *Rickettsia conorii* tails, which display longer and unbranched actin filaments (244).

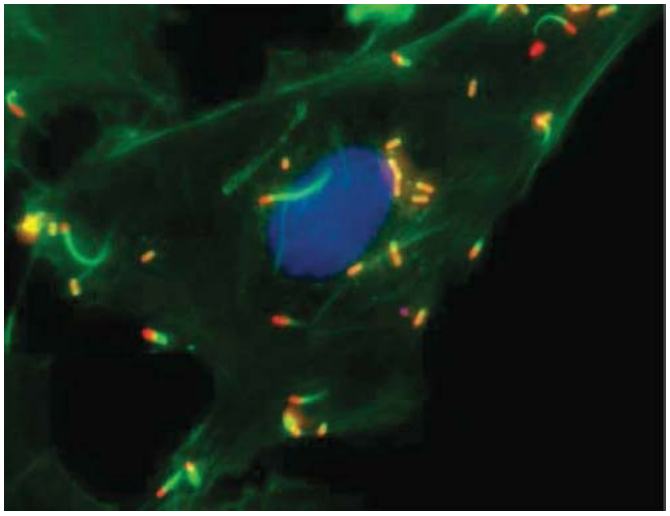

Figure 17.4 Directional actin polymerization by *L. monocytogenes*. *L. monocytogenes* isolates were processed for triple-labeling fluorescence microscopy, 5 h after the infection of Vero cells was started. Bacteria (red) were visualized with a polyclonal anti-*Listeria* antibody, actin (green) with phalloidin, and cell nuclei (blue) with DAPI (4′,6′-diamidino-2-phenylindole). Magnification, ×100.

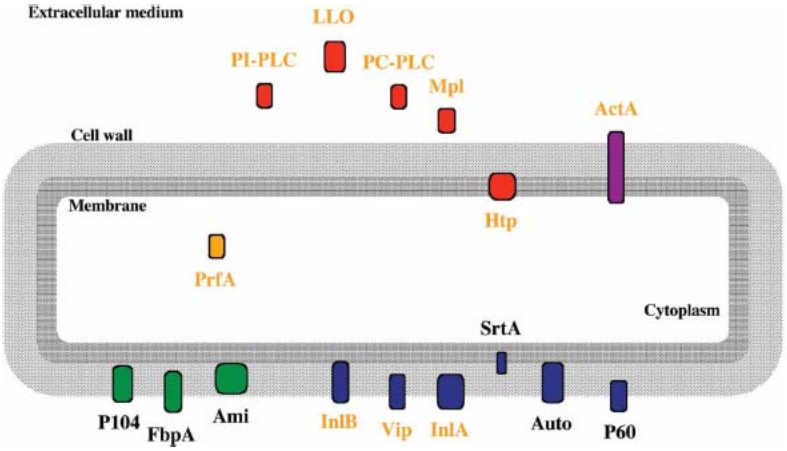

Figure 17.5 Schematic representation of *L. monocytogenes* virulence factors. The localization of factors implicated in adhesion (green), entry (blue), escape from the phagosome and intracellular growth (red), and intracytoplasmic movement and cell-to-cell spreading (purple) is indicated. The names of factors whose expression is regulated by PrfA are in orange. PI-PLC, phosphoinositide-phospholipase C; PC-PLC, phosphatidylinositol-specific phospholipase C.

Coregulation of Virulence Factors

Most *Listeria* virulence genes involved in the steps of the infection cycle (i.e., *prfA*, *plcA*, *hly*, *mpl*, *actA*, *plcB*, *inlA*, *inlB*, *inlC*, *hpt*, *bsh*, and *vip*) are regulated by the transcriptional activator PrfA (Fig 17.5) (245). PrfA is a protein comprising 233 amino acids that belongs to the Crp/Fnr family. Genes regulated by PrfA contain a binding site in the –41 region, the PrfA box, consisting of a 14-bp palindromic sequence to which the putative helix-turnhelix motif of PrfA binds *in vitro* (246). Expression of *prfA* is a complex phenomenon. *prfA* is the second gene of the *plcA-prfA* operon, whose primary promoter is regulated by PrfA. Hence, PrfA autoregulates (activates) its own synthesis. *prfA* can also be transcribed from its own promoter region. It has been determined that in a *prfA* mutant transcription at the *prfA*-specific promoter is upregulated. PrfA-regulated virulence factors such as LLO, PlcA, PlcB, and Vip are produced at higher levels as temperature increases to 37°C, the temperature of the host (237). At low temperatures, the untranslated leader region of the *prfA* mRNA

forms a stable secondary structure masking the Shine-Dalgarno sequence (247). Consequently, PrfA is not translated. At high temperatures, this structure, named the thermosensor, melts. Mutations destabilizing the thermosensor at 30°C mimic the effect of an increase in temperature in that they unmask the ribosome-binding site and lead to virulence gene expression. Knowledge of the *L. monocytogenes* genome sequence (161) allowed analysis of the complete PrfA regulon. A whole-genome array based on the sequence of the *L. monocytogenes* EGDe strain was constructed to study the PrfA regulon (241). This transcriptomic analysis revealed that PrfA could act both as an activator and as a repressor. It led to the identification of many new PrfA-regulated genes in addition to genes previously known to be part of the PrfA regulon. However, in many cases, the effect of PrfA is probably indirect. This analysis has been expanded upon in a second transcriptional analysis to identify the genes that are positively controlled by PrfA and upregulated in the host (210).

Stress Proteins of *L. monocytogenes*

L. monocytogenes has evolved a series of adaptive responses in order to cope with a large variety of stresses to survive and/or multiply under harsh environmental conditions, outside as well as inside the host. The LisRK two-component signal transduction system is implicated in virulence, acid and ethanol tolerance, and oxidative stress (248). *virR*, a gene encoding the response regulator of another two-component system, was shown to regulate a key regulon in *L. monocytogenes*, controlling virulence by a global regulation of surface component modifications (198). The DnaK heat shock chaperone protein is required for survival of *L. monocytogenes* at high temperatures and under acidic conditions as well as for efficient phagocytosis with macrophages (249). The major heat shock chaperones, GroES and GroEL, are induced at high temperature, at low pH, and during cell infection (250). The ClpC stress protein is required for survival under iron deprivation or high temperature or osmolarity in bone marrow macrophages and in organs of mice (251). Two other proteases have been reported to be involved in stress response and virulence, namely, ClpE and ClpP (252, 253).

The *fri* gene, which encodes ferritin, is necessary for optimal growth in minimal medium in both the presence and absence of iron, as well as after cold and heat shock. Ferritin also provides protection against reactive oxygen species and is essential for full virulence of *L. monocytogenes*. A comparative proteomic analysis revealed an effect of *fri* deletion on the levels of LLO and several stress proteins (254, 255). Adaptation to osmotic stress depends on the intracellular accumulation of osmolytes and thus on uptake systems that include BetL, GbuABC, OpuC, OpuB, and OppA (256, 257). Bile tolerance of *L. monocytogenes* involves the bile salt hydrolase Bsh, an enzyme that deconjugates bile salts and that is required for both intestinal and hepatic phases of listeriosis (258). The transporter BtlA (259) and other systems, such as the putative transporter of the glutamate decarboxylase GadE and the zinc uptake regulator ZurR, contribute to tolerance to bile or various other stresses, e.g., low pH, salt, ethanol, detergent, and antibiotic (260). The alternative sigma factor B contributes to the ability of *L. monocytogenes* not only to survive and/or multiply under stressful conditions outside the host (acid, osmotic, or oxidative stresses, low temperature, or carbon starvation) (261) but also to persist within the host during the infectious process.

It has been demonstrated that σ^B contributes to survival following exposure to bile salts (262) and also to transcription of the virulence gene activator PrfA (1). Characterization of the σ^B-dependent general stress regulon confirmed the broad role of this sigma factor (263). The lessons learned in relation to *L. monocytogenes* responses to stressors within the host are beginning to be used to study the impact of the pathogen's expression of stress responses and virulence determinants in foods and food processing environments (264, 265).

CONCLUDING REMARKS

Public health surveillance, outbreak investigations, and applied and basic research conducted during the past 40 years have helped to characterize the disease listeriosis, define the magnitude of its public health problem and its impact on the food industry, identify the risk factors associated with disease, and develop appropriate and targeted control strategies. The food processing industry has made

progress towards reducing the prevalence of *L. monocytogenes* in processing plant environments and in high-risk foods, and preventive measures have been developed and implemented for persons at increased risk of infection. These gains were reflected in a substantial decline in the incidence of listeriosis during the late 1990s and early 2000s. For example, in the United States, the incidence of listeriosis in 2005 was only 0.3 case per 100,000 population. However, since that time, the number of listeriosis cases has plateaued, with no substantial declines in the United States, and several European countries and South Africa have experienced increased incidences of listeriosis during the past 10 years. Furthermore, we have seen the association of listeriosis outbreaks with new foods such as fresh-cut produce. Despite ever-increasing knowledge concerning this pathogen, translation of that knowledge into effective control programs has lagged. It also implies that "doing the same old thing" is not likely to further reduce the public health burden of *L. monocytogenes*. Hopefully, the same progress in understanding the basic biology of this important pathogen during the past decade will translate in the next decade into effective risk-based food safety systems for preventing this rare but potentially lifethreatening foodborne disease.

Clostridium botulinum

Botulism is a neuromuscular paralytic disease in humans and animals resulting from the actions of botulinum neurotoxins (BoNTs), which are produced by *Clostridium botulinum* and rare strains of *Clostridium butyricum* and *Clostridium baratii* (1–4). BoNTs are the most poisonous toxins known for humans and vertebrate animals (5–7) and are unique among most foodborne toxins in being highly toxic by the oral route (2, 8, 9). *C. botulinum* produces seven serotypes of BoNTs (A, B, C1, D, E, F, and G), which are distinguished by neutralization of toxicity in mice using homologous antisera prepared against the purified toxins (10). In the United States, *C. botulinum* and BoNTs are categorized as tier 1 select agents (11), the most dangerous group of biological agents (5, 7, 12, 13; www.selectagents.gov), and work with *C. botulinum* and SA quantities (>1 mg) of BoNTs requires high-security laboratory facilities and rigorously trained personnel (5, 12, 14, 15). Botulism is a serious neurological disease and can be life threatening, generally due to respiratory paralysis and suffocation and occasionally due to secondary disease sequelae (2, 7). After being absorbed into the circulation, BoNT binds to and is internalized in nerve terminals. The pri mary target of BoNTs is neuronal end plates, particularly the neuromuscular junction of the motor nerve, which has been termed “the most vulnerable synapse” (16). Although botulism is an acute and not a permanent intoxication, the syndrome can paralyze all muscles in the body, and the paralysis can last for days to several months, with severe morbidity and approximately 5% fatality (2, 17–19).

Human botulism has been an important public health issue ever since its recognition in the 1800s, when it was contracted from consumption of contaminated blood sausages in Germany (20–23). The importance of botulism to the food industry stems from the wide distribution of *C. botulinum* spores in the environment, the high resistance of endospores to food processing technologies, and the ability of *C. botulinum* to grow and form BoNTs in foods, even under conditions that are inhibitory to most other foodborne bacterial pathogens (24–26). Spores can form BoNTs in foods, in the intestines of infants, in wounds, and by inappropriate injection of BoNTs in therapeutic and cosmesis applications (5, 27, 28). The control of *C. botulinum* and formation of BoNTs in foods are a continuing challenge, particularly with increasing consumer demands for fresh and organic commodities, since these foods undergo minimal processing and are not treated with preservatives inhibitory to *C. botulinum*. Botulism is considered a public health emergency in the United States and many countries worldwide, and its occurrence triggers intensive regulatory and medical responses (5, 29, 30).

Consequently, a perennial goal of the food industry and of regulatory agencies is to limit the occurrence of viable *C. botulinum* spores in raw foods and to prevent their germination and vegetative-cell growth with formation of BoNTs in foods for consumption. Certain regulations, laws, and preservation practices have been designed and enacted in the food industry primarily to prevent growth and BoNT formation by *C. botulinum*, specifically, the 12D “bot cook,” low-acid-food regulations, and inhibitory water activity (a_w) values (see chapter 2 of this volume). Botulism has the highest costs per hospitalized human patient of all foodborne diseases (31–33). Due to the importance of *C. botulinum* and BoNTs in food safety, *C. botulinum* and BoNTs have served as archetypes for food safety systems and have stimulated global innovation in research strategies and advances in food microbiology and processing technologies (34, 35).

The structure, pathophysiology, and molecular mechanisms of BoNTs causing neuromuscular paralysis in animals and humans have been expertly and extensively reviewed (36–40). The remarkable development of BoNT for medical treatment of nearly 200 neuronal diseases in humans has also been described (41–44), and clinical and basic studies of structure-function and clinical uses of BoNTs in medicine currently constitute the most active area of BoNT research, providing the majority of publications in the *C. botulinum* literature. Although botulism is rare in humans, its importance in food safety is highlighted by the severity of the illness with an approximately 5% fatality rate, the requirement of intensive critical care for hospitalized patients, and the necessity of weeks to months for recovery of normal functions. Botulism outbreaks can have a dramatic impact on the human and animal populations in which they occur (2, 45–49). Animal botulism is the most prevalent type of botulism worldwide, and annual outbreaks cause devastating losses of thousands of domestic and wild animals, particularly of wild waterfowl and fish, as well as domestic animals such as cattle, mink, and some other farmed animals (20, 47).

This chapter focuses primarily on areas of neurotoxigenic clostridia and BoNTs that impact food safety and emphasizes the microbiology and control of neurotoxigenic clostridia in foods and properties of BoNTs related to food safety.

DISCOVERY OF *C. BOTULINUM*, BoNT, AND THE PATHOPHYSIOLOGY OF BOTULISM

Botulism was suspected as a dreaded food poisoning over 1,000 years ago during the reign of Emperor Leo VI of Byzantium (886 to 911 CE) (20, 21, 23). The first definitive studies of human botulism were conducted in Germany in the early 1800s by Georg Steinbuch and Justinus Kerner, who reported that consumption of raw blood and liver sausages was associated with a disease characterized by muscle paralysis, decreased secretions such as salivation and sweating, and ensuing suffocation in the patient (21–23). Kerner showed that a poison developed within the sausages and extracts of the sausages, which caused severe paralytic symptoms and death in animal models. Kerner even experimented on himself: he administered a “few drops” of diluted poisoned-sausage extract on his tongue and reported symptoms including drying of his tongue and throat, difficulty swallowing, altered tension of eye muscles, and reduced secretions including salivation and sweating, which are today recognized as anticholinergic symptoms (21).

Following the observations in Germany, the etiologic cause of botulism remained obscure for more than 50 years until a series of remarkable experiments were conducted by the Belgian microbiologist Emile Pierre van Ermengem (50). His background included studies under Robert Koch and Claude Bernard (5, 23), and he was well prepared to investigate the etiology of botulism. In 1897, van Ermengem published a classic comprehensive treatise describing isolation of an anaerobic bacillus from a raw salted ham implicated in a botulism outbreak that affected 34 individuals at a funeral wake in Belgium (50). van Ermengem (50) established the etiology of botulism by isolation of “*Bacillus botulinus*” from the ham and from the large intestines of persons who had died from consumption of the ham. He determined that the bacillus produced a very potent toxin that was released into the food. His success in isolating the anaerobe and demonstrating the extracellular nature of the toxin was a triumph in food and medical microbiology. In 1897, Kempner (51) subsequently determined that van Ermengem’s cultures produced a protein-like substance that on injection in an inactive form gave rise to antitoxin in the blood of goats, which subsequently prevented death when administered to animals prior to toxin challenge. These classic experiments provided the first evidence that antibodies to BoNT could neutralize toxicity in the circulation and prevent illness and death using serum therapy (52).

van Ermengem's and Kempner's landmark investigations established several principles of botulism that remain valid today and form the cornerstone for understandingand control of the disease: (i) foodborne botulism is a true toxemia caused by BoNTs and is not an infection; (ii) the toxin is produced by a bacterium, "*Bacillus botulinus*," currently designated *C. botulinum*; (iii) the toxin causes a paralytic disease and death in vertebrate animals when administered by the intravenous, intramuscular, and oral routes; (iv) the toxin is inactivated by moderate heat and alkali and is stable under acidic conditions; (v) *C. botulinum* does not grow and form BoNT in foods containing sufficient salt or acid; (vi) *C. botulinum* endospores are highly resistant to heat and certain chemicals; (vii) animals can develop immunity to BoNTs by exposure to inactive toxin (toxoid); (ix) antibodies in antitoxins can neutralize BoNT when they are present in the circulation but not after it has entered nerves in animal models.

Following van Ermengem's findings in Belgium, a similar paralytic disease was described in several countries worldwide from consumption of various foods, especially home-canned vegetables and meats in terrestrial environments and home-prepared fish and marine mammals in coastal regions of many countries (45, 53, 54). Foodborne botulism occurs worldwide from consumption of a variety of foods, yet the occurrence and kind of poisonous food vary depending on the geographic region, country, and food processing and handling practices. Most foodborne-botulism cases have resulted from home-prepared foods, while large outbreaks involving several persons have also resulted from food obtained from food service operations and restaurant-prepared foods (2, 19, 55). Foodborne botulism in a given class of foods is generally associated with a specific serotype of *C. botulinum* and its BoNT (53, 54, 56). Recent botulism outbreaks are listed in Table 18.1..

Following the discovery of foodborne botulism, different mechanisms of BoNT intoxication in humans and animals were discovered. In the 1940s, botulism from a wound infection was reported, and currently, wound botulism occurs mainly in intravenous-drug users (56–59). In 1976, botulism resulting from the colonization of the intestinal tracts of infants (<12 months of age) by *C. botulinum* and production of BoNT were discovered by Pickett et al. (60) and confirmed by Midura and Arnon (61). In the 1980s, strains of *C. butyricum* and *C. baratii* that produce serotypes E and F, respectively, were isolated in Italy and in New Mexico from infant botulism cases (62–64). Rare forms of botulism, including colonization of the intestinal tracts of adolescents and adults by *C. botulinum*, have also been observed, generally following surgery and antibiotic treatment of patients (18, 65–68). While foodborne botulism is considered the most common type of botulism in most countries world-wide, infant botulism is the most prevalent type of botulism in the United States (69, 70). Since its discovery in the United States in the 1970s, infant botulism has been recognized globally on all continents except Antarctica (70).

The worldwide occurrence of human botulism from commercial and home-prepared foods has been promulgated by globalization of the food supply, whereby ingredients in a food may be sourced from diverse geographic regions and most of the seven continents (see chapter 2).

In recent years, there has been an increase in incidence of iatrogenic botulism, which results from inappropriate injection of BoNTs for medical treatments for cosmesis and therapeutic disorders (71–73). There is also a growing problem of injection of counterfeit preparations of BoNTs and "BoNT-like substances" for cosmetic purposes, whereby the toxins are prepared without proper quality control and governmental approval (17, 71, 74).

In all categories of botulism, BoNT is solely responsible for morbidity and mortality, and thus, botulism is a true toxemia (2, 36). The fact that BoNT is the sole entity causing disease was proven in laboratory animal studies of intoxication using highly purified BoNTs and absence of *C. botulinum* organisms. For laboratory production of BoNTs, *C. botulinum* strains are grown in

complex culture media under anaerobic conditions. The titers of BoNTs produced depend on the strain, the medium, and the culture conditions (42, 75–77).

The beginnings of purification of BoNTs and the understanding of their pathophysiology occurred early in the 1900s. In 1916, Sommer determined that addition of a mineral acid to type A broth cultures to achieve a pH of ca. 3.5 resulted in flocculation of more than 90% of the active toxic activity which settled from the culture (42). Acid precipitation is the first step in most purifications of nearly all serotypes of BoNTs. In the 1940s at Fort Detrick, Maryland, the purification of the botulinum toxin type A complex from precipitated BoNT was accomplished (42, 78, 79), and this process was further perfected by Edward J. Schantz at the University of Wisconsin (42, 80). The purification in the 1940s entailed repeated acid precipitations, washing of the precipitates with water and sodium phosphate buffer, an ethanol precipitation of the toxin at −5°C, and formation of toxin crystals by slow and tedious addition of ammonium sulfate over several days (42). During this early period in protein purification and characterization, protein chromatography was not available for protein purification, and therefore, these differential precipitation techniques were exclusively used for toxin isolation. Ultracentrifugation and diffusion experiments revealed that botulinum toxin type A consisted of a large protein of approximately 900 kDa (42, 81). It was subsequently determined that this large molecule comprised a protein complex that contained the active neurotoxin of ca. 150 kDa noncovalently linked with nontoxic proteins, including hemagglutinins that coagulated red blood cells and a nontoxic nonhemagglutinin protein (42, 82). Depending on the serotype and production methods, these complexes vary in content and ratios of BoNTs and the nontoxic proteins. These large protein complexes were termed progenitor toxins by Japanese researchers (83–85).

Table 18.1 Examples of recent botulism outbreaks (adapted from Parkinson et al. [203])

Year	Product	Country	No. of cases	Probable cause
2017	Nacho cheese sauce	U.S.	10	Improper handling/temperature abuse
2016	Pruno/hooch	U.S.	16	Illicit potato fermentation
2016	Fish heads/seal oil	U.S.	2	Improper preparation and fermentation
2014	Pesto	U.S.	2	Inadequate heat treatment
2012	Adzuki bean soup	Japan	2	Temperature abuse
2011	Korma sauce	Scotland	3	Unknown
	Olive paste	France	9	Incorrect thermal processing
	Potato soup	U.S.	1	Temperature abuse
2010	Olives stuffed with almonds	Finland	2	Defective container
2009	Smoked fish	France	3	Unknown
2008	Chicken enchilada	France	2	Temperature abuse
2007	Hot dog chili sauce	U.S.	8	Incorrect thermal process
2006	Carrot juice	U.S./Canada	6	Temperature abuse
	Smoked fish	Finland	2	Unknown
	Bamboo shoots	Thailand	209	Improper preparation

The association of the neurotoxin components with nontoxic proteins was subsequently shown to confer stability on the BoNT in the intestinal tracts of animals and humans and probably to facilitate absorption of BoNTs from the intestinal tract (8, 83). Once absorbed into the lymph and then into the blood circulation, they are trafficked to peripheral nerves, which they enter and where they cause intoxication. The intoxication process results in reduced secretion of acetylcholine and likely other signaling molecules, including hormones (5, 36, 37). The inhibition of acetylcholine secretion at neuromuscular junctions prevents muscle activation and causes muscle atrophy and shrinkage. The early studies of the pathophysiology of BoNTs were recently reviewed (5).

In the 1960s, ion exchange and gel filtration column chromatography became available, which facilitated isolation of the 150-kDa neurotoxin component from the complexing proteins (82, 86). The isolation of the purified BoNT component enabled definitive studies on the mode of action of BoNTs (36, 37, 87). It was determined that BoNTs specifically bind to gangliosides and then to receptor proteins on the terminal surfaces of nerves, are internalized in them, and enter the nerve cytosol, where they cleave SNARE (soluble *N*-ethylmaleimide-sensitive factor protein receptor) proteins. SNARE proteins make up a superfamily of small proteins that constitute the machinery for transmission of vesicles to the cell surface and enable exocytosis. In 2013, the Nobel Prize in Physiology or Medicine was awarded for the elucidation of the mechanism of SNARE-mediated protein and metabolite trafficking. BoNTs played a role in understanding this intricate cellular process by cleaving the SNARE proteins as specific targets and preventing release of acetylcholine at the neuromuscular junction or hormones in nonneuronal cell types. The inhibition of acetylcholine prevents muscle contraction and is responsible for the symptoms of muscle paralysis, atrophy, and severe muscle weakness characteristic of botulism (38, 40, 88). When BoNT accesses the respiratory neuromuscular junctions, it causes suffocation and ensuing death through inhibition of acetylcholine release from nerves to muscle.

A triumph in botulism research was the determination of the three-dimensional structure of BoNT A by Stevens and his lab in the 1990s, which provided valuable insights into the mechanisms of intoxication (89, 90). The first structure determination of BoNT A was followed by structures for BoNT B, BoNT E, and the individual domains (40, 91). The availability of the structures of BoNT revealed that BoNTs have three major protein domains, including a receptor-binding domain, a translocation domain for passage of BoNTs into the nerve cytosol, and a domain with catalytic activity that specifically cleaves SNARE proteins and prevents neurotransmitter exocytosis (40, 88). Elucidation of the structure and demonstration of specific proteolytic activity on the SNARE apparatus provided a definitive understanding at the molecular level of the intoxication process of BoNTs. The intoxication process has been studied by several accomplished laboratories in molecular biology and has been definitively reviewed (36, 37, 40, 87).

TAXONOMY OF NEUROTOXIGENIC *CLOSTRIDIUM* SPECIES

The genus *Clostridium* is classified in the kingdom *Bacteria*, phylum *Firmicutes*, order *Clostridiales*, family *Clostridiaceae* (92, 93). Over the past 3 decades, the genus *Clostridium* became a collection (“dump”) of more than 200 heterogeneous bacteria, including nonsporeformers. To more concisely define the taxonomy of *Clostridium* species, the taxonomic classification of neurotoxigenic and related species of *Clostridium* has recently been reexamined by advanced taxonomic methods and described according to the *Code of Bacterial Nomenclature* (93). These studies have placed neurotoxigenic clostridia, including *C. botulinum* and BoNT-producing strains of *C. baratii*, *C. butyricum*, and *C. tetani*, in *Clostridium* taxonomic cluster I, as initially defined by the pioneering studies of John Johnson, David Collins, and colleagues (94,

95). Cluster I is designated *Clostridium sensu stricto*, and the type species is *C. butyricum* Prazmowski. *C. butyricum* is likely the species that Louis Pasteur isolated in his famous studies of spoilage of wines (5, 92). Nontoxigenic *Clostridium* spp. taxonomically similar to *C. botulinum* in group I include *C. sporogenes* (type A), *C. novyi* (type C), and *C. subterminale* (type G). *Eubacterium*, *Sarcina*, and many other "*Clostridium*" species need further study for clear delineation of the genus and species.

For many decades, neurotoxigenic clostridia have been classified as the single species *C. botulinum* based on BoNT formation, since this designation was convenient and easily recognized by the medical professions as well as by the food industry. Currently, clostridial isolates that produce BoNTs with the characteristic high potency of approximately 10^8 50% lethal doses (LD_{50}s) for mice per mg belong to the species *C. botulinum*, as well as BoNT-producing strains of *Clostridium argentinense*, *C. baratii*, and *C. butyricum*.

Recently, whole-genome sequencing, genome mining, and bioinformatics have identified gene clusters in various organisms that possess BoNT gene clusters analogous to those in *C. botulinum*. These strains include *C. botulinum* strain 111, an *Enterococcus faecium* strain, *Chryseobacterium piperi*, *Weissella oryzae*, and certain other bacterial groups (96–99). Although catalytic activity on SNARE proteins has been shown for the light chains of these organisms, the putative holotoxins in cell extracts have no activity in neuronal cell models and *in vivo* in mice. These species have not been shown to produce BoNTs with the neural specificity and high toxicity of BoNTs from *C. botulinum*, and therefore, at this time these organisms cannot be considered neurotoxigenic clostridia that produce authentic BoNTs. Efforts are in progress to carefully evaluate the ability of these distantly related bacteria to produce true BoNTs. Certain isolates produce toxins that are active on SNARE substrates, but their toxicity is not in the range of the select agent designations for BoNTs (≤100 ng/kg in a mouse bioassay).

ISOLATION AND CHARACTERIZATION OF BoNT-PRODUCING CLOSTRIDIA

An important aspect of investigations of neurotoxigenic clostridia is their isolation and culture. The isolation, identification, and maintenance of pure cultures of botulinogenic clostridia present certain practical difficulties. Clostridia tend to grow as consortia, and pure cultures are sometimes difficult to achieve and maintain. The purity of neurotoxic clostridia is ascertained by microscopy, by plating on nonselective media to ascertain uniform morphology colonies, and by phenotypic and molecular methods described below. Since botulinogenic clostridia have complex nutrient requirements, rich media are commonly used for their cultivation (4, 10, 100). Enrichment of spore-forming neurotoxic clostridia is often carried out by heating food, environmental, or clinical samples (e.g., 60 to 80°C for 10 min) or by treating the samples with 50% ethanol to kill vegetative bacteria and enrich for sporeformers (14, 101). For isolation of *C. botulinum*, a small quantity of food or clinical specimen extracts is added to 10 ml of cooked meat medium with 0.5% glucose or Trypticase-peptone-glucose-yeast extract broth in anaerobic tubes (14, 101). These are incubated for 1 to 3 days for vegetative growth and up to 4 weeks to promote endospore formation.

Once neurotoxic *Clostridium* cultures are isolated and maintained in pure culture, they are characterized phenotypically and genetically. Neurotoxic clostridia are strict anaerobes that obtain energy by fermentation and substrate-level phosphorylation and do not reduce sulfate to sulfide (92). Microbiological phenotypic characterization may include the lipase reaction, Gram and spore stains, proteolysis of meat particles and casein, and substrate utilization patterns (92, 102). Formerly, the carbon and nitrogen compound assimilation in cultures was determined by

growth tests, and formation of fatty acids and alcohol end products was routinely determined by gas-liquid chromatography (102), but these labor-intensive tests are not currently routinely performed with *Clostridium* species. Such phenotypic characterizations are still required for characterization of commercial strains of *C. botulinum* used for BoNT production as a pharmaceutical (Kevin Munson, personal communication). All manipulations of neurotoxigenic clostridia should be performed in an anaerobic chamber, since these organisms are strictly anaerobic and colonies are killed on exposure to air. For example, plating of a culture in an aerobic environment followed by placing it in an anaerobic jar or chamber will generally kill about 90 to 99% of the clostridial cells (my unpublished results).

Currently, cultures of *C. botulinum* are mainly characterized by cell morphology, genetic analyses, and partial-or whole-genome sequencing. In *C. botulinum* and *C. tetani*, the spores are generally wider than the vegetative organisms in which they are formed, imparting a spindle or "tennis racket" shape to the cells, the characteristic toxigenic clostridial form (4, 10, 22, 92) (Fig 18.1). In early stages of culture, neurotoxigenic clostridia typically grow as rod-shaped bacteria and often form filaments or chains. The vegetative cells are often curved, their sides parallel, and their ends rounded (4). Neurotoxigenic clostridia are generally referred to as Gram-positive spore-forming rods (92), but the Gram reaction may be weak or appear negative in 24-h or older cultures (4). Spores are generally formed when cells are grown in rich media, but their microscopic presence may require several days to weeks of incubation to reach a significant spore titer in the primary culture of vegetative cells. In media favoring BoNT formation, spore formation is usually limited and the cells in the culture undergo mass lysis following early stationary phase, which usually occurs at 12 to 24 h in the growth cycle (75). Autolysis has long been postulated to release BoNT from the cells, but it is likely there is also an active secretion system for BoNTs. Furthermore, in some serotypes, such as type E, the culture does not generally undergo mass lysis, and BoNT remains adhered to the surface of the cells.

Figure 18.1 Characteristic morphology of *C. botulinum* with an endospore.

In addition to morphology and growth tests, molecular techniques are primarily used for species and strain characterization. These include the determination of the nucleotide sequences of genes encoding rRNA, multilocus sequence typing and other DNA typing methods such as restriction fragment length polymorphism analysis, PCR analyses for BoNT and nontoxic nonhemagglutinin protein genes, and pulsed-field gel electrophoresis (PFGE) of isolated DNA digested with restriction enzymes (103–108). Whole-genome sequencing has become the preferred method of characterization of BoNT-producing clostridia and is rapidly being adopted in academic, industry, and government laboratories. A critical test for neurotoxigenicity is the demonstration of BoNT. The traditional method of testing for BoNT is by the mouse bioassay, which is currently the only method approved by the FDA for food and clinical detection of BoNT and is considered the gold standard (10, 109, 110). It involves injection of diluted extracts of foods or clinical samples intraperitoneally into mice and observation of the mice for symptoms of botulism and death. It is important to also inject a set of tubes containing neutralizing antibodies to specifically prevent toxicity, particularly since mice often die from toxic non-BoNT compounds in foods and clinical samples, referred to as nonspecific death. The lack of antibody neutralization indicates false-positive toxicity results, which can lead to hugely impactful

regulatory and industry responses, such as recalls of massive quantities of products (111). Several ancillary methods, including PCR and whole-genome sequencing, are used by some laboratories to determine the presence of the *bont* and *ntnh* genes in cultures (103, 107, 112). A method based on antibody binding and mass spectroscopy detection of SNARE protein cleavage is being evaluated as a more rapid test for BoNT that does not involve mice and can be performed more rapidly than the mouse bioassay (113, 114). Cleavage of SNARE proteins in cultured human neuronal induced pluripotent stem cells in culture is also being used for detection of BoNTs (115), and two tests have been approved by the FDA for quantitation of BoNT in pharmaceutical preparations. It would be valuable to determine if neuronal cells could be used to detect BoNT in foods, since such an assay would not use animals and would shorten the time required to obtain results for the presence of active BoNTs in foods.

A few other species of *Clostridium* also produce neurotoxins, most famously tetanus neurotoxin, produced by *C. tetani*, which causes a drastic spastic paralysis (116), and epsilon toxin from *C. perfringens*, which causes morphological changes and death of neurons in culture (117). Although *C. tetani* produces a neurotoxin with high homology to BoNTs, it does not form complexes with nontoxic proteins in the progenitor form and is not toxic by the oral route, and therefore, it does not cause foodborne disease.

METABOLIC AND GENOTYPIC CHARACTERISTICS OF NEUROTOXIGENIC CLOSTRIDIA

Neurotoxigenic clostridia are heterogeneous in their physiology and metabolism, and many of these differences are important in food safety, including conditions for spore germination, resistance properties of spores, temperature range for growth of vegetative cells, acid and salt tolerance, resistance to antimicrobials, proteolytic activity, substrate utilization, and BoNT expression (Tables 18.2 and 18.3; see also chapter 2) (102). In 1970, the observations of differences in metabolic properties of *C. botulinum* led to the designation of three metabolic groups (groups I to III) (Table 18.2.). When *C. botulinum* type G was isolated and characterized in 1970, it was placed in group IV (118, 119). *C. botulinum* type G (group IV) was taxonomically classified as *C. argentinense* (118). The classification of *C. botulinum* in physiological groups I to IV has been widely accepted (1–3, 23). Following this early metabolic classification, groups I to IV were determined to be genetically distinct and to comprise four species lineages (120–122). Groups I and II are responsible for human botulism, while group III mainly causes animal botulism, and group IV is not known to cause disease in humans or animals. Rare BoNT-producing strains of *C. baratii* and *C. butyricum* were initially recovered from infant botulism cases and more recently from foodborne-botulism cases as well as the environment (23,123–125). It has been suggested that neurotoxigenic *C. baratii* and *C. butyricum* make up metabolic groups V and VI of neurotoxigenic clostridia (126, 127), but most researchers in the botulinum field prefer to maintain the species names instead of adding more groups. Furthermore, the metabolism of *C. baratii* and *C. butyricum* has not been studied in sufficient detail to validate two additional metabolic groups (128). Extensive studies of phylogenomics by wholegenome sequencing have substantiated the six genomic lineages of neurotoxigenic clostridia. For many years, and recently, it has been proposed that the groups be designated with different species names (127), but such nomenclature would be confusing to the medical profession and the food industry, and *C. botulinum* should be currently retained as the sole species in groups I to IV.

METABOLIC PROPERTIES OF *C. BOTULINUM* GROUPS I TO IV, *C. BUTYRICUM*, AND *C. BARATII*

C. botulinum group I comprises the proteolytic strains of serotypes A, B, and F (Table 18.2.). The organisms in this group digest gelatin, milk, and meat particles in culture. The gene clusters encoding BoNTs reside on chromosomes and/or on plasmids (129–133) (Table 18.4.). Like all fermentative clostridia, neurotoxic *Clostridium* spp. produce short-chain organic acids and alcohols from anaerobic metabolism (92, 102). Group I *C. botulinum* also produces ammonia and putrefactive amines. Arginine and phenylalanine are the nutrients most strictly required for growth by group I type A and B strains (100). The nutritional requirements for amino acids and glucose in proteolytic type F strains have not been studied. Glucose, fructose, and maltose are utilized for growth and toxin production, while mannose, lactose, sucrose, and trehalose are not utilized (92). The optimum temperature for growth of group I is 35 to 40°C. The minimum temperature for growth of group I *C. botulinum* is 10°C, and the maximum growth temperature is 45 to 50°C. Growth is inhibited by an aw of 0.94 (with NaCl as the humectant in solution). The minimum pH for growth is designated as 4.6, but many strains do not grow below pH 5, especially with other inhibitory factors in the medium or food. The strains are sensitive to several antibiotics (134, 135), and although these are not used for control of foodborne or infant BoNT botulism, they may be used in wound botulism, especially since wound infections are polymicrobial. Group I has the highest heat resistance of organisms in groups I to IV and *C. baratii* and *C. butyricum* (see chapter 2). The *D* value for spore inactivation in group I varies, yet the food industry generally defines 0.21 min at 121°C as the standard value. The spores of group I *C. botulinum* have remarkable heat resistance, with a *D* value (100°C) of approximately 25 min (53) (also see chapter 2). Thus, from a practical perspective, the boiling of foods does not readily inactivate group I spores, and caution is needed in canning and production of foods in the home and in food service settings and restaurants. *C. botulinum* group I is closely related to *C. sporogenes*, but certain strains of this species, including *C. sporogenes* PA3679, have temperature resistance approximately 10 times greater than that of *C. botulinum* group I (53,136–138). *C. sporogenes* is often used as a surrogate for group I *C. botulinum* in processing and in food challenge studies (137). Due to its higher heat resistance, it is useful as an indicator of food processing efficacy, as it is a “worst case” surrogate and provides a conservative safety margin in processing and food challenge studies. *C. sporogenes* cannot be considered a true surrogate, as it is not isogenic to *C. botulinum*, except by only having a deleted *bont* gene, and *C. sporogenes* also has higher resistance properties than group I *C. botulinum*. Therefore, *C. sporogenes* has a genome distinct from that of group I strains of *C. botulinum* (138) (see chapter 2).

Table 18.2 Groups and relevant growth and resistance properties of BoNT-producing clostridia[a]

				Group		
		C. botulinum				
Property	I	II	III	IV (*C. argentinense*)	*C. butyricum*	*C. baratii*
Neurotoxin type(s)	A, B, F	B, E, F	C, D	G	E	F
Growth temp (°C)						
Minimum	10	3	15	12	10	20
Optimum	35–40	18–25	35–40	35–40	30–37	30–40
Maximum	48	45	NA	45	~40	NA
Minimum pH	4.6	5.0	NA	NA	~3.6	NA
Inhibitory a_w	0.94	0.97	NA	NA	0.97	NA
Inhibitory NaCl concn (%)	10	5	3	>3	~5	5
D value of spores (min) at:						
100°C	~25	<0.1	NA	NA	NA	NA
121°C	0.21	<0.005				

[a] Data are for a limited number of strains. Inhibitory factors interact, and hence, the inhibitory values may be affected by sublethal combinations of factors. *C. sporogenes*, often considered a surrogate for group I *C. botulinum*, has *D*121°C values ranging from 0.5 to 6 min. NA, insufficient data.

Group II includes nonproteolytic strains of types B and F, as well as type E. The BoNT genes are also located on chromosomes and/or on plasmids as described for group I. The organisms in this group are deemed nonproteolytic and they do not digest casein or meat particles, but gelatin is usually degraded. Glucose, fructose, maltose, and sucrose are fermented and support growth and toxin formation, but lactose is not utilized. This group is commonly referred to as saccharolytic due to their need for sugars to grow, which is in contrast to group I organisms, which primarily require amino acids as carbon and energy sources. The optimum temperature for growth is 25 to 30°C depending on the serotype. The minimum growth temperature is 3.3°C, and the maximum growth temperature is 40 to 45°C. At 3.3°C, and depending on the food system and the number of inoculated spores or cells, growth and BoNT formation occur very slowly, requiring weeks to months to form sufficient BoNT to cause mouse lethality (139). Growth is inhibited by an a_w of 0.97 (5% NaCl as the humectant in solution). The minimum pH for growth is 5.0. The spore heat resistance is much lower than that of group I, and strains typically have *D* values of <0.1 min at 100°C. Therefore, spores are readily killed at 80 to 100°C, and industry typically targets a 5-to 6-log thermal inactivation in thermally processed foods for group II nonproteolytic strains. Surrogate organisms for group II *C. botulinum* are not well defined, and there is a need to construct isogenic mutants of members of this *C. botulinum* group that have only a deletion of the gene encoding BoNT. Newer genetic methods such as the CRISPR (clustered regularly interspaced short palindromic repeats)-Cas method are being used to isolate mutants of other clostridial species (140–142), and this method should be valuable in creating defined true *bont* deletion surrogates for processing and food challenge studies in groups I and II.

Table 18.3 Nutritional substrates metabolized by botulinogenic clostridia[a]

Clostridium species and type(s) (group)	Glucose	Fructose	Sucrose	Maltose	Lactose	Gelatin	Milk	Meat	Lipase	Lecithinase
C. botulinum										
Types A, B, F (I)	+	+/-	+/-	+/-	-	+	+	+	+	-
Types B, E, F (II)	+	+	+/-	+/-	-	+	-	-	+	-
Types C, D (III)	+	+/-	+/-	+/-	-	+	+/-	-	+	-
C. argentinense (IV)	-	-	-	-	-	+	+	+/-	-	-
C. baratii, toxigenic	+	+	+	+/-	+/-	-	-	-	-	+
C. butyricum, toxigenic	+	+	+	+	+	-	-	-	-	-

[a] Symbols: +, positive; −, negative; +/−, weak or variable.

Table 18.4 Primary hosts and locations of toxin genes in *C. botulinum* serotypes A through G

Serotype	Susceptible species	Location of neurotoxin gene
A	Humans, horsesgene A	Chromosome, large plasmids in some strains
B	Humans, horses, swine, primates	Chromosome, large plasmids in some strains
C	Birds, horses, cattle, minks, foxes, dogs, turtles	Pseudolysogenic bacteriophage, plasmid
D	Cattle	Pseudolysogenic bacteriophage, plasmid
E	Fish, waterfowl	Chromosome, large plasmids in some strains
F	Humans (rare)	Chromosome, large plasmids in some strains
G	None known	Large plasmid

Group III includes *C. botulinum* types C and D, which are pathogenic for many wild and domestic animals but rarely cause human botulism (Table 18.4.) (20, 46). Organisms in this group generally digest milk proteins, meat particles, and gelatin. Toxin production is mediated by temperate phages in group III (143) (Table 18.4.). Glucose and mannose are fermented, whereas sucrose and trehalose are not. The optimum temperature for growth is 30 to 37°C, and the growth range is 15 to 40°C. Growth is inhibited by 3% salt. The minimum pH for growth is 5.0 to 5.2. Group III *C. botulinum* is variable in BoNT formation because the gene for BoNT is

present on an unstable temperate bacteriophage. On loss of the BoNT-containing phage, the organism is indistinguishable from *C. novyi* (143).

Group IV consists of *C. botulinum* type G, which has been taxonomically defined as *C. argentinense* for toxigenic and nontoxigenic strains (118). The gene encoding BoNT lies on a large plasmid (130). Gelatin and milk are readily digested, and meat is digested slowly. Ammonia and hydrogen sulfide are produced. Growth of *C. argentinense* relies on digestion of protein and the availability of amino acids for growth. Glucose, fructose, sucrose, maltose, mannose, and trehalose are not fermented. The optimum growth temperature is 30 to 37°C, and the minimum growth temperature is 12°C. *C. argentinense* is inhibited by 6.5% NaCl.

Sporadic strains of neurotoxigenic *C. butyricum* and *C. baratii* producing BoNT E and F, respectively, were isolated from infant botulism cases in the 1980s, and more recently, these two species have been involved in rare foodborne-botulism outbreaks (23, 123). The gene for BoNT F resides on the chromosome and/or on a plasmid. *C. butyricum* does not digest meat, but it does utilize pectin and starch. It ferments numerous sugars, including glucose, fructose, lactose, and sucrose. The optimum temperature range for growth is 30 to 37°C, and some strains will grow at 10°C. Growth is inhibited by 6.5% salt. The minimum pH for growth is 4.8. The thermal resistance of spores is low, with a *D* value of <0.1 at 100°C.

Neurotoxigenic strains of *C. baratii* have been involved in infant and foodborne-botulism cases (1, 23). *C. baratii* does not digest meat, and starch hydrolysis is variable. It ferments glucose, fructose, maltose, and cellobiose, whereas lactose fermentation is weak and trehalose is not fermented. Optimum growth occurs at 25 to 35°C, and some strains grow up to 45°C. The minimum temperature for growth is 10 to 15°C. The growth and resistance properties of neurotoxigenic *C. butyricum* and *C. baratii* (92) require further study, particularly as they are increasingly being associated with infant botulism and food botulism. The surrogate organisms are nontoxigenic strains of *C. butyricum* and *C. baratii* strains. Characteristics of the groups I to IV and neurotoxigenic *C. baratii* and *C. butyricum*, particularly pertaining to nutritional utilization, growth, and survival in foods, are summarized in Tables 18.2 and 18.3.

GENOMICS OF NEUROTOXIGENIC CLOSTRIDIA

Owing to advances in whole-genome sequencing and bioinformatics, full genomic sequences of several toxigenic *Clostridium* species, such as *C. tetani*, *C. difficile*, *C. perfringens*, *C. acetobutylicum*, and *C. botulinum*, have been determined and deposited in GenBank and other genomic databases. The genomic sequences of more than 200 strains of *C. botulinum* have been determined. These genome sequences have led to an in-depth examination of *C. botulinum* phylogenomics (122,144–146) and have also identified genes important in resistance properties in foods, spore formation, germination, and outgrowth, and BoNT expression and properties. The availability of the genomic sequences of *C. botulinum* and other botulinogenic clostridial species will enable future rational approaches for identification of genes and proteins for development of inhibitors and novel antimicrobials that target *C. botulinum* for enhancement of food safety (145).

The genes encoding BoNT and other proteins in the BoNT progenitor complexes are present on the chromosome, plasmids, and bacteriophages (Table 18.4.). It has long been realized that in *C. botulinum* type C and D, the *bont* genes can be mobilized and transferred between these serotypes and to *C. novyi* (143). More recently, plasmids containing BoNT genes that occur in *C. botulinum* groups I and II have been found, and certain of these plasmids have conjugative ability (131, 133, 147). Several of the plasmids harboring genes encoding BoNT have not been evaluated for lateral gene transfer (131), and the spread of genes encoding BoNTs may be wider

than currently realized. This hypothesis is supported by the recent finding of BoNT gene clusters in bacterial species distantly related to *C. botulinum* (98) that appear to produce BoNT-like proteins but have not been shown to have the specific toxicities (10^7 to 10^8 mouse LD_{50}s per mg) of authentic neurotoxic clostridia. The lateral transfer of genes encoding BoNTs could have a significant impact on food safety and public health.

ECOLOGY OF BOTULINOGENIC CLOSTRIDIA

BoNT-producing clostridia are widely dispersed in nature by virtue of their ability to form resistant endospores that can persist in nature for decades (see chapter 2). Unlike many other foodborne pathogenic bacteria, neurotoxigenic clostridia do not have an obligatory relationship with an animal host, and spores exist free-living in the environment and only adventitiously colonize animals as carriers.

The distribution of *C. botulinum* spores worldwide has been reviewed (20, 53, 148, 149). Although *C. botulinum* spores are distributed widely throughout the world, the different serotypes are mainly found in specific geographic regions and habitats. *C. botulinum* causing human foodborne botulism is primarily found in northern regions of the world. Proteolytic group I type A spores have been found in temperate regions, including soils of the western United States, southern and eastern European countries, and China. Group I type A *C. botulinum* spore distribution favors neutral to alkaline soils with low organic content; hence, they are mainly absent from the eastern region of the United States, as well as from western European soils. In the continental United States, proteolytic type A is most common west of the Mississippi River, whereas proteolytic type B is most common east of the Mississippi River. Twentyfour percent of the soils tested in the United States were found to harbor *C. botulinum* spores in an early survey (53). Distribution of type B spores appears to be more uniform worldwide. *C. botulinum* type B strains found in western Europe are usually nonproteolytic (group II). However, proteolytic type B spores (group I) have also been found in western European countries such as France, in Asian countries including Japan and China, and eastern European countries such as Poland and Russia. Type E spores are found mainly in aquatic sediments of colder regions of the northern hemisphere, such as Alaska, Canada, Scandinavia, Poland, Russia, and Japan. Type E levels are correlated with low sediment oxygen content, increased depth of the sediment, and absence of bioturbation activity.

C. botulinum spores have a relatively low prevalence in certain countries, including Great Britain, Sweden, The Netherlands, Switzerland, Austria, Greece, Australia, New Zealand, Mexico, South Korea, and many countries in the South American and African continents (53, 148, 150). *C. botulinum* spores have been isolated from the intestinal tracts of healthy fish, birds, mammals (but not humans), and certain invertebrates. *C. botulinum* is often associated with the decomposition of plants and animals, in which an anaerobic environment and rich source of nutrients promote the formation of spores. Spores are distributed in nature by fomites, including invertebrates and other organisms, and by natural and farming-related environmental processes, including dispersal of spores in soil by wind, rain, and runoff, bioturbation, farming practices, watershed management, and other routes (149, 151). Accordingly, the spores contaminate many foods as well as animals, soil and dust, buildings, and households. Recent investigations using metagenomics have revealed that various genera of sporeformers are more prevalent in soils and in the human microbiome than previously assumed (152). The future discovery of the presence of *C. botulinum* in previously barren regions could open new insights for their importance in disease.

The biological functions of *C. botulinum* and BoNTs in nature remain unknown, and their role remains speculative. The formation of BoNT is not necessary for growth and survival of *C. botulinum* in the laboratory, since inactivation of the toxin genes or deletion of the BoNT gene region does not alter growth, although it appears to increase sporulation (75, 153, 154). *C. botulinum* has been isolated from rotting vegetation and from animal carcasses (149, 155). Neurotoxigenic clostridia are generally considered saprophytic and do not have an obligatory relationship with an animal host (50). Due to their formation of the deadly BoNT with action on warm-blooded vertebrates, *C. botulinum* can be considered predatory in some ecological niches, and by killing the prey, it initiates the complex process of animal decomposition, important for recycling of animal biomass. The initial killing of prey is followed by a complex progression of a microbiome involved in decomposition (156–158). Considerable research has been conducted on the decomposition of plant biomass, which is wide-spread and mostly stationary, static, and abundant. However, comparatively little research has been performed on the ecology of decomposition of animal biomass in the wild, due to the mobility and spatial movement of animals prior to death, and probably the unpleasantness of studying rotting carcasses. Recently, detailed studies have been performed on the succession of the microbiome in already-dead decomposing animals and human carcasses (156–158). These studies have not defined the initial killing event that enables decomposition, and *C. botulinum* may provide this killing trigger in certain animals and humans.

PROPERTIES OF BoNTs

The exceptional feature of the neurotoxic clostridia is the production of a distinctive neurotoxin of extraordinary potency for humans and animals. BoNTs are the most potent protein toxins known for humans and many vertebrate animals (5–7, 42), having estimated human LD_{50}s of 0.5 to 3 ng per kg body weight by intravenous and intramuscular exposure, 0.10 to 1.5 μg per kg by the oral route, and 10 to 15 ng per kg by inhalation. Due to their extreme toxicity, laboratory research on *C. botulinum* and BoNTs is tightly regulated in the United States by select agent rules (159) (http://www.selectagents.gov).

BoNTs are produced as single-chain molecules of ca. 150 kDa that achieve their characteristic high toxicities of 10^7 to 10^8 mouse LD_{50}s per mg by posttranslational proteolytic cleavage and processing to form a dichain molecule composed of a light chain (~50 kDa) and a heavy chain (~100 kDa) linked by a disulfide bond (82, 160). Proteolytic strains of *C. botulinum* produce the proteolytic enzyme(s) for activation, whereas nonproteolytic strains depend on exogenous proteases (e.g., in food or in the gut) for activation. However, in certain BoNTs from proteolytic *C. botulinum* strains, such as type B strains, only partial activation (60 to 70%) occurs in culture, compared to >95% activation in type A cultures. Other factors are involved in posttranslational activation and stabilization or degradation of the BoNT component in cultures and during manufacture for pharmaceutical use (161) (Johnson lab, unpublished results).

The 150-kDa BoNTs exist naturally as components of large progenitor protein complexes ranging from 300 to 900 kDa in size and varying in complexity (42, 82, 83, 85). In these complexes, the 150-kDa neurotoxin component is associated with nontoxic proteins and RNA. The nontoxic proteins in the complexes provide protection of BoNTs during oral ingestion and passage and absorption in the gastrointestinal tract, experimental manipulations, and food processing (8, 42, 162).

Seven BoNT serotypes (A, B, C1, D, E, F, and G) are currently recognized (10, 82). Serotypes are experimentally distinguished by the neutralization in the mouse bioassay using serotype-specific antitoxins raised against purified neurotoxins in rabbits, horses, mice, and other

animals (10). The seven serotypes differ in potency in animal models and in humans, as gleaned from case studies of foodborne botulism in humans (2). Studies in animals and analyses of case studies have revealed that BoNTs from proteolytic serotype A cause the most severe and long-lasting botulism. Type B also causes severe foodborne and infant botulism but appears to be less potent than type A. Type E causes a milder botulism, but intoxication with type E can still require intensive care and be fatal. Foodborne botulism caused by type F has been extremely rare (2, 59). Infant botulism is mainly caused by BoNTs from proteolytic (group I) strains (59). Infant botulism has also been caused by rare strains of *C. butyricum* and *C. baratii* producing BoNTs E and F, respectively (59). Interestingly, several strains of *C. botulinum* isolated from infant botulism cases produce more than one serotype of BoNT, suggesting that transfer of genes encoding BoNTs may be promulgated in the infant intestinal environment. Wound botulism, which mainly occurs through injections of street drugs or by inhalation of cocaine (18, 163), is caused mainly by proteolytic strains of *C. botulinum* (164).

A landmark achievement in understanding the molecular pathology of botulism was the determination of the three-dimensional structure of BoNT A1 (89), which revealed that the 150-kDa BoNT consists of three primary domains. These three primary functional domains of approximately 50 kDa each include (i) H_C, the receptorbinding domain located in the C-terminal region of the heavy chain; (ii) H_N, the translocation domain residing in the N-terminal region of the heavy chain that enables entry of BoNT into neurons; and (iii) the light chain, which is the catalytic domain that has endopeptidase activity on neuronal substrates and cleaves substrates of the SNARE protein translocation apparatus, thus preventing release of neurotransmitter from neuronal cells (36, 38). Subsequently, the structures of BoNTs serotypes B and E were also found to have three primary domains (165). The importance of the discoveries of structures and associated functions in advancing the field of BoNT study cannot be overemphasized.

Studies during the past decade have revealed that subtypes (isoforms) of BoNTs occur within the serotypes, in which the 150-kDa proteins differ in amino acid sequence by >2.6%, as derived from amino acid sequences (121, 166). More than 40 subtypes of BoNT types A, B, and E have been detected by DNA sequencing, and sub types A1 to A6, which differ by 3 to 12% in amino acid sequence, have been purified and characterized (166, 167). Only a few subtypes of serotypes BoNT B, E, and F have been expressed, purified, and studied for toxicity, antibody neutralization by antitoxins, and other properties. Properties of BoNT subtypes related to foods, such as oral toxicity, stability in foods, production in foods, and other aspects, have not yet been studied.

In 2015, it was suggested that a new BoNT serotype, type H, was produced by an isolate of *C. botulinum* from a case of infant botulism (168). Definitive characterization of the purified BoNT FA "H" revealed that its activity was neutralized by antisera to BoNT A (169, 170). Therefore, by definition of a serotype, demonstration of its neutralization by antibodies against BoNT A precluded BoNT FA "H" as a new serotype.

CLINICAL ASPECTS AND CATEGORIES OF HUMAN BOTULISM

Botulism is a true toxemia, and BoNT is solely responsible for the illness. After being absorbed into the circulation, BoNT binds to and is internalized in the nerve terminals. The primary target is the neuromuscular junction, which has been termed "the most vulnerable synapse" (16). The symptoms of foodborne, infant, and wound botulism are clinically similar. The hallmark clinical symptoms of botulism are a bilateral and descending weakening and paralysis of skeletal muscles (2, 18). An adult patient with characteristic cranial flaccid paralysis is illustrated in Fig 18.2. The Working Group on Civilian Biodefense has described a classic triad of symptoms of botulism: (i) symmetric, descending flaccid paralysis with prominent bulbar palsies; (ii) lack of

fever; and (iii) a clear sensorium in the patient (7). The bulbar palsies can be summarized as the "four Ds": diplopia, dysphagia, dysarthria, and dysphonia. Autonomic dysfunctions, including constipation, urine retention, and mydriasis, also occur, particularly with certain serotypes of BoNTs (171). A recent in-depth review outlined the primary symptoms in adult and infant botulism (18). Intoxication by BoNTs can be exacerbated by the presence of underlying neuromuscular diseases in the patient, such as myasthenia gravis, and by neuromuscular blocking agents, such as aminoglycoside antibiotics (2).

In most cases of botulism, cranial nerves are first affected, particularly those innervating the eyes, and the first symptoms are blurred and double vision, dilated pupils, and drooping eyelids (Fig 18.2) (2). The eyes respond slowly to light in a darkened room. These abnormalities are followed by other symptoms in the cranium, including difficulty in swallowing, weakness of the neck and mouth, dysphagia (drooling and difficulty swallowing), and problems in speaking (18). As the paralysis descends, weakness of the upper limbs and the torso occurs, and in severe cases, muscles affecting respiration are weakened, and mechanical ventilation to prevent death by suffocation is required (2, 18). Generally, the patient's hearing remains normal, consciousness is not lost, and the victim is cognizant of the progression of the disease. Other symptoms may occur, including nausea or vomiting, dizziness or vertigo, diarrhea or constipation, dry mucous membranes in the mouth and throat, sore throat, and paresthesia, which may be related to botulinal neurotoxin or other toxins or pathogens in the contaminated foods (18). Infant botulism has certain distinct features, including constipation, weakness and hypotonia, poor sucking and feeding, weak cry, lack of head control, and cardiovascular abnormalities (hypotension and tachycardia) (172, 173). Certain cases of botulism have been associated with abnormalities of autonomic and sensory functions, such as constipation, dry mouth, and difficulty in urination. A patient's awareness of weakening of muscle activity and ensuing paralysis can lead to considerable emotional distress, including anxiety and depression (2). The most severe and longlasting type of botulism is foodborne botulism, which generally occurs with type A. In general, the duration of foodborne botulism illness follows the pattern A ≥ C > B > F > E in animal models and in humans (2). In infant botulism, nearly all cases are caused by group I strains of serotypes A and B, and rare cases are caused by type F. Recently, cases of type C and E infant botulism were documented (5). The fatality rate from foodborne botulism has decreased from 50 to 70% in the 1800s and 1900s to 5 to 10% in the past 20 to 30 years (5, 19, 174). Convalescence and recovery from botulism are usually prolonged, requiring weeks to months depending on the serotype of toxin and the quantity consumed. Recovery is usually complete, and patients regain full normal function (2).

Figure 18.2 Portrayal of a person with the flaccid paralysis symptoms characteristic of botulism. Drawing prepared by James K. Archer, Centers for Disease Control and Prevention, Atlanta, GA.

Several categories of botulism are recognized (2, 5). Foodborne botulism occurs following ingestion of preformed BoNT in foods. Infant botulism results from the growth and toxin production by *C. botulinum* in the infant (≤12 months of age) intestinal tract. In humans more than 12 months of age, intestinal botulism can also occur particularly after surgery, antibiotic treatment, and other predisposing conditions. *C. botulinum* can colonize skin punctures and incisions and cause wound botulism through infection of the wounds, with formation of BoNT that enters the systemic circulation. Inhalation botulism has been observed experimentally in mice, guinea pigs, and primate animal models (175, 176). Inhalation botulism has rarely occurred in humans, and one documented incident involved transfer of BoNT from the fur of laboratory animals (177). Iatrogenic botulism with systemic symptoms results from inappropriate injection of BoNT for medical use or by counterfeit BoNT preparations (17, 71, 73) and appears to be increasing in incidence (72). An "undetermined classification" of botulism is listed by the CDC and refers to cases of diagnosed botulism for which no plausible food vehicle or intestinal colonization by *C. botulinum* can be determined (2, 5, 14, 178). Intentional botulism through bioterrorist activities has been inflicted in humans, particularly during World War II (7, 179), but attempts to induce botulism in humans by transmission in water, foods, and aerosols have failed. Even so, concerns and possible scenarios of intentionally caused botulism associated with terrorist activity have periodically reemerged, including those concerning the supply of milk for school children (179, 180). Overall, foodborne and infant botulism appear to be the most common forms in humans worldwide, but the incidence of botulism is quite low.

Most botulism cases worldwide are caused by BoNT types A, B, and E, and rarely by F (2, 54, 59). The incubation time for onset of symptoms of foodborne botulism varies with BoNT serotype and with the quantity of neurotoxin that is ingested and reaches target nerves. Foodborne botulism occurs following the consumption of food contaminated with preformed BoNT, and probably with *C. botulinum* cells present in the food. It has been observed in certain foodborne-botulism cases that the food consumed has viable *C. botulinum* cells and spores, and it is possible that these contribute to the incidence and duration of the disease during ingestion and in the intestinal tract, but this has not been adequately studied (5). In foodborne-botulism cases, the onset time is usually 12 to 36 h following consumption of the toxic food (2). The incubation period can be as short as 2 h when large concentrations of toxin are ingested or as long as 2 to 14 days with serotypes B, E, or F or ingestion of small amounts of BoNT (2). Wound botulism usually has a relatively long incubation period of 4 to 14 days, reflecting the time needed for

neurotoxigenic clostridia to colonize the wound and produce neurotoxin (18). Infant botulism has an incubation time of 6 to 8 hours to several days (2), although a more rapid onset has occasionally been reported (2). It is controversial whether rapid onset of fulminant botulism is a cause of sudden infant death syndrome (181, 182). Intestinal botulism has also occurred concurrently with other clostridial intestinal infections, such as that caused by *Clostridioides* (formerly *Clostridium*) *difficile* (2). It is likely that the microbiome affects the ability of *C. botulinum* to colonize in intestinal botulism, and this field is only beginning to be explored (183).

DIAGNOSIS OF BOTULISM

Diagnosis of botulism involves a physician's assessment of clinical signs, including the initial visual disturbances and other cranial effects, skeletal muscle weakness, and detection of BoNT from appropriate specimens by the mouse bioassay (2, 18, 28, 29, 184, 185). Electrodiagnostic testing can provide presumptive diagnosis of botulism (18, 186). Electrophysiologic testing is also useful for differential diagnosis of other causes of acute flaccid paralysis syndromes, such as Guillain-Barré syndrome, myasthenia gravis, tick paralysis, and Lambert-Eaton syndrome (2, 186). Although clinical signs can provide a presumptive diagnosis of botulism, the definitive diagnosis is the detection of BoNT in the patient's serum, stool, wound, or vomitus and/or in suspect contaminated food (10, 14, 29). However, there are caveats related to the detection of BoNT in foods and clinical samples. The mouse bioassay may be negative for detection of BoNT in clinical samples, including serum and feces after 48 h of exposure, and foods may be unavailable for analysis (5, 10). False-positive results may result from lethal compounds in foods other than BoNT (5, 10). These limitations and their resolution have been carefully described (10).

The accepted procedure for BoNT detection is the mouse bioassay, which consists of two essential steps: (i) determining whether a food substrate or an extract in gel-phosphate (0.1 M sodium phosphate–0.2% gelatin, pH 6.2) is lethal on intraperitoneal or intravenous injection into mice and (ii) confirming the lethal agent as BoNT by neutralization with specific botulinum antitoxin (2, 10). When BoNT of a nonproteolytic *C. botulinum* strain is tested, it is necessary to activate the toxin to the light and heavy chains by limited proteolysis using trypsin (2, 10). A problem often encountered in testing of clinical and food samples is that these specimens may contain nonbotulinum substances that are lethal to mice and cause nonspecific deaths. These can be detected by evaluation of characteristic botulism symptoms and the onset time of symptoms in mice (generally >3 to 4 hours in mice injected intraperitoneally), by "diluting out" these substances, which generally have a lower toxicity than botulinal neurotoxin, and most definitely by use of serotype-specific antitoxins in a subset of the samples used for injection (2, 10). Another difficulty is that samples may contain more than one serotype of toxin due to a *C. botulinum* strain producing more than one serotype of BoNT or due to multiple strains forming BoNTs. These difficulties in BoNT analysis and their solutions have been described (2, 10). When delays in specimen collection and analysis occur, or if mouse-lethal substances other than BoNT are present in samples, laboratory detection of BoNT may not be conclusive. In clinical cases of botulism, a positive test may not be obtained more than 2 days after human exposure to neurotoxin. Therefore, it is important to process samples rapidly and to culture neurotoxigenic clostridia from the foods as described below.

Recently, our laboratory and others have developed neuronal cell lines sensitive to BoNTs, including primary spinal cord neurons and human stem cell pluripotent neurons, and these have outstanding potential for assay of and determination of the mechanisms of BoNTs (115, 187). Nonanimal cell assays that depend on all of the steps in the intoxication mechanism, including

receptor binding, internalization, and catalytic cleavage of neuronal substrates, such as cell-based assays (115), are excellent systems for the determination of toxin titers (115) as well as antibodies in patients' sera (188). Of particular promise is the use of human neuronal cell cultures, because toxicity to these cells depends on all domains of botulinal neurotoxin and the steps needed for intoxication (115). However, many neuronal cell lines are relatively insensitive to BoNTs, particularly cell lines derived from neuroblastomas. Recently, our laboratory and others have developed sensitive cell lines, including primary spinal cord neurons and human stem cell pluripotent neurons (91, 99–101), and these have outstanding potential for assay of and determination of the mechanisms of BoNTs. Recently, the FDA approved a cell-based assay for determination of botulinum type A toxin for use in medicine (115; www.fda.gov).

TREATMENT OF BOTULISM

Intoxication by BoNT at the neuromuscular junction of motoneurons prevents the release of acetylcholine to muscles innervating the eyes, face, and mouth, and then the toxicity descends bilaterally to motor nerves of the torso, causing a generalized paralysis. Currently, there is no antidote for botulism once it enters nerves, and the only treatment of the disease is thorough nursing care and, in severe cases, mechanical ventilation, parenteral feeding, and rehabilitation. Serum therapy by administration of human (BabyBIG) (189) in infants or heptavalent equine antibodies (currently heptavalent botulinum antitoxin) (30, 190) into the circulation of poisoned toddlers and adults (2, 191) can decrease the severity of the paralysis and duration of the illness. Antitoxin can effectively neutralize unbound toxin in the circulation, but it will not prevent the disease once receptor binding and the internalization process of BoNT are under way, while BoNT remains in the bloodstream.

CONTROL OF *C. BOTULINUM* AND FORMATION OF BoNTs IN FOODS

Botulism in the United States typically occurs in certain classes of foods, and these are subjected to certain processing and handling practices (Table 18.5.). Prevention of botulism is primarily dependent on proper food preparation, processing, formulation, and storage. The elimination of spores from raw ingredients is not practical, but spores can be eliminated by processing technologies (see chapter 2). Foodborne botulism is very rare, and the food industry and researchers in academia have extensively studied the control of *C. botulinum*, yet outbreaks continue to occur.

The primary factors that control the growth of *C. botulinum* in foods are temperature, pH and acidity, a_w, redox potential, nutrient sufficiency, the presence of antimicrobials, and competitive microbiotas (139) (Table 18.6.). In foods formulated to be botulism safe, inhibition relies on the inhibitory activities of combinations of factors (24, 25) (Table 18.6.). Among the most important inhibitory factors are an acidic pH and low a_w. For group I *C. botulinum*, the critical pH for botulism safety of foods is pH 4.6, below which *C. botulinum* spores will not germinate, outgrow, and form BoNT. Food products with a pH of <4.6 are termed high-acid foods and have an excellent record of botulism safety (24). Low-acid foods are those having an equilibrium pH of >4.6 and an a_w of >0.85. These foods require suitable processing or preservation procedures to prevent the survival and growth of *C. botulinum* (see chapter 2). For group II *C. botulinum*, the critical pH is 5.0 for prevention of spore germination and outgrowth with formation of BoNTs. Short-chain organic acids (e.g., lactic, acetate, and malic acid) with pK_a values in the range of 3.0 to 5.0 are generally used as acidulants, as these are more inhibitory than mineral

acids at equivalent pH values. When acids are used to adjust the pH of foods, adequate time and mixing are required for diffusion of the acids throughout the foods, occasionally several hours to days. If the foods will not be subsequently processed, then these acidulated foods should be refrigerated until equilibrium is reached.

Table 18.5 Typical foods associated with foodborne botulism

Fermented fish products
Home-canned vegetables (green beans, mushrooms, olives)
Foods preserved in oil (garlic, onions)
Cooked foods stored at room temperature (potatoes, onions)
Foods packaged in air-tight or modified-atmosphere containers with inappropriate refrigeration

The classification of foods into groups with high and low acidity has been a useful criterion for ensuring the botulism safety of most foods (24, 139). However, botulism outbreaks have been attributed to high-acid foods, particularly tomato products and certain homeprepared foods (24). Certain conditions can enable toxin formation in high-acid foods, including inadequate penetration of acids into larger pieces of food, thus creating microenvironments with higher pH. A second important factor has been termed metabiosis, whereby yeasts, molds, or bacteria can metabolize acids and other components such as proteins and raise the pH to a level at which *C. botulinum* can grow. For example, fungal mats can form at the surfaces of certain foods, thereby raising the pH under the mat and creating permissive conditions for *C. botulinum* growth and BoNT formation. Growth of *C. botulinum* has been reported in acid media in which precipitated protein or meat particles are present, probably forming a permissive microenvironment pocket for *C. botulinum* proliferation (24). Upper pH limits for growth of *C. botulinum* are in the range of pH 8 to 9, but inhibition by alkalinization is not practical in most foods.

Table 18.6 Primary physical treatments and intrinsic factors used in formulation of botulism-safe foods[a]

Thermal treatment
pH and acidity
a_w and solute composition

Nitrites, sulfites, phenolic compounds
Polyphosphates
Fatty acids and esters
Gas composition
Naturally occurring antimicrobials
Competitive microbiotas
Indirect antimicrobials

[a]Modified from reference 46.

Control of a_w, for example by addition of NaCl, is also critical for preventing growth of *C. botulinum* formation of BoNTs (24). Food preservation by brining is mainly due to the reduction of a_w, whereby adequate free water is not available to the organism for growth. Brining is the

most common practice for reducing a_w in food preservation. The limiting values for inhibition by brine alone are 10% and 5% for group I and group II *C. botulinum*, respectively (24). High concentrations of sucrose can also inhibit *C. botulinum* by reducing the a_w, but approximate concentrations of 30% and 15% sucrose are required to inhibit group I and group II strains, respectively. Similarly, other compounds, including glycerol, organic polymers, ions such as potassium, and other food components, can bind free water and reduce the a_w, but their efficacy in inhibiting *C. botulinum* growth is generally relatively poor on a weight percent basis compared to that of NaCl (24, 139). Therefore, when these compounds are used as preservatives, it is essential to measure the a_w of the food during its formulation and to conduct challenge studies of the food during development and before commercialization.

Refrigeration is commonly used to prevent *C. botulinum* growth and BoNT formation in foods. The minimum temperature for growth of group I strains is commonly accepted to be 10°C (50°F), whereas group II strains can grow at temperatures as low as 3.3°C (38°F). Growth at lower temperatures can require weeks to months due to the slowing of metabolism and lowering of the growth rate. The upper temperature limits for growth for group I and group II strains are 45 to 50°C (113 to 122°F) and 40 to 45°C (104 to 113°F), respectively. Refrigeration without processing or inclusion of preservatives is increasingly being used in the food industry for prevention of *C. botulinum* growth and BoNT formation, as many consumers desire “healthy” and “organic” foods that have minimal processing and contain low levels of salt or other preservatives. Certain minimally processed foods depend on refrigeration alone for botulism safety, yet this practice can result in *C. botulinum* growth and formation of botulinal toxin because of poor temperature control or temperature abuse in food stores, in food service establishments, or by consumers. Temperature abuse is one of the most common mishandling practices that result in BoNT production and botulism outbreaks. Therefore, it is not recommended to rely solely on low temperature for botulism safety, and adequate processing and/or formulation by inclusion of secondary barriers such as antimicrobials is recommended (Table 18.6.).

Since *C. botulinum* is a strict anaerobe, a permissive redox potential (E_h) is required for germination of spores and growth of vegetative cells (139). However, relatively high E_hs of approximately +200 mV can also allow germination and growth initiation of spores under certain conditions (192). The critical level of oxygen that prevents germination and growth by *C. botulinum* is approximately 1 to 2%. However, the level of oxygen in a food is extremely difficult to control, due to vaporization and growth of the microbiota, which can alter oxygen levels. Carbon dioxide can also be inhibitory to *C. botulinum*, partly due to lowering of the acidity in the food. Although reduced oxygen and increased carbon dioxide levels may be permissive for *C. botulinum* growth and toxin production, the safety risk depends not only on the gas environment but also on the product, storage temperature, packaging film used, and inherent competitive flora.

Modified-atmosphere packaging and high-barrier films can be used to effectively extend the shelf life of foods under refrigeration conditions (5, 192). Reduced oxygen levels and increased concentrations of carbon dioxide in refrigerated modified-atmosphere-packaged foods can decrease oxidative and chemical deterioration, as well as inhibiting common aerobic spoilage microbes, such as fungi and many bacteria (5). Concerns have been raised that these conditions may also select for anaerobic psychrotrophic microbes, such as group II *C. botulinum*, and increase the botulism risk. The combination of high-barrier films and respiring foods such as vegetables may also lead to decreased oxygen levels for packaged foods in an ambient atmosphere. The reduced oxygen content, in turn, may enhance the growth of *C. botulinum*. In packaged mushrooms, a high-barrier plastic film reduced oxygen concentration through

respiration of the mushrooms and permitted botulinum toxin production (193). Toxin was detected in prepackaged mushrooms after 3 days of storage, although mushrooms were still considered organoleptically acceptable. A simple solution to prevent botulinum toxin formation was to increase gas exchange by introducing three or four holes in the wrap covering the mushrooms. Similarly, packaging of garlic in oil and relying solely on refrigeration for botulism safety resulted in outbreaks and changes in regulatory formulation requirements. In summary, the presence of oxygen at low concentrations alone cannot be relied upon to inhibit botulinum growth and toxin production. The effect of food components, such as sulfhydryls or competitive microbiotas, may also reduce oxidative-reduction potential to a level at which *C. botulinum* can grow. Therefore, similar to relying solely on temperature to control *C. botulinum* growth, neither redox-potential nor enhanced oxygen transfer is recommended on its own to prevent the growth of *C. botulinum*; hence, suitable processing and inclusion of secondary barriers are recommended.

An important factor for prevention of *C. botulinum* growth and toxin formation in many foods is the presence of a competitive microbiota. Most foods have low levels of *C. botulinum* spores, and the pathogen is often inhibited by a competitive microbiota, such as lactic acid bacteria or yeasts, that ferments sugars and other substrates in the food with production of inhibitory levels of organic acids, alcohols, and bacteriocins. A competitive microbiota or fermentates derived from cultures have been included in food formulations to control growth of *C. botulinum* (24).

Preservatives such as nitrite have traditionally been used for control of *C. botulinum* in foods (Table 18.6.) (24). Recently, there has been a trend to use “natural” inhibitors that generally have lower efficacy than traditional preservatives. For many foods, the use of a high level of a single inhibitor at high concentrations to control *C. botulinum* growth often diminishes the organoleptic acceptability of the food. Therefore, many foods are formulated to be organoleptically desirable by using combinations of inhibitory factors at sublethal levels, and they often receive minimal thermal processing or high-pressure treatment. The individual actions of these inhibitors often have cumulative or occasionally synergistic effects for inhibiting *C. botulinum* growth. An example of a low-acid food prepared in a botulism-safe way by using a combination of treatments and antimicrobials is cured meats, in which minimal heat processing is combined with the addition of nitrite (53). Another example is pasteurized processed cheese, in which sublethal heat processing is combined with subinhibitory levels of a_w (moisture and NaCl content), acid, and phosphate salts (194). Processed cheese and related products have an excellent safety record relative to botulism. Extensive studies on processed cheese at the University of Wisconsin Food Research Institute (Madison, WI) led to one of the first empirical models for botulism-safe product formulation (194). Strategies for controlling *C. botulinum* by using combinations of physical treatments and antimicrobials in various classes of foods have been described.

The nutrient composition of a food is also important in the control of *C. botulinum*. The minimal nutrient requirements have been determined for growth of *C. botulinum* types A, B, and E in chemically defined media (100). Certain nutrients are required in high quantities for growth of *C. botulinum*, such as arginine for group I *C. botulinum* and tryptophan for type E. Increasing the arginine content promotes growth of group I *C. botulinum* (195) in otherwise inhibitory foods, probably through active metabolism with release of ammonia and an increase in pH. The presence of glutamic acid in growth medium increases the salt tolerance in group I *C. botulinum*, possibly by serving as a compatible solute or as a precursor to a protective osmolyte (196). Substrate utilization as well as protein and lipid degradation varies among the different BoNT-producing clostridial groups (Table 18.2.). *C. botulinum* groups I to III can utilize glucose as a primary carbon source. Depending on the group, certain strains can ferment fructose, maltose, sucrose, and sorbitol to varying degrees. While *C. baratii* and *C. butyricum* utilize

lactose, insignificant acid production and growth from lactose are observed with *C. botulinum* groups I to IV, which is likely important in the botulism safety of dairy products and related foods containing lactose. The limitation of substrates required for growth and BoNT formation is valuable in the formulation of botulism-safe foods. Summaries of substrate characteristics are presented in Tables 18.2 and 18.3. An overview of food-related parameters used for control of *C. botulinum* is presented in Table 18.6..

An area that is increasingly gaining attention is the food microbiome and the roles of competitor bacteria and fungi in antagonizing *C. botulinum* and other pathogens and preventing toxin formation and foodborne infections (197). In practice, it has been realized for many years that competitive microbiotas are extremely important in controlling *C. botulinum* growth and BoNT formation in foods. A precise understanding of the species of microorganisms in foods should lead to new methods and formulations to control *C. botulinum* growth and BoNT formation. In addition, whole-genome sequencing and bioinformatics will be utilized to provide an in-depth understanding of the genome composition and the presence of genes involved in growth and toxin formation. The methods for identifying the microbiome and its role in *C. botulinum* control are described in chapter 2.

New genetic tools such as CRISPR-Cas for manipulation of the genome can be utilized to identify genes essential in the growth of *C. botulinum* and BoNT formation. Identification of these essential genes could provide a focused and advanced method for discovery of inhibitors that specifically inhibit the critical enzymes and prevent growth. “-Omics” technologies, including metabolomics, are advancing rapidly, and these technologies will be valuable for understanding the physiology of *C. botulinum* and BoNT formation and providing a foundation for control of the organism in foods.

In summary, prevention of BoNT formation in foods can be achieved by (i) avoiding contamination of foods by spores; (ii) inactivating spores that are present in foods; (iii) preventing spores from germination and vegetative cell growth, resulting in botulinal neurotoxin formation; and (iv) inactivation of botulinal neurotoxins in a food. Practically, it is difficult to prevent contamination of many foods by spores due to their widespread distribution and contamination of foods during harvesting, formulation, and processing. Hence, considerable research and development have been devoted to spore inactivation and prevention of growth in foods (see chapter 2).

Thermal and other processing methods for inactivating *C. botulinum* spores are described in chapter 2. The excellent safety record of botulism prevention in commercial, low-acid canned foods attests to the efficacy of industry thermal processing practices (198). In addition to thermal processing, newer food preservation methods under development, including high pressure, pulsed electric fields, ohmic heating, and high-intensity light and sound treatments, are in preliminary stages of evaluation for inactivating spores, particularly *C. botulinum* spores (see chapter 2).

BoNT INACTIVATION

The instability of BoNTs in foods and clinical samples is an important factor contributing to the safety of foods from botulism (199). In general, BoNTs are labile to heat, alkali, chlorine, and certain other physical and chemical treatments (199). Heat has long been recognized to be highly effective for inactivation of BoNTs. BoNTs are most stable to heat under acidic conditions such as pH 3.5 to 5 and in the presence of organic acids, proteins, and certain ions, such as Ca^{2+} and Mg^{2+}. Heating at 70°C for 1 h, heating at 80°C for 30 min, or boiling for 5 minutes inactivated toxicity in buffers and foods (199). However, the rate of thermal inactivation does

not follow a linear curve, and considerable tailing has been observed during heat inactivation of BoNT in various buffers and foods. The biphasic curves observed preclude the use of *D* values to model thermal inactivation of botulinal neurotoxin, and it has been proposed that heat resistance be expressed as the time required for reduction of activity to a minimal mouse LD_{50} (*F* value) (199). The basis for heat resistance of a fraction of the total content of BoNT is unknown, and it has been suggested that it could be due to the formation of protein complexes, aggregation, changes in physical shape, or renaturation on cooling. The tailing observed could affect the degree of inactivation of high levels of BoNT during pasteurization processes used for various foods, such as milk, and the possibility for retention of toxicity is a consideration in pasteurization procedures.

The stability of BoNTs in drinking water, lake water, and other liquids depends on the presence of organic matter, higher acidity, and hypochlorite (199). The BoNT A complex is stable in distilled water for 7 days, and stability is enhanced at lower pH values such as 4 to 5 and in the presence of proteins. BoNTs are sensitive to chlorine, and the concentrations of chlorine used in drinking water are generally adequate for inactivation. Contaminated objects or surfaces can be decontaminated with 0.1 to 0.5% hypochlorite solution. For routine sanitation and cleansing of surfaces, exposure to 0.1% hypochlorite (undiluted commercial bleach is about 5.25% hypochlorite) is adequate, and for higher levels of contamination, 0.5% should be used with 20 to 30 min of exposure, followed by rinsing with distilled water. For decontamination of spills, the toxin solution on a surface should be covered with absorbent material to prevent aerosolization. The BoNT A toxin complex is inactivated by alkali at pH values of >9.5 to 10 (ca. 0.1 M NaOH) (199). Limited studies have revealed that the BoNT A complex is inactivated by 250 ppm ozone (199).

BoNTs are not generally inactivated by freezing, particularly in the presence of proteins and organic acids at pH values of 5 to 6.5. The notable exception to stabilization by organic acids during freezing is acetate buffer, in which all toxic activity is lost for BoNT A (112). BoNTs are not significantly inactivated by gamma irradiation from a ^{60}Co source (199). Drying by vacuum drying or lyophilization can stabilize BoNTs, especially in the presence of proteins such as gelatin or albumin and excipients such as trehalose, which is used in commercial preparations of BoNTs for pharmaceutical uses (42). Overall, the effects of physical and chemical treatments on BoNT and its protein complexes have not been thoroughly studied, although such information would be useful to enhance the safety of foods.

SURVEILLANCE AND REGULATORY ACTIONS

In the United States, foodborne disease surveillance and epidemiology are conducted through the Foodborne Disease Outbreak Surveillance System (FDOSS) of the Centers for Disease Control and Prevention (CDC) and the National Outbreak Reporting System (reviewed in reference 5). Investigations of the causes and factors contributing to outbreaks of foodborne disease provide important insights for their prevention. The CDC provides monthly and annual summaries of outbreaks. FDOSS also provides information on the types of foods that are most commonly associated with outbreaks and provides insights into the routes and causes of contamination, including processing and handling of foods. This information can be used to apply preventive measures and controls to prevent outbreaks. Regulatory actions in response to a commercial foodborne-botulism outbreak have recently been reviewed (29).

Beginning in 1996, the CDC developed experimental procedures to facilitate a tracking program and national database, called PulseNet, for assisting in studying the epidemiology of foodborne disease outbreaks in real time (reviewed in reference 5). PulseNet involves a network of public

health national databases with different laboratories throughout the United States. The CDC and collaborators developed a standardized PFGE program for characterization of *C. botulinum* strains involved in foodborne outbreaks. The pulsotype method has certain drawbacks and cannot distinguish between certain closely related strains, particularly dual toxin producers. Due to these limitations, PFGE is gradually being succeeded by whole-genome sequencing and bioinformatics analyses, which are able to distinguish among closely related strains (200).

USE OF PREDICTIVE MODELING AND CHALLENGE STUDIES FOR EVALUATION OF *CLOSTRIDIUM BOTULINUM* NEUROTOXIN FORMATION

Predictive modeling can be useful in developing product formulations and assessing the processing and formulation parameters for a botulism-safe food. Among the earliest applications of predictive modeling in food microbiology was the development of processing models to determine commercial sterility in canned foods (see chapter 2). During the past 2 decades, advances in computing, software development, and bioinformatics have led to significant advances in the field of predictive microbiology (201, 202). These advances have led to the development and availability of predictive modeling tools (24, 202). These modeling approaches have provided valuable insights into the combined effects of biological and environmental factors on the growth, survival, and death of *C. botulinum*.

SAFETY PRECAUTIONS FOR WORKING WITH *CLOSTRIDIUM BOTULINUM* AND BoNT

BoNTs are extremely toxic molecules; they are considered the most potent poisons known (5) and are regulated by select agent rules (11). Because the consequences of an accidental intoxication are so severe, safety must be a primary concern of scientists studying these toxins (5, 13, 14). The CDC recommends biosafety level 3 primary containment and personnel precautions for facilities producing large quantities of BoNTs and in working with high-toxin-producing *C. botulinum* strains (18, 65). The CDC has defined an “exempt” quantity of BoNT as 1.0 mg, which can be used in biosafety level 2 laboratories. All personnel who work in the laboratory should be thoroughly educated on the hazards of working with *C. botulinum* and its toxins. They must have knowledge of spill control and toxin inactivation (0.1 to 0.5% hypochlorite or 0.1 M NaOH). Operations should be performed to prevent the formation of aerosols (104, 114), e.g., use of closed containers during centrifugation, avoiding pressurized containers containing active toxin, and application of absorbent materials to spills prior to decontamination. Proper personal protective equipment must be used, including eye protection, gloves, and lab coats. Personnel who work with large concentrations of toxin (1.0 mg and/or high-toxin-producing cultures) should be immunized. Formerly, pentavalent (A through E) toxoid was available from the CDC, but it has been phased out and a heptavalent toxoid is under evaluation. A biosafety manual should be posted in the laboratory and should contain the proper emergency phone numbers and procedures for emergency response, spill control, and decontamination. When possible, culture and toxin handling and manipulation should be performed in a class II or III biological safety cabinet with appropriate respiratory protection. The use of needles and syringes for bioassays requires extreme caution. Beginning in 1997, *C. botulinum* cultures and toxins were included in a group of select agents whose transfer is controlled by the CDC and for which restricted and secure working areas are mandatory (11). To transfer select agents, both the laboratory and personnel sending and receiving cultures and

toxins must be registered with the USDA and/or CDC and exchange the appropriate approval forms through their biosafety offices. The laboratory and principal investigator should maintain excellent and frequent communication with the biosafety office and responsible official within the organization.

CONCLUDING COMMENTS

Botulism is a rare and yet potentially fatal disease and is of high importance in food safety. Botulism is a true toxemia, since BoNT is solely responsible for the disease. BoNT is the most poisonous toxin known to humankind, and prevention of its formation in foods is of paramount importance to the food industry. BoNTs are produced by *C. botulinum* and rare strains of *C. butyricum* and *C. baratii*. These clostridia produce highly resistant endospores that are distributed throughout the earth and contaminate many foods. Remarkable advances have been achieved during the past 2 decades in elucidating the biochemistry, structure, and pharmacological mechanisms of BoNTs. Structural and biochemical studies of these potent neurotoxins have provided much insight into the mechanisms of substrate catalysis, neurospecific binding, and trafficking of botulinal neurotoxin to their neuronal targets. These advances have contributed to the remarkable success in using BoNT as a pharmacological agent for the treatment of various neuronal diseases and may lead to improved vaccines and countermeasures. The availability of genomic sequences and bioinformatic analyses has revealed that the genes encoding BoNT are often present as mobile genetic elements (Table 18.4.), and their lateral gene transfer is potentially a new hazard for the food industry and medicine. The development of genetic tools such as efficient gene replacement techniques will be invaluable in elucidating pathogenic mechanisms of BoNTproducing clostridia and the development of inhibitors targeted to essential functions.

Considerable information is available regarding the microbiological features of botulinogenic clostridia and preservation and formulation strategies for their control in foods. Nonetheless, botulism continues to occur through the consumption of foods, and new technologies and research are needed to enhance control. Newer processing procedures such as pulsed electric fields, ohmic heating, high pressure, and high-intensity light and sound require careful evaluation before they are widely applied in the food industry. Predictive models combined with physiological and genomic information will be valuable resources in the control of *C. botulinum* and the formation of BoNTs. Research for control of BoNT-producing clostridia in food systems has contributed to fundamental and applied knowledge in the food industry, and *C. botulinum* and BoNT formation serve as an excellent model for enhancement of the safety of foods.

Research in my laboratory has been supported by the NIH, USDA, University of Wisconsin, and industry sponsors of the Food Research Institute, University of Wisconsin–Madison. I thank Marite Bradshaw for excellent assistance in preparing the manuscript. I am grateful to my laboratory personnel over the years and collaborators and mentors on various projects involving neurotoxigenic clostridia.

Clostridium perfringens

THE ORGANISM

Clostridium perfringens (Fig 19.1) belongs to the genus *Clostridium*, which comprises a diverse group of sporeforming bacteria that are unable to grow in the presence of oxygen. *C. perfringens* was first described as *Bacillus aerogenes* in 1892 and was later named *Clostridium welchii* (1). *C. perfringens* is a Gram-positive, nonmotile rod that forms large, regular, round, slightly opaque and shiny colonies on the surface of agar plates. Although this organism is an anaerobe, it is capable of growing at E_h (redox potential) values of +350 mV and reducing its environment to less than −400 mV. Most strains grow at an optimum temperature of 37 to 45°C, but they can also grow in the range of 15 to 50°C, with growth temperatures as low as 6°C (1).

This bacterium is the most prolific toxin-producing species within the clostridial group. The pathogenic potential of *C. perfringens* is facilitated by the production of more than 20 toxins and enzymes, which can be classified into four broad categories: membrane-damaging enzymes, pore-forming toxins, intracellular toxins, and hydrolytic enzymes. Fortunately, these toxins are not produced by all strains (2). *C. perfringens* produces various toxins that are associated with diseases. Alpha toxin (CPA) has phospholipase C and sphingomyelinase activity, and it affects host signaling. Beta toxin (CPB), epsilon toxin (ETX), perfringolysin O (PFO; also known as theta toxin), necrotic enteritis toxin B-like toxin (NetB), and enterotoxin (CPE) are pore-forming toxins. Iota toxin (ITX) is

an actin-specific ADP-ribosyltransferase and toxin. *C. perfringens* large cytotoxin (TpeL) is a Ras-specific monoglucosyltransferase (3).

The toxins lecithinase, hemolysins, hyaluronidase, collagenase, DNase, and amylase allow the bacterium to scavenge nutrients from the environment. The bacterium lacks the ability to produce 13 of the 20 essential amino acids; therefore, it obtains these amino acids by breaking down host tissue using its toxins and digestive enzymes.

Generation times for CPE-positive *C. perfringens* strains grown between 41 and 46°C can be less than 8 min when the organism is cultured in autoclaved ground beef (2). Experimentally obtained values for generation times at 43°C were as low as 8.7 and 6.3 min in thioglycolate broth for CPE^+ and CPE^- strains, respectively. For autoclaved ground beef, the shortest generation times (7.1 min and 9.2 min) were obtained at 41°C and 46°C for two CPE^+ strains, respectively. For CPE^- strains cultured in autoclaved ground beef, a generation time of 6.6 min was observed at 43°C (4). CPE and heat-resistant spores were produced at similar concentrations, but they were generated more quickly at 43°C than at 37°C (5). In addition, there is a direct relationship between spore heat resistance and sporulation temperature (6).

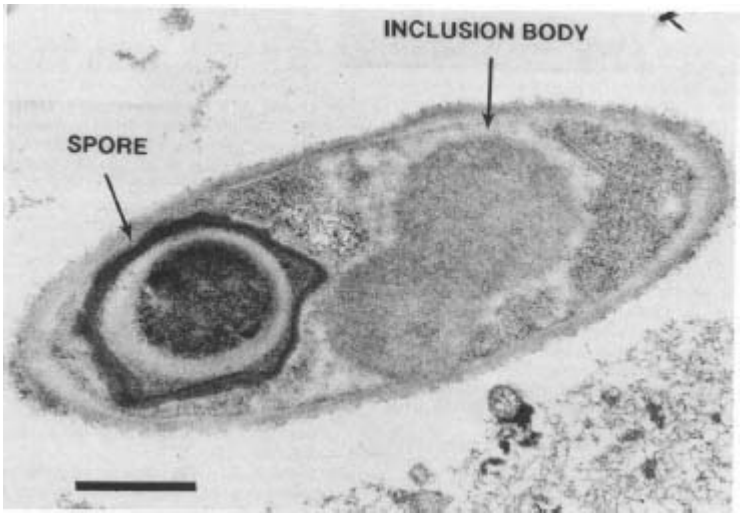

Figure 19.1 Electron micrograph of thin sections of *C. perfringens* FD-1041. Arrows indicate a spore and a CPE containing round inclusion body. Magnification, × 40,000. Bar, 0.5 μ. Reproduced with permission from reference 5.

C. perfringens causes several diseases, including gas gangrene (clostridial myonecrosis in infected wounds), food poisoning, antibiotic-associated diarrhea, enteritis necroticans (also called pigbel or Darmbrand; a serious enteric infection in humans), and other less severe diseases. Although the association of this organism with foodborne illness was first proposed approximately 100 years ago, it was not until the 1960s and 1970s that conclusive evidence accumulated showing that an enterotoxin is associated with the sporulation of *C. perfringens* in the intestines of affected individuals (2).

Various animal diseases are also caused by *C. perfringens* (type G in the new proposed toxinotyping scheme; CPA^+ $NetB^+$), including canine gastrointestinal disease and necrotic enteritis of poultry. The latter is an economically significant disease that has resulted in extremely high costs to the global poultry industry because of losses and control measures (7). *C. perfringens* type B (CPA^+ CPB^+ ETX^+) causes necrohemorrhagic enteritis in sheep (lamb dysentery), type C (CPA^+ CPB^+) causes necrotic enteritis in several neonatal animal species (horse, cattle, sheep, and pigs), type D (CPA^+ ETX^+) causes

enterotoxemia in sheep and goats, and type E (CPE^+ ITX^+) is suspected to cause gastrointestinal diseases in cattle, sheep, and rabbits (although this has not been confirmed) (7).

Classification

For many years *C. perfringens* was classified into five toxinotypes (A, B, C, D, and E) based on the production of four major toxins: CPA, CPB, ETX, and ITX (1). An updated toxinotyping system (Table 19.1.) based on the production of six major toxins (CPA, CPB, ETX, ITX, CPE, and NetB) has been proposed that incorporates two new toxinotypes (F and G). In this new proposed classification, *C. perfringens* type A strains are associated with gas gangrene but not with human food poisoning. *C. perfringens* type B, C, and D strains are mostly associated with enteric diseases in animals. *C. perfringens* type F consists of isolates that produce CPE but not CPB, ETX, or ITX and are responsible for *C. perfringens*-mediated human food poisoning and antibiotic-associated diarrhea. *C. perfringens* type G comprises isolates that produce NetB toxin and cause necrotic enteritis in chickens (8).

C. perfringens is a genetically diverse organism. The diverse nature of the *C. perfringens* pangenome likely stems from the fact that the organism prospers in multiple host species and environmental niches, interacting with many other bacterial species. Only a few bacterial studies have reported extreme pangenomic variation (9).

Ecology

C. perfringens is widely distributed in many environments, including soil, sewage, water, and the intestinal tract, and on almost every natural environmental surface examined thus far. The organism occurs in the intestine in both the vegetative and spore forms together with a complex mixture of microbes (10). Bacterial establishment in the neonatal gastrointestinal tract begins during birth when the neonate comes into contact with the maternal cervical and vaginal flora. Within 2 days after birth, *C. perfringens* is

found at higher numbers in newborns delivered by caesarean section. *C. perfringens* seems to be a precursor for the colonization of other anaerobic bacteria, such as *Bacteroides* and *Clostridium* spp. (11).

Table 19.1 *C. perfringens* toxin-based typing scheme based on the production of seven toxins[a]

			Presence of toxin[b]			
C. perfringens toxinotype	CPA	CPB	ETX	ITX	CPE	NetB
A	+++	–	–	–	–	–
B	+	++	+	–	–	–
C	+	++	–	–	±	–
D	+	–	++	–	±	–
E	+	–	–	+	±	–
F	+	–	–	–	+	–
G	+	–	–	–	–	+

[a]Modified from references 1 and 8.

[b]+, low production; ++, medium production; +++, high production; ±, some strains produce the toxin.

Heat-resistant spores of *C. perfringens* can survive in the environment for years (10). It is known that *C. perfringens* survives the longest in polluted waters and is, therefore, an excellent indicator of fecal contamination. The metabolic dormancy and resistance of bacterial spores to harsh environmental conditions are crucial to the ecological role of spores as survival structures (12).

VIRULENCE FACTORS

Signaling for Virulence through an Agr-Like QS System

C. perfringens strains encode a functional Agr-like quorumsensing (QS) system (referred to for simplicity as CpAL) that controls production of most *C. perfringens* toxins (13–15). CpAL also regulates sporulation (16) and formation of biofilm-like structures (17). As with several other QS systems, regulation of *C. perfringens* virulence factors via CpAL is mediated by population densityinduced autoinducer signaling molecules. At the structural and functional levels, CpAL is related to the Agr system from *Staphylococcus aureus* and other Grampositive organisms (13, 18). In *S. aureus*, the *agr* locus is a four-gene operon carrying in tandem the genes for a two-component system (TCS) comprising a transcriptional regulator (AgrA) and the membrane sensor (AgrC), the gene for the AgrD signaling peptide, and the gene encoding an AgrB transmembrane protein involved in AgrD processing (19) (Fig 19.2). Once secreted, extracellular AgrD binds to and activates AgrC, which then phosphorylates AgrA. In CpAL, the *agrB* and *agrD* genes are located in CPE1561 (strain 13 nomenclature) and within an intergenic region between CPE1561 and CPE1560, respectively (13, 18). Unlike the *S. aureus* Agr system, neither genes upstream nor downstream of *agrBD* in *C. perfringens* encode a TCS or are required to upregulate toxin gene transcription (13, 18).

Mechanistic Basis of CpAL Signaling

As mentioned, CpAL signals through a small secreted pheromone encoded by a short *agrD* gene, which is processed to a functional cyclic peptide by an integral transmembrane endopeptidase encoded by the *agrB* gene (Fig 19.2) (13, 18, 20). The pheromone is processed to an eight-amino-acid peptide containing a thiolactone ring, called 8-R. A linear version of this peptide, 8-L, was unable to activate production of *C. perfringens* CPB in a type C Δ*agrB* background (21). Further studies demonstrated that a pentameric peptide, containing only the thiolactone ring (5-R), was enough to activate signaling through CpAL to produce CPB in both type B and type C strains (22).

Figure 19.2 CpAL regulation of *C. perfringens* virulence factors (13, 15, 16, 18, 20–28, 36–40). CpAL is encoded by *agrD* and *agrB*, whose products are the AgrD signaling peptide (inset) and a transmembrane protein (AgrB) involved in its processing. The AgrD peptide is sensed by the membrane sensor (VirS), which in turn phosphorylates VirR, the response regulator. Upon CpAL activation, VirR directly upregulates transcription of several toxin genes or a small VR-RNA which ultimately activates expression of *plc* and *colA*. Whether VirR upregulates transcription of the CpAL operon is not clear.

In vitro studies have shown that CpAL regulates production of *C. perfringens* CPA, CPB, CPE, ETX, NetB, beta2 toxin (CPB2), and PFO in *C. perfringens* type A, B, C, and D strains. Regulation occurs at the transcription level (13, 15, 16, 18, 21). Two toxins that appear to escape from CpAL regulation, ETX and beta2 toxin, are produced by type B strains in which a mutation in genes encoding CpAL did not affect secretion of toxins into the supernatants (23).

A major role for CpAL in *C. perfringens* virulence was demonstrated using two animal models of necrotic enteritis. A rabbit ileal loop

model and a chicken necrotic enteritis model both showed that CpAL was required for full virulence and for production of CPB in the intestines of rabbits infected with a type C strain (21) or NetB in chicken infected with a type A (type G in the new toxinotype scheme) strain (15), respectively.

By the time when CpAL was discovered, it was well known that a TCS called VirSR was needed to regulate, at the transcriptional level, *in vitro* production of toxins and expression of several virulence genes, including the toxin genes *pfoA* and *cpa*, in type A strains (24–26). VirSR, where VirS is a membrane kinase and VirR is its cognate response regulator, was therefore the obvious candidate (18, 27–30). *virS* and *virR* form an operon (Fig 19.2) that is encoded by all sequenced *C. perfringens* toxigenic types (31–33). VirR can either bind to specific DNA sites via its C terminal DNA binding domain (34, 35) or regulate an RNA regulatory molecule, known as VR-RNA (VirSRregulated RNA), to regulate transcription (18, 36–38). Experiments demonstrated that the membrane sensor kinase, VirS, is activated by AgrD and this in turns activates the transcriptional regulator VirR (27, 28, 39, 40). As expected, both CpAL and VirSR are necessary for full virulence in animal models of *C. perfringens* necrotic enteritis (27, 41).

C. perfringens Toxins

C. perfringens produces several different toxins in various combinations. Besides the four well-known typing toxins, CPA, CPB, ETX, and ITX, this microorganism can produce a variety of other toxins of human and veterinary importance, such as PFO, CPE, and CPB2. The two toxins directly implicated in foodborne disease in humans are CPB and CPE, which are discussed below (42, 43).

CPB

CPB is a lethal toxin produced only by *C. perfringens* type B and type C isolates (44–46). Type B isolates cause an often fatal hemorrhagic dysentery in sheep, and possibly in other species,

while type C isolates cause enteritis necroticans in humans and enteritis and enterotoxemias in almost all livestock species. As a common trait, both type B and type C diseases are often accompanied by sudden death or acute neurological signs (46–49).

CPB mechanism of action

It was experimentally demonstrated that CPB is sufficient to cause type C pathology in a rabbit ileal loop model (44, 50). Type C disease has also been linked to endogenous trypsin deficiency or the presence, in the intestines, of trypsin inhibitors from the diet, as explained below. This results in persistency of CPB and maybe other toxins in the intestine (46, 50–52). CPB targets human endothelial cells, as evidenced by its presence in the lamina propria and submucosa in necrotic small-intestinal sections. CPB is also cytotoxic for *in vitro* human platelets, forming oligomers that result in a time-and dose-dependent death (53, 54).

Necrotizing enteritis in Papua New Guinea results from an increased consumption of a dish containing pork along with sweet potato containing trypsin inhibitors (called “kaw-kaw”) (46, 55). As CPB is highly sensitive to trypsin, the presence of trypsin inhibitors in the diet renders the innate response unable to inactivate CPB, allowing the intestinal colonization of type C bacteria, present in contaminated pork, with the subsequent intestinal damage caused by CPB (46, 50, 55). Prior to vaccination against this foodborne pathogen, which was undertaken in the 1980s, type C-induced necrotizing enteritis was the most prevalent cause of death in children over the age of 12 months in the highlands of Papua New Guinea (56, 57).

CPE

Characteristics of CPE

Nearly 5% of *C. perfringens* strains produce the toxin CPE (*C. perfringens* enterotoxin) (42). Evidence has been provided to link

CPE with *C. perfringens* type A (type F in the new proposed toxinotype scheme) foodborne illness. For example, there is a strong positive correlation between illness and the presence of CPE in feces, in contrast to the absence of CPE in feces of healthy individuals. CPE from the feces of food poisoning victims causes intestinal damage in animal experiments. Furthermore, when healthy volunteer adults were fed purified CPE, they developed the characteristic gastrointestinal symptoms, including diarrhea and cramping, of natural *C. perfringens* food poisoning (42, 58, 59).

CPE is a 319-amino-acid (~35-kDa) single polypeptide with a unique primary amino acid sequence. Although most CPE-producing stains belong to type A(F), some type C and type D strains carry the enterotoxin gene *cpe* and produce a CPE nearly identical to that of type A(F) strains (42, 45). The primary amino acid sequence of CPE is highly conserved among CPE-producing type A(F), C, and D strains, but a few type E strains carry a *cpe* gene variant that encodes a toxin with 10 amino acid differences (60, 61). Whereas the plasmid-borne *cpe* locus in type C isolates resembles that of type A(F) strains carrying *cpe* on the chromosome, in type D strains the chromosomal *cpe* locus contains two copies of an open reading frame likely encoding a transposase and thus presents substantial variation (60).

Molecular basis of CPE toxicity

As explained below, CPE is produced in sporulating cultures, and the toxin is released upon their lysis (62). Lysates from sporulating, but not vegetative, cultures of CPE-producing food poisoning strains cause gastrointestinal pathology, including unidirectional fluxes of sodium and Ca^{2+} and histopathological damage of the intestinal villi in animal models (63, 64). Sporulating lysates from a *cpe*-null mutant of a food poisoning strain failed to cause any intestinal pathology in animal models, while complementation reversed it to the wild-type phenotype (Fig 19.3) (65). In addition, physiologically relevant concentrations of highly purified CPE are sufficient to fully

recapitulate, in animal models, the gastrointestinal effects caused by sporulating culture lysates of CPE-producing type A(F) food poisoning strains (17, 18).

As briefly mentioned above, full-length CPE (~35 kDa) is cytotoxic for *in vitro* cultures of humans and animal cells (58, 66, 67). The first 44 amino acids of CPE, however, are not required for cytotoxicity (68, 69). These amino acids are not a signal peptide, as the toxin is not secreted but rather produced inside the spores and released upon lysis. Once CPE is released in the intestinal lumen, the toxin binds its receptor on enterocyte proteins that form the tight junction belt on epithelial and endothelial cells and belong to the family of claudins (58, 70). There are 27 different claudins; the topology of all claudins is similar, and they are composed of four transmembrane domains and two extracellular loops (ECL), named ECL-1 and ECL-2 (71). Whereas claudins 3 and 4 were initially identified as CPE receptors and have exhibited the highest affinity for the toxin, claudins 6, 7, 8, 9, 14 (55, 69–71), and 19 (71) also serve as receptors for CPE.

Regarding CPE, amino acids 290 to 319 are required for binding to claudins, while several residues, including Y306, Y310, Y312, and L315, are key for CPE to bind to its receptor (72, 73). On the other hand, the C-terminal half of claudins plays an essential role in CPE binding and action; this was elegantly demonstrated by using chimeric CPE-sensitive claudins expressed in fibroblasts (74). More recent studies by Robertson et al. (75) specifically mapped the CPE-binding region to the residue N149 of ECL-2 of claudin 4 (76).

After binding, CPE forms a small protein complex of ~90 kDa in plasma membranes of sensitive cells; this complex contains CPE and both receptor and nonreceptor claudins (42, 58). Formation of the small complex proceeds to oligomerization of the small complex to form a large complex of ~450 kDa that contains, besides receptor and nonreceptor claudins, CPE hexamers (76). The large complex is inserted into the membrane to form a pore, inducing cytotoxicity by permeabilizing the plasma membrane and allowing the influx of

Ca^{2+} into the cells, which triggers cell death (77–79). When low doses of toxin are incubated with sensitive host cells, CPE-induced Ca^{2+} influx can lead to apoptosis via activation of caspase-3, and at high doses of toxin, the massive Ca^{2+} influx produces a form of necrotic cell death (i.e., oncosis) (42, 80).

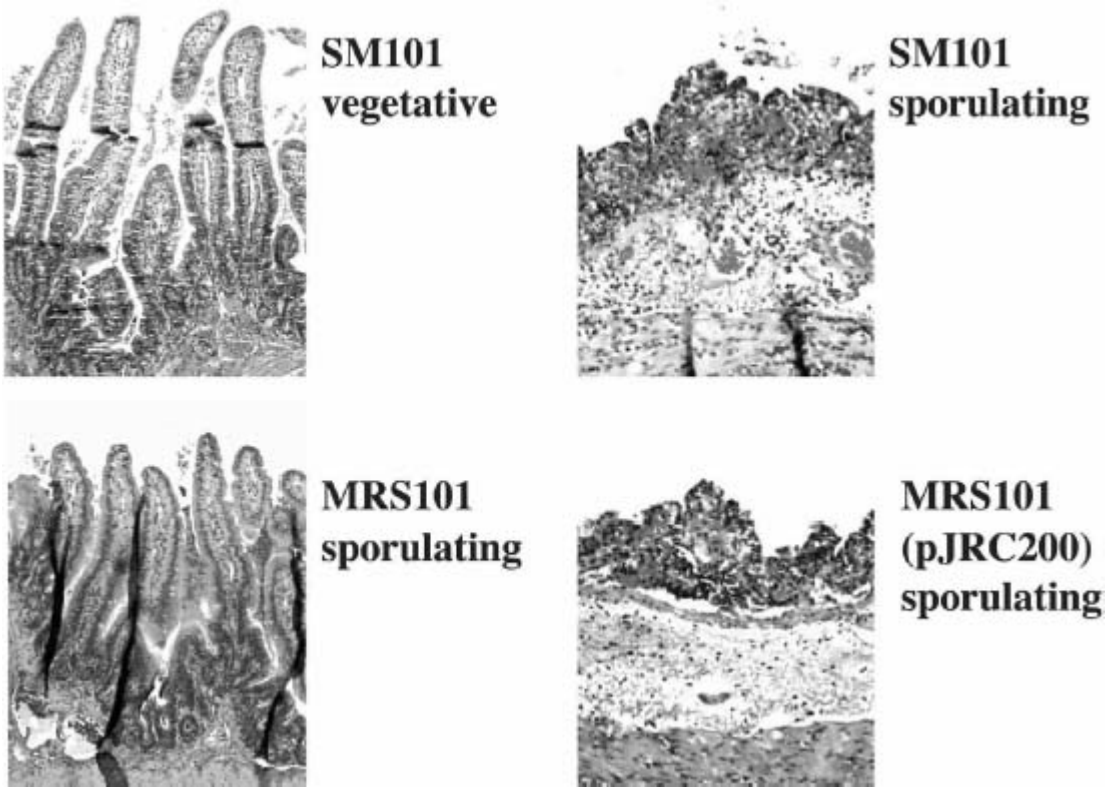

Figure 19.3 Histological damage is induced by *C. perfringens* lysates. Tissue specimens shown were collected from rabbit ileal loops treated with either concentrated vegetative (FTG) or concentrated sporulating (DS) culture lysates of *C. perfringens* wild-type, mutant, or complemented strains. Tissue specimens shown were treated with 50-fold-concentrated DS or FTG (as indicated) lysates of wild-type SM101, *cpe* knockout mutant MRS101, or complemented strain MRS101(pJRC200). Tissue specimens treated with 50-fold-concentrated FTG lysates prepared from either MRS101 or complemented strain MRS101(pJRC200) were indistinguishable from specimens treated with FTG lysates of SM101 (data not shown).

CPE causes histological damage to the human ileum epithelium which has been reproduced in different animal models (64, 81–86). A decrease in transepithelial resistance observed in cell culture models, including *ex vivo* cultures of human ileal cells, and fluid accumulation in rabbit ileal loops correlate with diarrhea observed in human volunteers fed up to 12 mg of CPE (59) and with clinical signs in patients who have suffered food poisoning where a mild and self-limiting diarrhea is observed (84).

Genetics of CPE

The CPE gene, *cpe*, is prevalent in <5% of *C. perfringens* strains, but these strains cause nearly 1 million cases of food poisoning cases every year in the United States (85). The CPE gene can be carried on the chromosome or on a large plasmid but has never been identified in both locations (i.e., in duplicate copies) (86, 87). There is an epidemiological correlation between the CPE-associated gastrointestinal disease and the genomic location of the *cpe* gene. Isolates carrying *cpe* on the chromosome have been linked to food poisoning cases, whereas isolates with plasmidborne *cpe* are strongly associated with antibiotic-associated diarrhea and sporadic diarrhea. Although *cpe*-positive type A(F) nonfoodborne human isolates and *cpe*-positive food poisoning isolates were found to produce similar amounts of spores and CPE, spores produced by food poisoning isolates are more resistant to low and high temperatures (explained in detail in "Sporulation" below) (58, 88).

Most *C. perfringens* type A(F) food poisoning isolates (~70%) that carry a copy of *cpe* on the chromosome have been associated with insertion sequences, including the IS*200*-like element IS*1469* and two copies of IS*1470* (a member of the IS*30* family) located upstream and downstream; the *cpe* gene, therefore, has been proposed to correspond to a 6.3-kb Tn*5565*-like transposon (89, 90). This putative transposon also includes open reading frame 3, located downstream of the *cpe* gene (89, 91). The remaining foodborne and nonfoodborne isolates carry the *cpe* gene on a large (70-to 75-kDa) plasmid that also includes the IS*1469* element and

IS*1470*-like elements along with a cytosine methylase gene (*dcm*) (92). The IS*1469*-like elements are present opposite to IS*1470*, which is found in foodborne type A(F) isolates carrying the *cpe* gene on the chromosome and appears to be defective (92). The prevalence of plasmid-borne *cpe*-positive isolates appears to be driven by vertical transmission rather than by transposition and recombination events which may occur in strains carrying a chromosomal *cpe* (42).

Synthesis and regulation of CPE

CPE is produced only during sporulation, resulting in a mature spore that, in food poisoning type A(F) isolates carrying *cpe* on the chromosome, is extremely resistant. Production of CPE is linked to sporulation, whose regulatory cascade is explained below (93, 94). During sporulation, chemical signs in the microenvironment, such as inorganic phosphate or bile salts, activate a master regulator of sporulation known as Spo0A. This regulator is also essential for formation of spores by several other C*lostridium* species and *Bacillus* species. Spo0A activates transcription of sigma factors, which in turn upregulate transcription of the *cpe* gene via three upstream promoters (95). The same promoters are present in the *cpe* gene whether it is plasmid borne or carried on the chromosome.

There are other regulators required for production of CPE, although the specific pathways have not been solved yet. Among them, for example, the catabolite control protein A (CcpA), which regulates utilization of carbon and nitrogen, is required for CPE production (96). CcpA regulation of sporulation does not appear to be linked to carbohydrate regulation, since the presence of glucose (5 mM) represses sporulation to the same extent in both a wild-type strain and an isogenic *ccpA* mutant (96). The CpAL QS system, found in most *C. perfringens* isolates whose genomes have been sequenced, is also involved in production of CPE and sporulation by upregulating transcription of genes encoding Spo0A and two sigma factors required to activate *cpe* transcription, SigF and SigE (16). Whether CpAL directly or indirectly upregulates *spo0A*

transcription remains to be elucidated. Another regulator, CodY, was recently linked to production of CPE and sporulation in type A(F) and type D strains (97, 98).

Sporulation

Sporulation is a long-term survival mechanism allowing the cells to survive until a more suitable environment is established (99). *C. perfringens*, like many other clostridia, initiates sporulation when unfavorable conditions (e.g., nutrient deprivation and changes in cell density) are encountered in the environment. Differentiation and spore morphogenesis are regulated by a fine mechanism involving transcriptional and posttranslational changes in several sigma factors, transcription factors, proteases, and phosphatases (100).

During sporulation, *C. perfringens* cells undergo significant morphological changes that can be divided into stages. In stage 0, bacteria experience vegetative reproduction by binary fission. Once bacteria enter sporulation in stage I, *C. perfringens* cells form an axial filament; the cells can revert to a vegetative state or continue the sporulation process. In stage II, cells initiate sporulation with asymmetric division of the cytoplasm membrane, where the asymmetric septum will become the endospore. This compartment is often termed the forespore, while the large compartment is called the mother cell. Stage III is engulfment, when the cells are fully committed to sporulation. Stage IV involves cortex formation, in stage V the deposition of spore coat proteins is observed, and in stage VI the endospore matures. Finally, the mother cell lyses in stage VII, releasing the spore into the environment (100, 101). Unlike other species, *C. perfringens* spores lack an exosporium, having instead a spore coat (101). The outer membrane is located immediately beneath the spore coat. The outer membrane is essential for spore formation.

Sporulation in *C. perfringens* requires inorganic phosphate (P_i). In the presence of P_i, the sigma factor Spo0A upregulates its

transcription, leading to spore formation. Unlike spores produced by nonpathogenic bacteria, *C. perfringens* spores not only are essential for survival in the environment but also contribute to pathogenicity, as sporulation leads to production of CPE, which is important for foodborne disease (101). During sporulation, Spo0A is phosphorylated, perhaps by orphan histidine kinases that have yet to be identified in *C. perfringens*. The phosphorylated form of Spo0A triggers transcriptional regulation of several genes involved in sporulation (101). In *Bacillus subtilis*, four sigma factors in addition to Spo0A are required for spore formation, named SigF (σ^F), SigE (σ^E), SigG (σ^G), and SigK (σ^K). *C. perfringens* carries genes encoding homologs of these four sporulation-associated sigma factors, and, as in *B. subtilis*, these sigma factors were found required for formation of mature spores in *C. perfringens*. Mutants carrying mutations in each gene were unable to sporulate, and the phenotype was rescued by genetic complementation (93, 94).

The CpAL system is required for sporulation at an early stage. An *agrB* mutant prepared in a spore-producing strain F5603 reduced sporulation by more than three orders of magnitude with concurrent reduction of Spo0A and SigF (16). The details of CpAL control of sporulation and CPE production remain to be determined.

Spore Resistance

Spores produced by *C. perfringens* are extremely resistant to conditions usually utilized in the food industry to reduce bacterial load, including exposure to low or high temperature, osmotic pressure, radiation, desiccation, chemical preservatives, and low or high pH (99, 101). For example, spores made by some strains remained viable after up to 60 min of incubation at a temperature of 100°C. Importantly, spores produced by some food poisoning isolates with chromosomally carried *cpe* survived for ~2 h in boiling temperatures (102, 103). Heat resistance appears to be an intrinsic mechanism of *C. perfringens* type A(F) strains carrying *cpe* on the

chromosome, which are associated with food poisoning, as it favors survival in incompletely cooked food.

Studies addressing the molecular basis of heat resistance of spores have concluded that it is influenced by both environmental factors and genetic factors. For example, food poisoning isolates that carry a chromosomal *cpe* gene were found to have a 60-fold-increased capacity to resist heat compared to *C. perfringens* isolates carrying a plasmid-borne *cpe* gene (103). Food poisoning isolates from the United Kingdom and Finland and strains from retail meats in Japan have shown a similar association between heat resistance and the presence of a chromosomal *cpe* gene (104–106). Therefore, rapid identification of isolates carrying the CPE gene and determination of its genomic location are important for outbreak investigation. As with the heat resistance phenotype, *C. perfringens* spores produced by isolates carrying a chromosomal *cpe* gene are considerably more cold resistant than vegetative cells or plasmid *cpe* isolates (107). The average log reduction of *cpe*-negative type A strains and isolates with plasmid-borne *cpe* was >3-fold greater than that of type A(F) strains carrying a *cpe* gene on the chromosome.

The extreme heat or cold resistance of type A(F) isolates carrying a chromosomal *cpe* gene is mediated by small acid-soluble protein 4 (SASP4). SASP4 is produced by most *C. perfringens* strains. Bioinformatics studies conducted by Li and McClane identified a SASP4 variant that contains an Asp at position 36 instead of Gly in *C. perfringens* strains producing heat-sensitive spores (108). This Asp36 variant of SASP4 binds more tightly to DNA, especially to AT-rich DNA, than Gly36 and was enough to confer heat, cold, and sodium nitrite resistance (108, 109).

Biofilm Formation

Biofilms are bacterial communities surrounded by a matrix which provides mechanical stability and mediates their adhesion to surfaces. The matrix ultimately forms a cohesive three-dimensional polymer network that protects bacteria from the host response and

antibiotics (110, 111). *C. perfringens* strains form biofilm-like structures on host tissues, epithelia, and abiotic surfaces (17, 112, 113). Biofilms are particularly important to food microbiology, as these structures allow bacteria to survive in the environment and thus to constitute a main source of food contamination (114). Recent studies demonstrated that most *C. perfringens* strains produced biofilm-like structures *in vitro* on abiotic surfaces such as glass and polystyrene (17, 112, 113). Moreover, *C. perfringens* biofilms have been harvested from different substrates, including steel, concrete, and polyvinyl chloride, thus representing a source of contamination of water for human consumption (112, 115, 116).

Evidence that *C. perfringens* Biofilms Are a Risk for Human Disease

A study in southern Africa reported that increased contamination of water was due to biofilms harboring heterotrophic bacteria, including coliforms and *C. perfringens* strains (117). In this study, authors found that mixed biofilms containing *C. perfringens* strains developed during the storage of water in containers prior to its distribution, rendering the water unsafe for human consumption (117). More evidence for the importance of *C. perfringens* biofilms was provided in a study conducted in Romania. Biofilms with a density of up to ~3.4×10^2 CFU/g were detected in their public water system. These *C. perfringens* biofilms were specifically isolated from steel and concrete walls in a clarifier (115). *C. perfringens* biofilms have been also isolated from wound tissues using a drip-flow reactor incubated for 7 days (118). The reactor was also utilized to simulate formation of multispecies biofilms, where a strain of *C. perfringens*, a strain of methicillin-resistant *S. aureus*, and a *Pseudomonas aeruginosa* isolate were inoculated and demonstrated to form mucoid biofilms with gas bubbles present throughout the biofilm structure. In this model, *C. perfringens* biofilms reached a density of ~1×10^7 CFU per membrane of drip-flow reactor (118).

Despite the interest in *C. perfringens* biofilms, we have limited information on antibiofilm approaches. A recent study by Charlebois and colleagues showed that potassium monopersulfate, quaternary ammonium chloride, hydrogen peroxide, and glutaraldehyde solutions reduced *C. perfringens* biofilms from a density of $>10^6$ CFU/ml to undetectable levels, including *C. perfringens* grown in dual-species biofilms with either *Escherichia coli* or *S. aureus* (119). These disinfectants are commonly used in farms and the food industry (120–122).

The *C. perfringens* Biofilm Matrix

As in biofilms produced by other pathogenic bacterial species, the matrix of *C. perfringens* biofilms is made of various proteins, including the hemolysins CPA and PFO, β-1,4-linked polysaccharides, and extracellular DNA (Fig 19.4) (17, 113, 123). Type IV pili are also required for biofilm formation; these pili are located on the biofilm matrix (112). More recently, Obana et al. (123) reported that biofilms formed at 37°C have an increased biomass and a phenotypically different biofilm matrix in comparison to those formed at 25°C. Furthermore, incubation at 37°C, but not at 25°C, upregulated levels of *pilA2* mRNA, which encodes the main pilin subunit of the matrix-associated *C. perfringens* type IV pilus (123). Moreover, chicken necrotic enteritis strain CP4 differentially regulated ~25% of its genome to adapt to changes at 44°C in biofilms, in contrast to planktonic bacteria (124). These data clearly indicate that *C. perfringens* biofilms are differentially regulated when they are produced at environmental temperatures versus that maintained in the human body. This was further clarified in a study conducted with QS mutants in a type A strain and a type C strain. QS CpAL mutants were not able to produce biofilms, and this was directly related to the downregulation, in the mutants compared to wild-type strains, of genes encoding the hemolysins CPA and PFO (17).

DISEASE

Food Poisoning

Symptoms associated with *C. perfringens* type A(F) food poisoning appear within 6 to 24 h and include stomach cramps and diarrhea. Although vomiting and nausea are uncommon in isolated cases, these symptoms have been reported during outbreaks of food poisoning (125–127). *C. perfringens* type A(F) *cpe*$^+$ isolates are the etiologic agents of food poisoning. As mentioned above, ~75% of type A(F) food poisoning cases are caused by isolates that carry the *cpe* gene on the chromosome, whereas the other ~25% are caused by strains carrying *cpe* on plasmids.

A typical pathogenesis cycle of *C. perfringens* type A(F) food poisoning is illustrated in Fig 19.5. Given that *C. perfringens* is ubiquitous, spores of *cpe*-positive *C. perfringens* type A(F) isolates can potentially contaminate food items at any given point of the food processing and serving chain at a variable density. Due to mishandling of food items from preparation through ingestion, along with the pathogenic properties of heat-resistant spores produced by type A(F) strains, the density of *C. perfringens* can reach ≥10^5 CFU/g of food; this infectious dose has been reported in suspected meals linked to food poisoning cases (126).

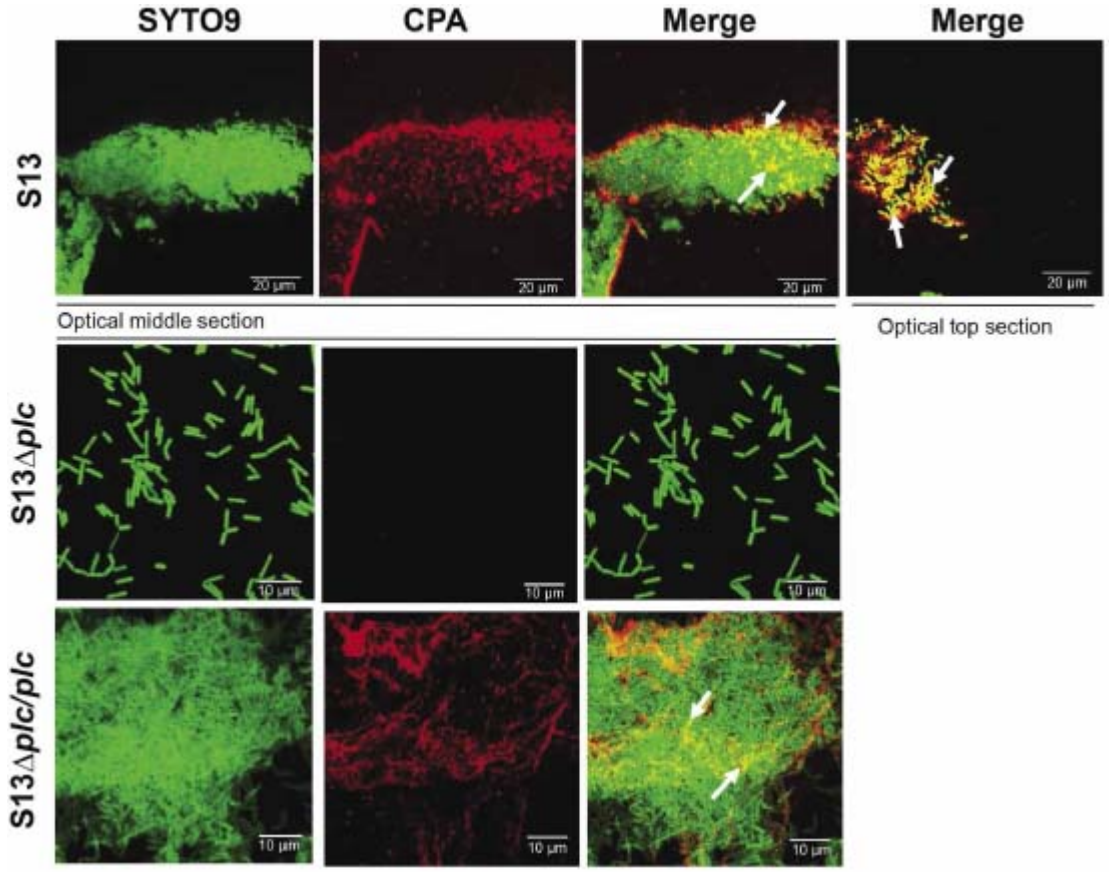

Figure 19.4 Detection of CPA on *C. perfringens* biofilms. Strain S13Δplc or S13Δplc/plc was inoculated into a four-well chamber slide containing tryptone glucose yeast extract, followed by incubation for 24 h at 37°C. Bacteria were stained with SYTO9, and CPA was detected using rabbit polyclonal anti-*C. perfringens* CPA antibodies, followed by goat anti-rabbit immunoglobulin secondary antibodies conjugated to Alexa Fluor 555. Optical middle and top sections were obtained with a confocal microscope. Arrows point to areas of colocalization.

Importantly, during outbreaks of food poisoning, the attack rate can be as high as 70% (126, 127). When food is undercooked (127), stored at abusive temperatures (126), or slowly cooled after cooking, bacteria can rapidly multiply until they are consumed with the contaminated food. Upon ingestion of *C. perfringens* vegetative cells, bacteria will probably die when exposed to stomach acidity. If the food vehicle, however, is contaminated with $>10^5$ *C. perfringens*

cells per g, some ingested bacteria survive the passage through the stomach and remain viable when entering the small intestine, where they multiply and sporulate. CPE is produced within these sporulating *C. perfringens* cells and is eventually released into the intestinal lumen, where the sporulating cells lyse to release their endospores. Once released, CPE quickly binds to intestinal epithelial cells and exerts its action, which induces intestinal tissue damage. This CPE-induced intestinal tissue damage initiates intestinal fluid loss, which clinically manifests as diarrhea.

Diarrhea, the hallmark of type A(F) food poisoning, is observed in nearly 100% of patients, whereas abdominal cramps occur in 95 to 70% of those who have eaten food contaminated with *cpe*$^+$ type A(F) strains. The onset of symptoms is generally observed within 10 h after ingestion of the contaminated food (125, 126). Because type A(F)-associated food poisoning requires bacteria to infect the intestines and then sporulate to cause the symptoms, the disease spontaneously resolves within 24 h after onset, likely because the toxin is expulsed from the intestines through diarrheic feces.

The largest outbreak of *C. perfringens* type A(F) food poisoning so far reported occurred in Washington State in 1978; in this outbreak, more than 500 people became ill after eating lobster Newburg at a restaurant (128). Fatalities due to type A(F) food poisoning are very rare, occurring in <0.03% of cases. Death usually is caused by dehydration and occurs among the very young, the elderly, and patients who have an immunodeficiency or are debilitated by illness. For example, there were reports of severe cases in patients from psychiatric hospitals in Oklahoma and Louisiana that were intoxicated with CPE and developed a severe form of food poisoning. These patients suffered secondary fecal impaction (i.e., constipation) due to drug therapy and therefore were unable to excrete CPE from the intestine, resulting in colonic perforation which in turn led to death (127, 129).

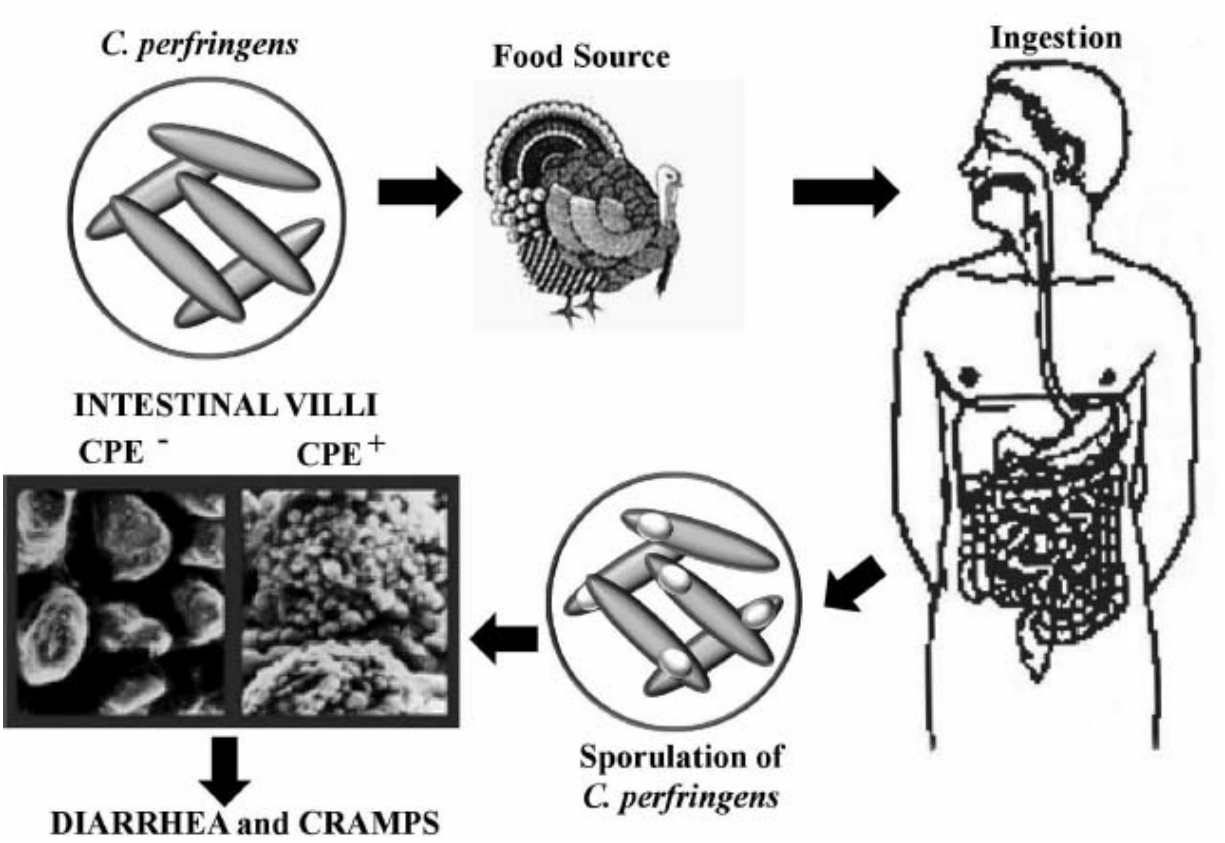

Figure 19.5 Pathogenesis of *C. perfringens* type A food poisoning. Vegetative cells of an enterotoxin (CPE)-producing *C. perfringens* strain multiply rapidly in contaminated food (usually a meat or poultry product) and, after ingestion, sporulate in the small intestine. Sporulated *C. perfringens* cells then produce CPE, which is released at the completion of sporulation, when the mother cell lyses to release its endospore. CPE then causes morphologic damage to the small intestine, resulting in diarrhea and abdominal cramps. Modified and reproduced with permission from reference 236.

The two most common symptoms of type A(F) food poisoning, diarrhea and cramps, correlate with the physiopathology induced by CPE in the intestines. Studies have clearly documented that electrolyte and fluid loss (i.e., diarrhea) is observed only with a dose of CPE high enough to cause intestinal damage. Cytotoxic damage, with fluid accumulation, in the intestinal epithelium has been reproduced in different animal models, although the most common is a rabbit intestinal model (64, 81–83). In rabbits, CPE-induced

intestinal damage includes villous shortening, along with epithelial necrosis and desquamation. CPE affects mainly the mucosa of the jejunum and ileum, with less damage of the duodenum; the colon is also sensitive to purified CPE, where it causes fluid accumulation, necrosis, and hemorrhage (43, 83). Several lines of evidence indicate that CPE-induced intestinal damage appears to be an important, if not essential, contributor to fluid and electrolyte secretion and therefore diarrhea. For example, in rabbit small-intestinal loops, a close temporal association exists between the onset of CPE-induced histologic damage and the start of fluid and electrolyte loss.

Other Human Diseases

Besides food poisoning, *C. perfringens* strains cause other diseases of biomedical importance, including human and animal myonecrosis (gas gangrene), nonfoodborne gastrointestinal disease, canine gastrointestinal disease, and necrotic enteritis in poultry. For example, type B strains can cause necrohemorrhagic enteritis in sheep (lamb dysentery), whereas type C isolates cause human necrotic enteritis (also called enteritis necroticans or pigbel) and necrotic enteritis in neonates of several animal species (horse, cattle, sheep, and pigs). Type D produces CPA and ETX, and it causes enterotoxemia in sheep and goats. Type E produces CPE and ITX. Although it has no known association with any human disease, it is suspected to be associated with gastrointestinal diseases in cattle, sheep, and rabbits. All types of *C. perfringens* may also produce several other toxins, including (but not limited to) CPB2, PFO, and TpeL (7).

Antibiotic-Associated Diarrhea

Although *C. perfringens* is not a major inhabitant of the intestinal flora, fecal carriage of enterotoxigenic strains appears to be important in the development of infectious diarrhea. The disease occurs in patients undergoing prolonged antibiotic therapy, which disrupts the stable intestinal microbiota and provokes an

overgrowth of enterotoxigenic strains. The average duration of infectious diarrhea is 11 days, and the elderly are most susceptible. Some studies report that *C. perfringens* is responsible for 10 to 15% of all cases of antibiotic-associated diarrhea (130, 131).

Gas Gangrene (Clostridial Myonecrosis)

C. perfringens cannot synthesize various amino acids because it lacks many genes related to amino acid biosynthesis. When infecting an organism, *C. perfringens* degrades host tissues to obtain nutrients for growth. During this process, *C. perfringens* produces abundant gas, which makes the conditions more suitable for further growth (20).

C. perfringens type A causes gas gangrene, which is an acute, rapidly progressive histotoxic infection in humans and animals that affects muscle tissue. It also causes infections of the fascia and skin, which are characterized by marked tissue destruction, sepsis, and massive tissue death. It develops after tissue injury or in patients suffering from various illnesses, such as diabetes or colon cancer. In these cases, vegetative cells or germinated spores of *C. perfringens* grow rapidly, invading and killing tissues, in addition to producing gas that causes an anoxic environment with reduced blood flow. This ultimately reduces the efficacy of antibiotic therapy. CPA and PFO, whose genes are carried on the chromosome, are essential for the development of gangrene. They act synergistically to provide essential nutrients to the microbe (7). The Agr-like QS system and the VirS/VirR system regulate the production of both toxins. However, PFO expression is directly modulated by the VirR response regulator, whereas CPA production is controlled by the VirR-regulated VR-RNA molecule (38).

Enteritis Necroticans

C. perfringens type C causes enteritis necroticans in humans, which is characterized by abdominal cramps, shock, bloody diarrhea, acute inflammation, and a pronounced necrosis of the intestinal mucosa

(132, 133). The disease is a life-threatening necrotizing infection of the jejunum and ileum. A high mortality rate is observed if the disease is not diagnosed early and treated with antibiotics. Infected persons can suffer from toxemia and segmental necrotizing enteritis, which is visible in the small intestines. This requires surgical excision of the necrotic small bowel and antibiotic treatment (2, 134). Necrosis of the intestinal epithelium always coincides with the presence of Gram-positive rods, characteristic of *C. perfringens*, attached to the surface of the necrotic mucosa, forming a biofilm-like structure (135, 136). CPB, the most important toxin for developing enteritis necroticans (50, 134, 137), is found underneath the attached bacteria, indicating that *in situ* production of this toxin is important for pathogenesis (136).

The disease was called Darmbrand ("fire bowels") during outbreaks in Germany following World War II. It is also called pigbel because of its association with the pig feasts of the aboriginal people in Papua New Guinea, which include huge quantities of sweet potatoes and inadequately cooked pork contaminated with pig intestines (138). Other foods associated with type C disease include poorly preserved pork sausage (139), turkey sausage (140), pork (132, 135), chicken stew, salmon, and crab (136).

Enteritis necroticans is particularly aggressive in diabetics and immunocompromised patients in developed countries (they survive less than 48 h after the onset of symptoms) (84, 132, 135, 136, 139, 140). Malnourishment, protein deprivation, poor food hygiene, uncooked food containing trypsin inhibitors, and pancreatic disorders are risk factors for developing this disease. Epidemiological studies have indicated that this disease accounted for 10% of all deaths and 50% of deaths in children between 6 and 10 years of age in Papua New Guinea. However, since 1980, immunization with a *C. perfringens* type C toxoid has reduced mortality and morbidity dramatically. Improved nutrition has provided proteolytic protection against CPB, making immunization unnecessary (138, 140).

The disease occurs sporadically in parts of Asia, Africa, and the South Pacific, where it primarily affects children with severe protein malnutrition. Although less common, this disease also occurs in developed countries, where it has been seen primarily in diabetics (138).

CONTAMINATION OF AND GROWTH ON FOODS

C. perfringens contaminates food at a variety of points in production and processing. Foods rich in protein are ideal for this organism. *C. perfringens* requires amino acids and several vitamins for its growth, which are typically present in meat. Of the 144 outbreaks caused by *C. perfringens* in the United States from 1998 to 2010, beef was the most commonly contaminated product (66 outbreaks; 46%), followed by poultry (43 outbreaks; 30%) and pork (23 outbreaks; 16%). Meat-and poultry-related outbreaks accounted for 92% of outbreaks that involved an identified single food commodity (84).

The following sections contain data regarding the detection of *C. perfringens* in a wide variety of foods all over the world. These sections also discuss the ability of this organism to thrive in a diversity of environments and nutrient conditions.

Meats

Animal carcasses and cuts of meat can become contaminated with *C. perfringens* following contact with soil or animal feces. Contamination can also occur during slaughtering and processing. Beef and beef products have been the most commonly contaminated food causing *C. perfringens* infection outbreaks in various countries, suggesting that beef is the primary source of *C. perfringens* infection in cases of foodborne poisoning in humans.

C. perfringens was found in beef from four types of markets in Seoul from June to September 2015. Eightytwo beef samples were

collected from six department stores (n = 12), 14 butcher shops (n = 28), 16 traditional markets (n = 32), and five supermarkets (n = 10). Beef samples from the department stores had the highest prevalence of *C. perfringens* (16.67%), followed by the butcher shops (3.57%) and traditional markets (3.12%); *C. perfringens* strains were not isolated from samples collected at a supermarket (0%) ($P > 0.05$). All isolates were type A, and they were negative for the CPE gene. For *C. perfringens* detection, a standard culture method and real-time PCR assay were used, and the authors concluded that the real-time PCR assay was useful for rapid detection and screening of this pathogen in beef (141).

The presence of *C. perfringens* was assayed in 300 meat samples in Turkey. *C. perfringens* strains were isolated from 95 (31.7%) samples. Of the 95 *C. perfringens* isolates, 40 (40%), 31 (31%), and 24 (24%) were isolated from beef, chicken, and turkey samples, respectively. The *cpa* gene was detected in all *C. perfringens* isolates by PCR. Furthermore, 84 of 95 *C. perfringens* isolates were type A, while two expressed both the *cpa* and *cpe* genes [type A(F)-cpe], and eight (five from beef, two from chicken meat, and one from turkey meat) expressed the *cpa* and *cpb2* genes (type A-cpb2). None of the strains expressed both the *cpe* and *cpb2* genes. *cpe*-positive *C. perfringens* type A(F) was isolated from one beef sample (1%) and one (1%) chicken sample. Also, of the 95 *C. perfringens* isolates, six, three, and two were genotyped as type C, type D, and type E, respectively. One of the six type C strains and one of the three type D strains were positive for the *cpb2* gene (142).

To evaluate the ability of *C. perfringens* to survive in Korean traditional seasoned beef rib prepared sous vide (galbi-jjim), spores of this organism were inoculated into the samples, and then germination and growth of the spores were assayed at different temperatures for several days. Processed samples were stored for 24 days at 4 and 10°C and for 4 days at 20°C. To evaluate the effect of temperature abuse, samples stored at 4°C for 6, 12, and 18 days were transferred to 10°C and stored for an additional 6 days. The samples originally stored at 4°C for 6 days were also transferred to 20°C and

stored for 1 day. The results indicated that there was no difference in the water activity or pH of the samples during storage at any temperature. However, the salt content of the samples significantly increased as storage time increased, and storage temperature affected the salt content. *C. perfringens* did not grow at 4°C or 10°C for 24 days; however, bacterial growth was detected at 20°C after 2 days of storage (143).

In the United States, a total of 445 whole-muscle and ground or emulsified raw pork, beef, and chicken product mixtures acquired from industry sources were analyzed over a 10-month period for *C. perfringens*. Samples that were positive after a 15-min heat shock at 75°C were considered presumptively positive for spores. Of the 194 cured whole-muscle samples, 1.6% were positive for the microorganism, but spores were not detected in those samples. Populations of vegetative cells did not exceed 1.70 $\log_{10}$ CFU/g, and they averaged 1.56 $\log_{10}$ CFU/g. Of the 152 cured ground or emulsified samples, 48.7% and 5.3% were positive for spores, respectively. Populations of vegetative cells did not exceed 2.72 $\log_{10}$ CFU/g, and they averaged 1.98 $\log_{10}$ CFU/g. Spores did not exceed 2.00 $\log_{10}$ CFU/g, and they averaged 1.56 $\log_{10}$ CFU/g (144).

The presence of *C. perfringens* in chicken meat parts (breast, wing, drumstick, and leg quarters) from Turkey and the expression of the *cpa, cpb, etx, iA, cpe*, and *cpb2* toxin genes in the isolates were determined. Two hundred samples of raw chicken breasts (n = 50), wings (n = 50), drumsticks (n = 50), and leg quarters (n = 50) were collected from various retail stores. Forty-seven (94%) wing samples, 40 (80%) leg quarter samples, 34 (66%) drumstick samples, and 33 (66%) breast samples were contaminated with *C. perfringens*. Furthermore, 558 isolates were identified as *C. perfringens*. Of these, 545 (97.6%) carried only the *cpa* toxin gene (type A), 12 (2.1%) carried both the *cpa* and *cpb2* toxin genes (type A-cpb2), and one (0.1%) carried both the *cpa* and *cpe* toxin genes [type A(F)-cpe] (145).

Pâté is a food prepared from a minced mixture of offal (particularly liver), muscle, fat, vegetables, herbs, and spices. Products from different animal species are used in pâté production. This mainly includes pigs or poultry (e.g., chickens and ducks), although fish and shellfish can also be used. A study investigated the microbiological quality of liver pâté in England. From 2012 to 2013, a total of 870 samples unrelated to the investigation of food poisoning outbreaks were collected either at retail (46%), during catering (53%), or at the point of manufacture (1%). Of the 870 samples collected, *C. perfringens* was present at a satisfactory level (<10 CFU/g) in 868 samples (99%) and at a borderline level (≥10 to 10^4 CFU/g) in only two samples. The bacterium was not present at unsatisfactory levels (≥10^4 CFU/g) in any samples. There was no evidence of differences in the distributions of *C. perfringens* between samples collected at retail and those from catering events (146).

The prevalence and molecular characterization of *C. perfringens* in edible offal of broiler in Ankara, Turkey, were determined. A total of 90 samples, including 45 hearts and livers and 45 gizzards, were obtained from different supermarkets. Twenty-one (46.7%) of the 45 hearts and livers and eight (17.7%) of the 45 gizzards were contaminated with *C. perfringens*. All isolates expressed the *cpa* gene, and none were positive for the *cpe* gene. Only two gizzard isolates were positive for the *cpb2* gene (147).

Fish and Seafood

Seafood-borne pathogenic bacteria can be grouped based upon their ecology and origin based upon whether they are (i) indigenous to an aquatic environment and naturally present in fish, (ii) indigenous to multiple environments and frequently found on seafood, or (iii) found on the outer and inner surfaces of diseased or asymptomatic animal or human carriers (148). The second group includes *Listeria monocytogenes*, *Clostridium botulinum* (proteolytic types A and B),

C. perfringens (type A from soil and types B, C, and D from animals), and *Bacillus* spp. (149).

C. perfringens can be isolated from seafood, but there appear to be no systematic data concerning its incidence. Although fish are less commonly involved in *C. perfringens* food poisoning outbreaks (1), the organism has been determined to be the cause of outbreaks of food poisoning after the consumption of boiled salmon and tuna salad. Seafood has also been involved in two *C. perfringens* outbreaks reported in Spain from 1993 to 1998 (150). *C. perfringens* was confirmed in 17 (5%) of 347 fresh and processed retail seafood samples in the United States. Bacteria were found at an abundance corresponding to a most probable number of 3.6 to 240 per g, and only one of the *C. perfringens* isolates possessed the CPE gene, as determined by PCR (151).

Although various authors have argued that *C. perfringens* contaminates fish and shellfish during processing, Rahmati and Labbe (151) and Oka et al. (152) detected the organism on the body surfaces and in the alimentary canals of several fish species (153). Enterotoxigenic *C. perfringens* was detected in freshwater fish, marine fish, and marine shellfish in southern Hokkaido. This organism was detected in 31.1% (19/61) of isolates from the intestinal tracts of freshwater fish and in 14.8% (8/54) of isolates from the intestinal tracts of marine fish. In addition, 6.3% (4/63) of the isolates from marine shellfish were also enterotoxigenic (152). Other studies indicated that *C. perfringens* was more frequently detected on the external surfaces of fish rather than in the intestinal contents, regardless of whether fresh fish were collected from aquaculture ponds or from markets in Egypt. No significant differences were found in the contents of the intestinal tract between fish from aquaculture ponds (9.1% of positive samples) and those from markets (6.7% of positive samples). Furthermore, a higher percentage of fish collected from markets (45.6%) had *C. perfringens* on the external surface than of those from aquaculture ponds (31.8%). When the hands of handlers, aquaculture water, and water tanks in markets were analyzed, *C. perfringens* was found in

63% of samples taken from the handlers' hands and 27.3% of samples from the water, suggesting that hands may be the primary contaminating factor. Multiplexed PCR indicated that CPE-negative *C. perfringens* type A was the predominant isolate, although types C and E were also detected (154).

When *C. perfringens* was inoculated into fish fillets of jack mackerel and subsequently packaged under an air or a controlled CO_2 atmosphere (40% CO_2–60% N_2) followed by incubation at 15°C and 30°C, the bacteria were unable to grow at the lower temperature during the 3 days of storage. However, all samples were spoiled. Interestingly, *C. perfringens* rapidly grew after a 2-to 4-h lag phase at 30°C (abuse temperature) regardless of the package type, but growth was significantly faster under the controlled atmosphere within 6 h of storage (155). No growth of *C. perfringens* was detected in these foods when they were incubated at 5°C in air or under a controlled atmosphere for 6 days (156).

Although *C. perfringens* has been reported to be a potentially important histamine producer in suboptimal temperatures under anaerobic conditions, a study indicated that histamine production by *C. perfringens* in scombrotoxin-forming fish was minimal compared to that of Gram-negative histamine-producing bacteria. Thus, *C. perfringens* may not be significantly associated with scombrotoxin fish poisoning (157).

Spices

Culinary herbs and spices are minor food components that have widespread use. Their low water activity is not a barrier to the survival of some spore-forming microorganisms, including *C. perfringens* (158). Studies in different countries of the microbiology of herbs and spices have demonstrated the presence of important foodborne bacteria and toxigenic molds, including *Salmonella, E. coli*, *C. perfringens*, *Bacillus cereus*, and aflatoxigenic *Aspergillus* (159). The addition of microbially contaminated herbs and spices to

ready-to-eat foods in combination with improper food storage can pose a serious health risk to the consumer.

Several foodborne disease outbreaks have been associated with microbially contaminated spices. These foods are thought to have been contaminated with spores of CPE$^+$ *C. perfringens* as a result of the addition of spices. Because of its spore-forming ability and rapid generation time, improper heating, cooling, and holding conditions can lead to elevated levels of *C. perfringens* in foods, which can subsequently cause a foodborne disease (158).

Various studies have been conducted in many parts of the world to determine the presence of *C. perfringens* in spices. Three hundred eighty samples of spices and herbs (cumin seeds, black pepper, oregano, garlic powder, and bay leaves) widely used in Mexico were analyzed for the presence of *C. perfringens*, while the potential enterotoxigenicity of the isolates was determined by detecting *cpe* using a dot blot technique. The spices were stored in three different commercial presentations (polyethylene bag, glass container, and nonpackaged) and were purchased from retail markets in Monterrey, Mexico. *C. perfringens* counts varied from <100 to 500 CFU/g in garlic powder, from <100 to 200 CFU/g in black pepper, from <100 to 433 CFU/g in cumin seed, from <100 to 340 CFU/g in oregano, and from <100 to 450 CFU/g in bay leaves. Significant differences in the extent of contamination were observed among the three different commercial presentations. Nonpackaged samples of garlic powder, cumin seed, and oregano were more extensively contaminated than those packaged in polyethylene bags, perhaps because of sanitary deficiencies during collection, storage, transportation, packaging, and sale. No detectable contamination by *C. perfringens* was found in the 30 samples stored in glass containers, probably because of a pretreatment of the spices. The dot blot technique detected the *cpe* gene in eight (4.25%) of 188 confirmed isolates of *C. perfringens* (160).

The abundance and characteristics of the spores of *C. perfringens* from 247 samples of spices in U.S. retail were determined. Forty-

three confirmed isolates from 17% of the samples were observed. The microorganism was present at levels ranging from 3.6 to 2,400 CFU/g. Twenty-seven (63%) of the *C. perfringens* isolates were positive for the *cpe* gene. Seven random spice isolates produced CPE at levels between 4 and 16 ng/ml, which were lower than the levels produced by each of three outbreak (control) strains, which were >1,024 ng/ml. Five of the 43 isolates expressed *etx* as well as *cpe* (158).

Other Foods

C. perfringens has been isolated from milk and milk products in India. A study revealed that of the 55 milk (cow) and milk products sampled, isolates were recovered from 11 (20%). Of these, 10 were isolated from raw milk, and the remaining one was obtained from paneer. All of the isolates were found to be type A based on the expression of the *cpa* gene. One of the isolates was positive for the *cpe* gene (161). Other surveys indicated an incidence (percent positive samples) of *C. perfringens* in raw milk of 1.4% (Normandy, France) and 9.3% (various raw-milk surveys, 1990 to 1995) (162).

The contamination of cereals, vegetables, and fruits by spores of pathogenic bacteria present in the soil (such as *C. perfringens*) is not uncommon. Bacterial pathogens that cause disease by contaminating cereal grains and cereal products include *C. perfringens* (163). However, this microorganism is usually of concern only when produce is handled under conditions that enable germination of the spores and growth of the vegetative cells.

In a study conducted in Mexico, the microbial contamination of 300 fresh produce samples from six different products (green onions, parsley, tomatoes, serrano peppers, jalapeño peppers, and cantaloupe) in retail stores was assessed. Fifty samples of each item were obtained, including 25 from popular markets and 25 from supermarkets. *C. perfringens* was detected in only six samples of parsley (2% of the total and 20% of the parsley samples). However, PCR did not detect any CPE genes in the isolates (164). *C.*

perfringens in contaminated refried beans in Mexican food has been associated with foodborne outbreaks in the United States (165).

Factors Contributing to Growth and Survival

Various physical, chemical, and biological factors contribute to the growth of *C. perfringens* in food. The optimal growth temperature of this organism is 43 to 46°C, resulting in generation times as short as 7.1 min. The ability to grow quickly in foods allows the bacteria to reach an abundance necessary to cause food poisoning. The microorganism can grow at temperatures ranging from 12 to 50°C, and spores can survive at even higher temperatures. However, *C. perfringens* is unusually sensitive to refrigeration and freezing. At temperatures below 10°C, no growth is detected, although some strains grow in food maintained at 12°C. During cooking or processing of foods, many organisms that compete with *C. perfringens* are killed. However, the spores of this microorganism can be difficult to eliminate. Instead, they can be heat activated, facilitating germination when temperatures become favorable for growth. Furthermore, during cooking, E_h values drop, favoring the growth of *C. perfringens* (1).

It has been shown that the thermotolerance of vegetative cells and spores increases as the incubation temperature of the culture is raised. Heat-shocked cells of *C. perfringens* are more heat tolerant than controls. It has also been demonstrated that vegetative cells and spores can survive various cooking procedures (166). At 55°C, the vegetative cells of chromosomal-*cpe* isolates are twice as resistant as isolates expressing the *cpe* gene from a plasmid. Furthermore, cells expressing the chromosomal *cpe* gene produce spores that are 60-fold more heat resistant than those of cells expressing the *cpe* gene from a plasmid (42). $D_{95°C}$ values (i.e., the time needed to reduce the population by 1 log at 95°C) of 1.0 to 3.3 min for spores from four randomly selected spice isolates suggest the presence of a plasmid-expressed *cpe* gene, while one isolate had a $D_{95°C}$ (>45 min) consistent with a chromosomal *cpe* gene (158).

Heat-resistant chromosomal-*cpe* strains showed less growth potential in vacuum-packed ground beef stored at 12°C than the plasmidic-*cpe* and *cpe*-negative strains. Meanwhile, no significant differences were observed at 25°C. These results suggest that the latter strains may have a competitive advantage over chromosomal-*cpe* strains at reduced temperatures during food storage that supports the growth of *C. perfringens* (167). Isolates of *C. perfringens* that grow, sporulate, and produce more heat-resistant vegetative cells and spores that are capable of growth over a wide range of temperatures would be of major concern. This could constitute a major source of food poisoning and other diseases (166).

The use of water-depressing solutes other than salt affects minimal a_w (water activity) levels during the growth of *C. perfringens*. For example, this bacterium grows at an a_w of 0.97 to 0.95 in laboratory media in which a_w is adjusted using sucrose or sodium chloride and at 0.93 in media adjusted with glycerol. Growth at low temperatures allows *C. perfringens* to respond by reducing fatty acid chain lengths rather than increasing unsaturated fatty acids (168).

The ability of *C. perfringens* to produce a biofilm protects the bacterium from exposure to atmospheric oxygen and high concentrations of antibiotics or other agents (124). It has been suggested that an extracellular polysaccharide matrix of biofilm could play a major role in the initial attachment of *C. perfringens* to chicken intestinal cells, and this could be linked to the persistence of the bacterium in chickens' intestines despite antibiotic treatment of the environment (124).

Predictive Modeling of Growth in Foods

Microbial pathogen computer modeling programs can be valuable analytical tools, helping develop critical limits and evaluate the relative severity of problems caused by process deviations (169). Accordingly, predictive microbial models for *C. perfringens* growth from spores have been developed to estimate growth during the

cooling of cooked or heat-treated meat and poultry products (i.e., under nonisothermal conditions or in continuously varying temperature). These cooling models are the tools most commonly used by regulatory agencies and the meat and poultry industry when evaluating the risk of *C. perfringens* growth during cooling (stabilization) deviations, which can occur because of malfunctions in refrigeration equipment or electrical outages. The models are also used by meat processors to develop customized or alternative cooling methods when they cannot follow the stabilization compliance guidelines for the cooling of cooked or heat-treated meat and poultry products issued by the Food Safety and Inspection Service of the U.S. Department of Agriculture (USDA FSIS).

Juneja et al. (170) provided the first critical assessment of the effect of cooling rates on the outgrowth of *C. perfringens*, which demonstrated the effectiveness and validity of the square root model under nonisothermal conditions. This work also established the safe cooling rate for cooked beef. A number of cooling models have been developed that take into account the effect of temperature in order to predict the relative growth of *C. perfringens* from spores at temperatures relevant to the cooling of cooked meat products (171–189). Amézquita et al. (171) developed an integrated model for the heat transfer phenomenon and dynamics of *C. perfringens* growth during the cooling of cooked boneless cured ham. To take into account other environmental factors, Le Marc et al. (190) developed a dynamic model for the effects of temperature, pH, and NaCl concentration on the growth of *C. perfringens* during the cooling of bulk meat.

Another dynamic model for the growth of *C. perfringens* spores during the cooling of cooked beef in the presence of NaCl (0 to 3% [wt/wt]), sodium pyrophosphate (0 to 0.3% [wt/wt]), and sodium nitrite (0 or 200 ppm [wt/wt]) as controlling factors was developed (191). Predictive models for *C. perfringens* growth from spores related to the cooling of cooked pea soup (192), refried beans (165), and rice (193) have also been published. Fazil et al. (194) conducted a probabilistic analysis of the growth of *C. perfringens* during food

service operation and reported that hot holding is the most critical step for the growth of this pathogen. However, growth during inadequate chilling occurs more frequently. In a study by Juneja et al. (195), the effects and interaction of NaCl, pH, sodium pyrophosphate, and temperature were assessed in order to develop quadratic and cubic models that could be used to predict the behavior of *C. perfringens* vegetative cells. This latter study suggested that sodium pyrophosphate exhibits bacteriostatic activity against *C. perfringens*, particularly when used in combination with low pH, high NaCl concentrations, and adequate refrigeration.

The published models have been incorporated into user-friendly computer programs (e.g., the USDA Pathogen Modeling Program [PMP]). Mohr et al. (196) evaluated the relative performance of six cooling models (the PMP 7.0 broth model; Predictive Microbiology Information Portal [PMIP] uncured beef, chicken, and pork models; Smith-Schaffner [version 3]; and the United Kingdom Institute of Food Research's ComBase Perfringens Predictor) for predicting *C. perfringens* growth using 188 datasets that represented various single-rate and dual-rate exponential cooling conditions, in addition to the extended chilling of cooked meat, uncured meat, and poultry products. The performance of the models was evaluated using three sets of criteria based on different definitions for accurate, fail-safe, and fail-dangerous predictions. The first criterion used to evaluate model performance (i.e., an accurate prediction is when the residual, observed minus predicted value is −1 log to +0.5 log; a fail-safe prediction is when the residual is <−1.0 log; and a fail-dangerous prediction is when the residual is >+0.5 log) was based upon the acceptable prediction zone method (197). The boundaries for the second criterion (i.e., an accurate prediction is when the residual is −1 log to +1.0 log; a fail-safe prediction is when the residual is <−1.0 log; and a fail-dangerous prediction is when the residual is >+1.0 log) were based on the extent of microbial growth that an expert food microbiologist would not consider significant. The boundaries for the third criterion (i.e., an accurate prediction is when the residual is −0.5 log to +0.5 log; a fail-safe prediction is

when the residual is <−0.5 log; and a faildangerous prediction is when the residual is >+0.5 log) were based on a half-log resolution limit generally accepted for microbial testing. The combined percentages of accurate and fail-safe predictions based on the three performance criteria during single-rate exponential cooling were 34.66 to 42.61% for the PMP 7.0 beef broth model, 100% for the PMIP cooling models for uncured beef, uncured pork, and uncured chicken, 80.11 to 93.18% for the Smith-Schaffner cooling model, and 74.43 to 85.23% for the ComBase Perfringens Predictor. Mohr et al. (196) concluded that, with the exception of the PMP 7.0 broth model, the cooling models were reliable tools for estimating *C. perfringens* growth in cooked meat, uncured meat, and poultry products in the event of cooling deviations. These models were also useful for developing customized cooling schedules.

METHODS FOR DETECTING *C. PERFRINGENS*

To implicate *C. perfringens* as a cause of food poisoning, at least one of the following must be found: (i) CPE-producing *C. perfringens* present in epidemiologically implicated food at a significant abundance (usually more than 10^5/g, provided that the specimen is properly handled); (ii) more than 10^6 organisms/g of stool from two or more sick persons; or (iii) CPE in the stools of two or more sick individuals (1, 198, 199). One problem associated with implicating this bacterium as a cause of disease is that most laboratories do not routinely test for *C. perfringens* because of the labor requirements and high cost. Although various less expensive methods are available (such as PCR), detection often requires anaerobic culturing, which requires more labor and resources (200). In general, the available methods for detecting CPE-producing *C. perfringens* are classified as metabolite-based biochemical assays, antigen-based immunological methods (mainly for CPE), or nucleic acid-based molecular techniques to detect *cpe* (3).

To identify and enumerate *C. perfringens* in food or feces, the recommended commercially available selectiveplating medium is tryptose sulfite cycloserine (TSC) agar, and plating is followed by incubation in an oxygen-free environment (1). Confirmation using biochemical tests (lactose fermentation, nitrate reduction, and motility assay) from 10 presumptive black colonies via plating is recommended (1). When egg yolk emulsion is added to TSC agar, *C. perfringens* produces an opaque white zone surrounding the colonies as a result of lecithinase activity (3). TSC agar has various advantages over other selective media developed for the isolation and quantification of *C. perfringens*, including iron sulfite agar, Shahidi-Ferguson perfringens agar, sulfite cycloserine azide, differential clostridial agar, and oleandomycin polymyxin sulfadiazine perfringens agar (3).

For the detection of *C. perfringens* in water samples, the membrane filtration technique using a modified form of TSC agar (which lacks sodium metabisulfite but is supplemented with sodium pyruvate) is recommended in order to improve recovery. This procedure allows the isolation and confirmation of *C. perfringens* within 18 to 24 h (201). Furthermore, the m-CP agar base with a selective supplement allows the differentiation of *C. perfringens* strains based upon the microorganism's ability to ferment sucrose and produce yellow colonies (3).

Recently, a colorimetric paper-based one-step assay for *C. perfringens* was reported. It detects nitrophenyl liberated by the hydrolysis of paranitrophenyl phosphatidyl choline by phospholipase C (202). PCR is also a well-accepted, rapid, and sensitive technique for detecting *C. perfringens*. Moreover, it is efficient under circumstances in which bacteria are present in low numbers. Multiplex PCR techniques have been developed that permit the simultaneous detection of *cpe* and other extracellular toxin genes. This assay is commonly used for toxigenic typing of the organism, and it has been useful for epidemiological purposes (1, 142). Other available methods for subtyping the bacterium include

pulsedfield gel electrophoresis, randomly amplified polymorphic DNA analysis, and ribotyping (1).

To determine whether a *C. perfringens* isolate is the etiological agent of an outbreak, it is useful to serotype or molecular genotype samples using pulsed-field gel electrophoresis for microbial source tracking (203). However, this technique does not reflect genetic sequence diversity, although it does pinpoint the clonal lineage of outbreak strains (204). More recently, multilocus sequence typing has emerged as a more precise technique to investigate relationships among isolates, diseases, and/or host preferences (204).

Since only a small subpopulation of *C. perfringens* (usually less than 5%) harbors the *cpe* gene, the presence of this bacterium in food does not always indicate that it will cause disease. Unfortunately, an assay for CPE production, which could help in identifying dangerous isolates, is not included in standard diagnostic procedures. Furthermore, an assay for CPE can be inaccurate, because this toxin is not always present at high enough concentrations for detection (205). Since CPE-positive and CPE-negative *C. perfringens* strains are usually present in low numbers in food ingredients or contaminated environments, an enrichment culture step can increase the number of *C. perfringens* cells. In the case of molecular methods, diluting out interfering substances present in the food matrix can also help with the assay (206).

Although not common, bioassays can be used to determine the action of CPE. The intestinal loops of rabbits and mice are most commonly used, where severe necrosis of the small intestinal epithelium is observed along with fluid accumulation. Other animal models used to study the effects of this toxin include rats, nonhuman primates, sheep, and cattle (43).

Since bacterial sporulation is required for CPE production (5), the detection of CPE in isolates of *C. perfringens* can prove difficult, because not all strains sporulate well in certain media and not all occur in large enough amounts to be detected. To overcome this

problem, various media have been developed to increase bacterial sporulation, and several enzyme-linked immunosorbent assay procedures for CPE detection are commercially available that have limits of detection in the range of several nanograms per gram of sample (1).

Data provided by whole-genome sequencing of a chromosomal-*cpe* strain and several strains harboring large *cpe*-expressing plasmids have allowed the development of molecular approaches to more precisely study the circulating strains (204). Several molecular methods have been developed to detect CPE and CPE-producing *C. perfringens* in various matrices if they are present at levels of 10^3 cells/g or greater. This assay distinguishes between the *cpe* locus located on a chromosome versus that carried on a plasmid. These techniques include PCR, nested PCR, real-time PCR, and loop-mediated isothermal amplification (206). The sensitivity of these methods can be improved if they are combined with enrichment culture, allowing the detection of fewer than three viable CPEpositive *C. perfringens* cells in the original sample (204).

EPIDEMIOLOGY OF *C. PERFRINGENS*

The high prevalence of CPE-positive *C. perfringens* in the intestines of animals used for food (10 to 40%) and in foods of animal origin (up to 12%) has been reported (207). It is well known that *C. perfringens* is highly prevalent in the intestinal tract of poultry, and it is detected in the feces of 80% of the animals (208). The bacteria are associated with different phases of poultry growth and production.

Additionally, the intestinal tracts of others animals are considered a reservoir for CPE-positive *C. perfringens*, and they constitute potential contamination sources. The presence of this bacterium has been demonstrated in domestic pets, including dogs (31%) and cats (20%), and 17% and 3% of all isolates, respectively, express the *cpe* gene (209). Additionally, the organism has been isolated from

24% of feces samples from horses (14% *cpe* positive), 36% of feces samples from cattle (10% *cpe* positive), and 2% of feces samples from pigs (208). It has also been detected in the feces of captive wild animals from India, such as ruminants (34.1%), nonruminants (36%), and birds (22.5%), and in the feces of caretakers (6.7%). In these cases, the bacterium has been detected only in feces samples, and no *cpe*-positive isolates have been detected (210).

Various studies have identified healthy humans as reservoirs for CPE-positive *C. perfringens* (211). These studies suggest that CPE-producing *C. perfringens* strains are frequently present in the intestines of healthy humans (207), and this is one source of contamination for foods.

C. perfringens can be dispersed in the environment as spores, allowing it to survive under extreme conditions and germinate in raw or cooked foods (1, 84). *C. perfringens* can be isolated from a range of environments, including soil and marine and freshwater sediments (212). One report even showed that 10% of all strains isolated from water samples near shores or mouths of rivers were *cpe* positive (213).

In general, foodborne diseases are globally important because they result in considerable morbidity, mortality, and economic costs, accounting for 3.6% of the total disease burden. This results in a substantially higher impact in low-income countries and regions with poor water quality, sanitation, and food safety (214). The case fatality ratio associated with *C. perfringens* in low-mortalityrate countries is estimated to be 0.003%, and this is higher than ratios associated with the enterotoxigenic bacteria *S. aureus* (0.0025%) and *B. cereus* (0%) (9). Data available from 2010 indicate that 5,409,083 cases of bacterial intoxication (uncertainty interval, 2,187,762 to 12,929,293) occurred worldwide, and 3,998,164 cases (uncertainty interval, 837,262 to 11,529,642) were attributable to C. *perfringens* (215).

Foodborne illnesses caused by *C. perfringens* are among the most common illnesses of this type worldwide. These are the second

most common foodborne illnesses in the United States (84) and the third most common in England and Wales (216). Although many sporadic illnesses caused by *C. perfringens* are usually not reportable, it is estimated that this pathogen causes 1 million episodes of foodborne illness (or 10% of all cases) in the United States annually (200). In particular, 16 to 31 outbreaks are typically reported each year (84), resulting in an estimated medical cost of $539 per case and an annual economic loss of $382 million (84, 85).

C. perfringens outbreaks occur throughout the year. However, outbreaks are most common during November and December, when many holiday gatherings and social events occur. During these celebrations, people tend to meet in groups to eat seasonal foods, such as roasts, gravies, and poultry. These dishes are often cooked in large batches or prepared long before serving (84). The roasting or baking of meat and poultry is the most common method of preparation (48%) associated with outbreaks, followed by preparation as part of a large, solid mass of food (29%) (199). Food service establishments, such as restaurants (43%), are the most likely sites for contracting food poisoning caused by *C. perfringens*. Other settings include catering facilities (19%), private homes (16%), prisons (11%), and miscellaneous locations (10%) (1, 84).

Problems in food processing and preparation account for 93% of all causes of *C. perfringens* outbreaks. The most frequent mistakes include (i) maintaining foods at room temperature for several hours (58%), (ii) insufficient cooking times or temperatures during reheating (57%), (iii) slow cooling of prepared foods (44%), (iv) insufficient cooking times or temperatures during the initial cooking process (40%), (v) preparing foods in advance by more than half a day (33%), and (vi) insufficient times or temperatures used during hot (33%) or cold (22%) holding (199). According to USDA FSIS compliance guidelines (Appendix B of the FSIS Performance Standards for the Production of Certain Meat and Poultry Products [217]), to avoid *C. perfringens* growth, it is necessary to chill uncured meat and poultry products for no longer than 1.5 h in order

to shift from 54.4°C to 26.7°C (130°F to 80°F). Furthermore, the chilling from 26.7°C to 4.4°C (40°F) should take no more than 5 h (1). The contamination of raw products or ingredients has been a principal factor (21%) contributing to *C. perfringens* outbreaks, followed by cross-contamination in the food processing and preparation environment (13%) and contamination by a food worker (6%) (199).

METHODS OF CONTROL

Historic information gathered from reports of outbreaks provided data regarding the causes of *C. perfringens*-associated illnesses, helping to establish adequate control measures in order to avoid outbreaks. Furthermore, knowledge about environmental reservoirs for CPEproducing *C. perfringens* and factors associated with contamination of food vehicles might lead to control measures that could decrease food contamination (84). In general, *C. perfringens* outbreaks are preventable with proper food handling and preparation protocols, including cooling and hot holding, particularly in restaurants and catering facilities (1, 84).

C. perfringens is commonly found in retail meat and poultry at levels of 10 to 100 CFU/g (1). Thus, efforts must be made to avoid the growth of the bacteria that increase the risk of a foodborne out break. To ensure that vegetative cells are inactivated, they must reach temperatures above 60°C. For this, foods should be cooked or reheated to a temperature of ≥75°C (1). The refrigeration of foods at temperatures below 10°C also inhibits bacterial growth (84). Sodium nitrite (0.2%), sorbate (0.3%), and benzoate (0.1%) inhibit the vegetative growth of *C. perfringens* isolates (218). Ascorbate enhances the antimicrobial effects of nitrite on *C. perfringens* at concentrations commonly used in alternatively cured meats (219). Buffered sodium citrate alone and in combination with sodium diacetate reduces the population of *C. perfringens* vegetative cells during the abusive chilling of roast beef and pork (220).

If the spores of the bacterium are present, it is important to consider that the organism can survive cooking and multiply rapidly at 37 to 45°C (1). The heat resistance of *C. perfringens* spores varies depending on the strain and temperature at which they are produced. There is a direct relationship between spore heat resistance and sporulation temperatures (5, 6). The germination and outgrowth of *C. perfringens* spores during the improper cooling of thermally processed meat products have been reported (221). In these cases, it is not always possible to apply enough heat during food processing to kill the spores. However, other interventions can be useful, such as a combination of temperature and pressure (84), proper cleaning and disinfection with hypochlorite (pH < 8), the avoidance of bacterial overgrowth by cooking and rapid cooling, and proper reheating above 60°C throughout all parts of the food product (222).

Some chemicals widely used as flavor enhancers and/or antimicrobial agents are alternatives for the biological control of *C. perfringens*. These products inhibit *C. perfringens* spore germination and outgrowth during extended cooling periods in a variety of meat systems. These chemicals include 2% NaCl (221), sodium nitrite (223), organic acid salts (such as sodium, potassium or calcium salts of acetic, citric, or lactic acids) (224), sorbate, and benzoate (225). The organic acids added to foods exist in a pH-dependent equilibrium between the undissociated state and the dissociated state. The antimicrobial activity of organic acids primarily results from the uncharged and undissociated state of the molecule, which crosses the bacterium's plasma membrane into the cytoplasm and releases charged anions and protons. This inhibits the microbe's metabolism (224). However, although sorbate (0.3%) and benzoate (0.1%) have been reported to effectively arrest the growth of germinated *C. perfringens* spores in rich medium, these compounds could not control the growth of spores in chicken meat stored under extreme conditions (218).

The bacteriocin nisin (which is produced by *Lactococcus lactis* subsp. *lactis*) has been used as a food preservative due to its lethal

action and wide spectrum of activity (226). Other bacteriocins, such as those produced by *Pediococcus acidilactici* (227) and *Lactococcus lactis* strain WNC 20 (226), among others, also display activity against *C. perfringens*.

Many studies have explored ways to reduce, inhibit, and kill *C. perfringens* in foods, and other strategies for controlling this pathogen include reducing or eliminating *C. perfringens* colonization of the gut in reservoir animals. *Lactobacillus* has been widely used as a probiotic in feeds to improve poultry growth performance and overall health. *L. acidophilus* and *L. fermentum* inhibit the pathological effects of *C. perfringens* in intestinal epithelial cells of chicken embryos (228). The ingestion of *L. acidophilus* (229) and *B. licheniformis* (230) modulates the relative abundance of some bacteria taxa, increasing the concentrations of lactate and butyrate while decreasing the relative abundance of undesirable bacteria (such as *Escherichia*), reducing disturbances in the cecal microbiome, promoting intestinal health, and contributing to the recovery of the microbial community disrupted by a *C. perfringens* infection (229).

The inhibitory effects of plant extracts and essential oils on the growth of *C. perfringens* have also been studied. Lemon juice concentrate and vinegar, either alone or as a mixture, are effective in controlling the germination and outgrowth of *C. perfringens* spores in ground roast beef (221) and ground turkey roast (224). When used in combination with small amounts of sodium nitrite (100 ppm), the winter savory (*Satureja montana* L.) essential oil (in which the major compounds are thymol [28.99%], *p*-cymene [12.00%], linalool [11.00%], and carvacrol [10.71%]) effectively controls the growth of *C. perfringens* in mortadella (231). The essential oil and ethanoic extract of *Eugenia caryophyllata* (232), in addition to the ethanoic extracts of *Agave lechuguilla* Torr. (Agavaceae), *Baccharis glutinosa* Pers. (Compositae), and *Larrea tridentata* (DC.) Cov. (Zygophyllaceae) (233), shows growth-inhibitory activity against *C. perfringens*.

Chitosan, a natural carbohydrate polymer derived from the deacetylation of chitin, is the primary component of crustacean and insect exoskeletons and the cell walls of fungi. This carbohydrate displays strong growthinhibitory activity against *C. perfringens* in laboratory medium at 1.0 mg/g. However, to achieve a similar inhibition of spores inoculated into chicken meat, higher levels (2.0 mg/g) are required (225). Other antimicrobial replacements for antibiotics include fatty acids, such as caprylic, capric, lauric, myristic, and oleic acids (234).

To treat or prevent disease, it is important to kill the pathogen that causes the disease, thereby stopping the production of that pathogen's virulence factors. Aqueous extracts of *Psidium guajava* L., *Haematoxylon brasiletto*, and *Euphorbia prostata* are effective not only as inhibitors of *C. perfringens* growth but also against spore formation and CPE production (235).

CONCLUDING REMARKS

Significant progress has been made in the last few years towards our understanding of the epidemiology, pathogenicity, and control measures of foodborne disease, including food poisoning, caused by *C. perfringens* strains. Despite this, a significant burden of food poisoning illnesses still occurs in the United States every year, with nearly a million cases reported. The challenge for us in the field of food microbiology is to identify and design strategies to help reduce the burden of food poisoning. We have learned that food poisoning cases commonly occur as outbreaks in institutions where food is prepared in large quantities. These prepared meals become contaminated with CPE-producing *C. perfringens* strains, commonly those carrying the enterotoxin gene *cpe* on the chromosome, and contaminated food is not thoroughly cooked and also improperly stored. As a result, *C. perfringens* vegetative cells multiply and sporulate, producing enough enterotoxin to cause diarrhea once consumed. Therefore, prophylactic measures to prevent food poisoning should focus on restricting multiplication of

vegetative cells in cooked foods. Cooking at proper temperatures and for the right time, along with rapid cooling after cooking with subsequent refrigeration, is the most effective action to control the multiplication of *C. perfringens* and thus avoid food poisoning outbreaks.

The ultimate responsibility to guard against the pathogens lies with the food industry and retail food service establishments. Processors can take advantage of multiple food formulation factors or hurdles in foods, e.g., water activity, pH, and added preservatives, to restrict growth from spores in cooked foods. Predictive models have been developed to estimate growth under conditions that are relevant to food processing operations. Recent advances in molecular techniques have enabled researchers to characterize *C. perfringens* virulence factors, toxins, sporulation, and spore heat resistance, to carry out epidemiologic trace-back of foodborne illness and toxigenic typing methods, etc. Future research efforts should be directed towards efficient tracing of *C. perfringens* strains of public health significance, multiple hurdles in formulated foods, proper processing of ready-to-eat foods, and consumer awareness of handling such foods.

Bacillus cereus

The *Bacillus cereus* group currently consists of nine *Bacillus* species, i.e., *B. anthracis*, *B. cereus*, *B. mycoides*, *B. pseudomycoides*, *B. thuringiensis*, *B. weihenstephanensis*, *B. cytotoxicus*, *B. bombysepticus*, and the most recently classified member of the group, *B. toyonensis*. The *B. cereus* group is often referred to as *B. cereus sensu lato*, and the species *B. cereus* is referred to as *B. cereus sensu stricto*. The species within the *B. cereus* group are so closely related that they could be one species; however, *B. anthracis* (not treated here) can be distinguished from other members of the *B. cereus* group since it is nonmotile and nonhemolytic and carries two large plasmids containing toxin and capsule genes. The broad spectrum of *B. cereus sensu lato* toxicity ranges from avirulent strains used as probiotics for humans to highly toxic strains responsible for foodrelated fatalities (1).

B. cereus sensu stricto (referred to herein as *B. cereus*) can cause two different types of foodborne illness: the diarrheal type, first recognized after a hospital outbreak associated with vanilla sauce in Norway in 1948 (2), and the emetic type, which was described about 20 years later after several outbreaks associated with fried rice in England (3). The diarrheal type is caused by an enterotoxin(s) produced during vegetative growth of *B. cereus* in the small intestine (4), whereas the emetic illness is caused by a small heat-stable emetic toxin that is preformed by *B. cereus* in the food (5). For both these types of foodborne illness, the food involved has usually been heat treated, and surviving spores are the source of the food poisoning. *B. cereus* is not a very competitive microorganism but grows well in food after cooking and cooling (<48°C; 55°C for *B. cytotoxicus*). Heat treatment induces germination of spores, and in the absence of competing flora, *B. cereus* grows well, with a generation time as short as 12 minutes for some strains under optimal conditions (6). The members of the *B. cereus* group are common soil saprophytes and are easily spread to many types of foods, especially those of plant origin (rice and pasta), but are also frequently isolated from meat, eggs, and dairy products (5). Detection of an increasing number of psychrotolerant strains, mainly *B. weihenstephanensis* strains associated with the dairy industry, has led to increased surveillance for *B. cereus* in recent years (7–11).

B. cereus foodborne illness is probably highly underreported, as both types of illness are usually relatively mild and typically last for less than 24 hours (5). However, more severe forms of *B. cereus* foodborne illness are reported occasionally, including three deaths caused by the necrotic enterotoxin CytK (12) and also fatalities due to ingestion of large amounts of emetic toxin (13–15).

CHARACTERISTICS OF *B. CEREUS SENSU LATO*

Aerobic endospore-forming bacteria have traditionally been placed in the genus *Bacillus*, belonging to the family *Bacillaceae*. Phylogenetic analyses based on 16S rRNA have revealed that the family *Bacillaceae* is paraphyletic; some genera are misassigned to the family, and some species are misassigned to the genus *Bacillus*. However, a reclassification of this often-abused taxon has so far not been done. The genus *Bacillus* has expanded over the decades and today accommodates more than 100 species, mainly divided into 11 phylogenetic subclusters, named subclusters a through d (16, 17). Subcluster d comprises the members of the *B. cereus* group: *B. anthracis*, *B. cereus*, *B. mycoides*, *B. thuringiensis*, and more recently, *B. pseudomycoides* (18), *B. weihenstephanensis* (10), *B. cytotoxicus* (19), *B. bombysepticus* (20), and *B. toyonensis* (21). These species have highly similar 16S and 23S rRNA sequences, indicating that they diverged from a common evolutionary line relatively recently (22–24).

The *B. cereus* group of bacteria can be divided into three distinct clades, where pathogenic *B. cereus* strains are evenly distributed among clades 1 and 2 (25). *B. thuringiensis* is primarily found in clade 2, while clade 3 contains *B. cereus*, *B. mycoides*, and *B. weihenstephanensis*. *B. anthracis* is a monophyletic clone derived from *B. cereus* and *B. thuringiensis* and is restricted to clade 1. Although *B. anthracis* is genetically closely related to the other species within the *B. cereus* group (24), it is the most distinctive member of this group, due to its highly virulent pathogenicity, introduced by two large plasmids (pOX1 and -2). However, strains of *B. cereus* may cause anthrax-like symptoms (26–29); hence, it is difficult to identify definite criteria to differentiate the two species. In addition, extensive genomic studies including full-genome sequencing of strains of *B. cereus* and *B. thuringiensis* have revealed that there is no taxonomic basis for separate status for these two species (24). Nevertheless, the name *B. thuringiensis* is retained for strains that synthesize a crystalline inclusion (Cry protein) or δ-endotoxin that is highly toxic to specific insects. The *cry* genes are usually located on plasmids, and without the relevant plasmid(s), the bacterium is indistinguishable from *B. cereus*.

The cells of the species in the *B. cereus* group are large (cell width, >0.9 μm) and produce central to terminal ellipsoid or cylindrical spores that do not distend the sporangia (10, 16, 18). Bacteria of these *Bacillus* species sporulate easily in most media after 1 to 3 days. *B. cereus*, *B. anthracis, B. thuringiensis*, and *B. mycoides* can be differentiated by the phenotypic traits listed in Table 20.1.. *B. weihenstephanensis* can be differentiated from *B. cereus* based on growth below 7°C and not at 43°C, by 16S RNA sequences, or by PCR targeting *cspA*, the cold shock protein A-encoding gene (10). *B. pseudomycoides* is not distinguishable from *B. mycoides* by physiological and morphological characteristics but can be clearly differentiated by fatty acid composition and 16S RNA sequences (18). *B. cytotoxicus* can be differentiated from other species of the *B. cereus* group by maximum growth at 50°C and minimum growth at 20°C, the absence of starch hydrolysis, and the absence of growth on synthetic media without tryptophan (19). *B. toyonensis* is distinguished from other *B. cereus* group members by pairwise calculation of the average nucleotide identity (21). *B. bombysepticus* produces parasporal crystal and infects the silkworm *Bombyx mori*; however, it is very closely related to *B. thuringiensis*, with a genome sequence identity of more than 96% (20, 30).

Table 20.1 Criteria to differentiate members of the *B. cereus* group[a]

Species	Colony morphology	Hemolysis	Motility	Susceptibility to penicillin	Parasporal crystal inclusion
B. cereus	White	+	+	-	-
B. anthracis	White	-	-	+	-
B. thuringiensis	White/gray	+	+	-	+
B. mycoides	Rhizoid	(+)	-	-	-
B. pseudomycoides	As for *B. mycoides* above. Differentiated from *B. mycoides* based on fatty acid composition and 16S RNA sequences (18).				
B. weihenstephanensis	As for *B. cereus* above. Differentiated from *B. cereus* based on growth at <7°C and not at 43°C; it can be identified rapidly using rRNA gene-or *cspA* (cold shock protein A gene)-targeted PCR (10).				
B. cytotoxicus	As for *B. cereus* above. Differentiated from *B. cereus* by maximum growth at 50°C and minimum growth at 20°C, by absence of starch hydrolysis, and by absence of growth on synthetic media without tryptophan (19).				
B. toyonensis	*B. toyonensis* is distinguished from other *B. cereus* group members by pairwise calculation of the average nucleotide identity (21).				

[a]Symbols: +, positive; –, negative; (+), weakly positive.

RESERVOIRS

B. cereus is widespread in nature and frequently isolated from soil and growing plants (5). From this natural environment, it is easily spread to foods, especially those of plant origin. It is frequently present in raw materials and ingredients used in the food industry, such as vegetables, starch, and spices (30% of samples contain 10^2 to 10^5 CFU/g). In addition to rice, pasta, and spices, dairy products are among the most common food vehicles for *B. cereus*. *B. cereus* is spread to milk and dairy products largely through soil and grass that come into contact with the udder of the cow and then are passed into raw milk. *B. cereus* spores survive milk pasteurization, and after germination, the cells are free from competition from other vegetative cells (31). According to the classical literature, *B. cereus* is unable to grow at temperatures below 10°C

and cannot grow in milk and milk products stored at temperatures between 4 and 8°C. However, psychrotolerant species such as *B. weihenstephanensis* can grow well at temperatures as low as 4 to 6°C (7, 8, 32). The majority (if not all) of *B. weihenstephanensis* isolates are unable to cause diarrheal food poisoning (33) and will outcompete mesophilic *B. cereus* in foods stored at temperatures below 8°C. *B. weihenstephanensis* is, however, able to produce emetic toxins at low temperature (8 to 10°C) (34, 35).

The closely related *B. thuringiensis* can produce enterotoxins (36–38) and can cause foodborne illness when administered to human volunteers (37). This may pose a problem, as spraying of this organism to protect crops against insect infestations has become a common practice in several countries. In 2005, it was shown that 31 of the 40 randomly selected *B. cereus*-like strains isolated from foods were classified as *B. thuringiensis* due to crystal production and/or carriage of *cry* genes (39). However, because the procedures normally used for identification of *B. cereus* would not differentiate between the two species of *Bacillus* (Table 20.1.), outbreaks caused by *B. thuringiensis* may be unrecognized. To ensure safe spraying of *B. thuringiensis*, the organism used should not produce enterotoxins. Although all members of the *B. cereus* group harbor genes for at least one of the enterotoxins (Nhe), some strains do not produce detectable amounts of toxin(s) (38), included the newly described species *B. toyonensis* (21).

FOODBORNE OUTBREAKS

The number of outbreaks of *B. cereus* foodborne illness is greatly underestimated. This is mainly due to the relatively short duration of both types of illness (usually <24 hours) and to the fact that complete recovery is, with a few exceptions, rapid after the symptoms subside. The dominating type of disease caused by *B. cereus* differs among countries. In Japan, the emetic type is reported about 10 times more frequently than the diarrheal type (40), whereas in Europe and North America, the diarrheal type is most frequently reported (5, 41). This is likely attributed to eating habits, although contaminated milk was reported to cause at least one large outbreak of the emetic type in Japan (42). Some patients experience both types of *B. cereus* foodborne illness concurrently (43), with about 5% of *B. cereus* strains producing both types of toxins (5, 44).

Surveillance of foodborne illnesses differs greatly among countries. Hence, it is not possible to directly compare the incidence of outbreaks reported by different countries. The percentage of outbreaks and cases attributed to *B. cereus* in Japan, North America, and Europe varies from approximately 1 to

47% for outbreaks and from approximately 0.5 to 33% for individual cases (reports are from different periods between 1960 and 2005) (5, 41). The highest numbers of reported *B. cereus* outbreaks and cases are from Iceland, The Netherlands, and Norway. However, in the past few years (2010 to 2014), *B. cereus* outbreaks have more than doubled in France, and this organism is now the second cause of foodborne outbreaks following *Staphylococcus aureus* (45). There are relatively few outbreaks of salmonellosis and *Campylobacter* enteritis reported in Norway and Iceland; these are the two most frequently reported causes of foodborne illness in most of Europe and the United States, and the increase in France is also in part due to a strong reduction in salmonellosis (45). In The Netherlands, between 1993 and 1998, *B. cereus* was responsible for 12% of outbreaks of foodborne illness for which the causative agent was identified. However, the actual incidence of *B. cereus* illnesses was only 2.0% of the total number of reported cases, because most cases of foodborne illness were of unknown etiology (41). According to the European Food Safety Authority, *B. cereus* food poisoning was caused mainly by mixed buffet meals and food of plant origin (46) (Fig 20.1). Examples of foods involved in foodborne outbreaks are shown in Table 20.2..

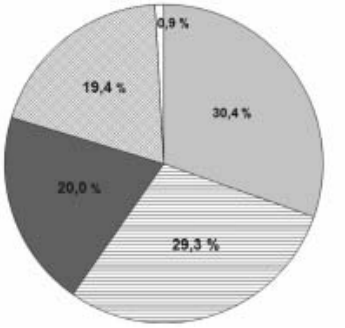

Figure 20.1 Types of foods involved in *B. cereus* food poisoning in Europe (European Food Safety Authority) (46).

CHARACTERISTICS OF DISEASE

There are two types of *B. cereus* foodborne illness. The first type, which is caused by an emetic toxin, results in vomiting, whereas the second type, which is caused by enterotoxin(s), results in diarrhea (5). In a small number of cases, both types of symptoms occur (5), likely due to production of both types of toxin. There has been some debate about whether enterotoxin(s) can be preformed in foods. In reviewing the literature, it appears that the incubation time (>6 hours; average, 12 hours) is too long for the diarrheal illness to be caused by preformed enterotoxin (5), and experiments in animal models revealed that the enterotoxin(s) is degraded as it proceeds to the ileum (47).

However, there is no doubt that *B. cereus* enterotoxins can be preformed in food, but the number of *B. cereus* cells necessary to produce enterotoxin in such food is at least 2 orders of magnitude higher than the number of cells needed to cause emetic toxin food poisoning (7, 47). Usually, foods with such large populations of *B. cereus* will no longer be acceptable to the consumer, although food containing $>10^7$ *B. cereus* cells/ml may not always appear spoiled. The characteristics of the two types of *B. cereus* foodborne illness are described in Table 20.3..

Severe illness associated with *B. cereus* food poisoning is of great concern, and deaths caused by both enterotoxin and emetic toxin have been reported. *B. cereus* cytotoxin K (CytK), similar to the β-toxin of *Clostridium perfringens*, was the causative agent of a severe outbreak of *B. cereus* foodborne illness in France in 1998 (12). Several people in this outbreak developed bloody diarrhea, and three died. This was the first recorded outbreak of *B. cereus* necrotic enteritis, although the symptoms were not nearly as severe as symptoms seen after *C. perfringens* type C foodborne illness (48). The organism isolated from this outbreak, *B. cytotoxicus*, differed from other members of the *B. cereus* group and grew at higher temperatures (thermotolerant). *B. cytotoxicus* is now recognized as a species (19).

Table 20.2 Examples of foods involved in *B. cereus* food poisoning events

Type of food	Country	No. of people involved	Type(s) of syndrome[a]
Barbecued chicken	Many countries	—[b]	E, D
Cooked noodles	Spain	13	D
Cream cake	Norway	5	D
Eclair (pastry)	Thailand	>400	E(D)
Fish soup	Norway	20	D
Hibachi steak	United States	11	E, D
Lobster pâté	United Kingdom	—	D

Vegetable sprouts	United States	3	E, D
Wheat flour dessert	Bulgaria	—	D

[a] E, emetic syndrome; D, diarrheal syndrome.

[b] —, data not available.

Table 20.3 Characteristics of the two types of illness caused by *B. cereus*[a]

Characteristic	Diarrheal syndrome	Emetic syndrome
Dose causing illness	10^5–10^7 cells (total)	10^5–10^8 cells (per g in foods)
Toxin production	In the small intestine of the host	Preformed in foods
Type of toxin	Protein; enterotoxin(s)	Cyclic peptide; emetic toxin
Incubation period	8–16 h (occasionally >24 h)	0–5 h
Duration of illness	12–24 h (occasionally several days)	6–24 h
Symptoms	Abdominal pain, watery diarrhea occasionally with nausea	Nausea, vomiting, and malaise (sometimes followed by diarrhea, due to production of enterotoxin)
Foods most frequently implicated	Meat products, soups, vegetables, puddings/sauces, and milk/milk products	Fried and cooked rice, pasta, pastry, and noodles

[a]Based on references 5, 42, and 47.

In 1997, the emetic toxin cereulide was responsible for the death of a 17-year-old Swiss boy, due to fulminant liver failure (14). A large amount of *B. cereus* emetic toxin was detected in residue in the pan used to reheat the implicated food (pasta) and in the boy's liver and bile. In 2005, a 7-year-old girl died in Belgium only 13 hours after ingesting a pasta salad that had been stored for several days in a refrigerator where the temperature was 14°C. Her 2-year-old brother, who had eaten only a small amount of the salad, was hospitalized for 8 days (13). Yet another lethal case was described in Belgium in 2008 (49). The latest report of a serious outbreak of *B. cereus* emetic type is from Japan (15), where three family members began vomiting 30 minutes after consuming reheated fried rice. After 6 hours, a 1-year-old boy died of acute encephalopathy. A 2-year-old girl recovered rapidly only after plasma exchange and subsequent hemodialysis. Their mother recovered after fluid therapy.

An outbreak in Norway in 1991 associated with eating stew containing approximately 10^4 to 10^5 *B. cereus* cells per serving affected 17 people, of whom 3 were hospitalized, one for 3 weeks. The onset for these three patients was late, more than 24 h, and the illness was probably due to ingestion of spores.

DOSE AND SUSCEPTIBLE POPULATIONS

After the first recognized diarrheal outbreak of *B. cereus* foodborne illness in Oslo (vanilla sauce), S. Hauge isolated the causative agent, grew it to 4×10^6 CFU/ml, and drank 200 ml of the culture (2). Approximately 13 hours later, he developed abdominal pain and watery diarrhea that lasted for approximately 8 hours. The number of *B. cereus* cells he ingested was approximately 8×10^8. Counts of *B. cereus* ranging from 200 to 10^9 CFU/g (or ml) have been reported in foods incriminated in outbreaks (2, 5, 47, 50), indicating ingestion of a total number of 5×10^4 to 10^{11} cells. The total number of *B. cereus* cells required to cause illness is likely in the range of 10^5 to 10^8 viable cells or spores. In the lower part of this range, it is likely that only the spores, which survive the stomach acid barrier, can cause illness. Still, the wide range of infective doses is also due to differences in the amount of enterotoxin produced by different strains (47). Hence, food containing more than 10^3 *B. cereus* spores/g cannot be considered completely safe for consumption. Little is known about susceptible populations, but the more severe types of illness have occasionally involved young athletes (<19 years) or the elderly (>70 years) (12, 50, 51). More studies are needed to address this important question.

VIRULENCE FACTORS AND MECHANISMS OF PATHOGENICITY

The two types of *B. cereus* foodborne illness are caused by very different types of toxins. The emetic toxin, cereulide, is a 1.2-kDa dodecadepsipeptide synthesized by a nonribosomal peptide synthetase (44, 52, 53), whereas the diarrheal disease is caused by enterotoxins of protein nature (12, 54, 55).

Emetic Toxin

The emetic toxin (Table 20.4.) causes emesis and vomiting only, and its structure was for many years a mystery because the only detection system involved living primates (5, 56, 57). However, the discovery that the toxin could be detected by HEp-2 cells (vacuolation activity) has led to its isolation and structure determination (52, 53). The emetic toxin has been named cereulide and consists of a ring structure of three repeats of four amino acids and/or oxyacids: (D-*O*-Leu-D-Ala-l-*O*-Val-L-Val)^3. The toxin acts as a K^+ ionophore (like valinomycin), is resistant to heat, pH, and proteolysis, and is not antigenic (52, 53) (Table 20.4.).

Table 20.4 Properties of the *B. cereus* emetic toxin cereulide[a]

Trait	Property or activity
Molecular mass	1.2 kDa (many isoforms)
Structure	Ring-shaped peptide
Isoelectric point	Uncharged
Antigenic	No
Biological activity in living primates and Asian house shrew	Vomiting
Receptor	5-HT3 (stimulation of the vagus afferent)
Ileal loop tests (rabbit, mouse)	None
Cytotoxic	No
HEp-2 cells	Vacuolation activity
Stability to heat	90 min at 121°C
Stability to pH	Stable at pH 2–11
Effect of proteolysis (trypsin, pepsin)	None
Conditions under which toxin is produced	In food (rice and milk at 12–32°C)
Mechanisms of production	Produced by a nonribosomal peptide synthetase

[a]Based on references 5, 34, 42, 52, 53, 57, and 58.

Cereulide causes inhibition of mitochondrial activity (inhibition of fatty acid oxidation) and stimulates the afferent vagus nerve by binding to the 5-HT3 receptor (52). Mice injected intraperitoneally with synthetic cereulide developed histopathological changes in the liver, and massive degeneration of hepatocytes was observed (32). The levels of hepatic enzymes in mouse serum were highest on days 2 and 3 after the inoculation of cereulide and rapidly decreased thereafter. General recovery from pathological changes and regeneration of hepatocytes were observed after 4 weeks.

Cereulide is nonribosomally synthesized by the multienzyme complex Ces-NRPS, which is encoded on a megaplasmid with homology to the *B. anthracis* pXO1 plasmid (58, 59). However, the transcriptional regulators involved in *ces* synthetase regulation that have been identified so far are encoded chromosomally. The 24-kb cereulide synthetase gene cluster is transcribed as an operon, and transcription seems to be highly temporal and tightly regulated; *ces* mRNA is detectable only during mid-exponential-phase to late-exponential-

phase growth (60). Several promoters are identified within the *ces* gene cluster, although *ces*P1 has been shown to be the main promoter (61). This promoter is not subjected to regulation by the PlcR-PapR quorum-sensing system (see “Regulation of Enterotoxin Production” below) but is directly repressed by the chromosomally encoded transition state regulator AbrB (62).

The majority of the characterized emetic strains do not grow below 10°C, nor do they produce the Hbl enterotoxin (44). However, a few strains of *B. weihenstephanensis* have been reported to produce cereulide (63). Although these strains grow at lower temperatures than other members of the *B. cereus* group, the emetic toxin is not produced below 8°C (34). Recently, it was shown that Ces-NRPS synthesizes at least 17 different isoforms of cereulide which differ significantly in their cytotoxic properties (64). All emetic *B. cereus* strains produce the same set of isocereulides, although at different ratios (64, 65). The formation of the cereulide isoforms is highly temperature dependent and is regulated at posttranscriptional levels, and surprisingly, production of a particularly cytotoxic cereulide isoform was elevated at low temperatures (12 to 15°C) (66). Cereulide synthetase gene expression and cereulide toxin production are influenced by complex interactions of various intrinsic as well as extrinsic factors, and this may be of great importance in terms of food safety and predictive microbiology (67).

Enterotoxins

B. cereus produces different proteins (or protein complexes), referred to as enterotoxins, that can cause foodborne illness (Table 20.5.). Two three-component enterotoxin complexes, hemolysin BL (Hbl) and Nhe (54, 55), and a single 34-kDa protein, CytK (12), have been thoroughly described. Hbl was the first to be characterized; it causes vascular permeability, is dermonecrotic, and leads to fluid accumulation in ligated ileal loops in rabbits (68, 69). Hbl consists of the components B, L_1, and L_2, which are all necessary for maximal enterotoxin activity, and a 1:1:1 ratio of the three components gives maximum biological activity (68). It was recently shown by priming the Hbl components on Chinese hamster ovary (CHO) cells that the order of assembly on the cell surface is B, L_1, and finally L_2 (70). About 60% of *B. cereus* strains carry *hbl* genes (71, 72), while the number is slightly higher for *B. thuringiensis* strains (71, 73). Some *B. cereus* strains carry a second *hbl* operon (71, 74), and a phylogenetic study indicated that the duplication of the *hbl* operon was an ancient event which occurred early in the evolution of *B. cereus sensu lato* (71).

Table 20.5 Toxins produced by *B. cereus*

Toxin	Type/size	Food poisoning	Reference(s)
Hemolysin BL (Hbl)	Protein, 3 components	Probably	68, 69, 91, 119
Nonhemolytic enterotoxin (Nhe)	Protein, 3 components	Yes	55, 75, 78, 110
Cytotoxin K (CytK)	Protein, 1 component, 34 kDa	Yes; 3 deaths	12
Emetic toxin (cereulide)	Cyclic peptide, 1.2 kDa	Yes; several deaths	13–15, 52, 53

Hbl was previously suggested to be a primary virulence factor in *B. cereus* diarrhea; however, strains without *hbl* genes have caused food poisoning (55). The second three-component enterotoxin, Nhe, was first described by Lund and Granum in 1996 after a large foodassociated outbreak caused by a *B. cereus* strain lacking Hbl-encoding genes (55, 75). Initially, the hemolytic activity of Nhe was not detected, but more recently, Nhe was found to possess hemolytic activity, although it is not as high as that of Hbl (76). The Nhe toxin components, NheA, NheB, and NheC, are secreted as soluble proteins (77), and the Nhe pore-forming complex is most active when the ratio between NheA, NheB, and NheC is 10:10:1 (76, 78). However, NheC is expressed in lower ratios *in vivo* than the optimal ratio, and this is likely why NheC is not detected on two-dimensional sodium dodecyl sulfate-polyacrylamide gel electrophoresis (79, 80). If higher-than-optimal ratios for NheC activity are used in experiments, the biological activity is rapidly reduced, and at a 1:1:1 ratio, very little biological activity is left (76, 78). Like Hbl, Nhe requires a specific binding order of the three components for pore formation (70, 81, 82). The first step is a complex formation between NheB and NheC in solution, followed by binding of the complex to the cell surface, probably to a specific surface structure recognizing the NheB-NheC complex (82). This step is accompanied by conformational changes in NheB (83), leading to oligomerization and attachment of NheB proteins, forming a ring-shaped structure on the cell surface. NheA then binds to cellbound NheB, and a conformational rearrangement of NheA finalizes the pore formation (84).

The X-ray crystal structures of NheA and HblB have recently been solved, and the two toxin components are structurally related to each other, as well as to the hemolytic enterotoxins HlyE, ClyA, and SheA of *Escherichia coli*, *Salmonella enterica*, and *Shigella flexneri*, respectively (85, 86). They all

belong to the ClyA superfamily of α-helical pore-forming toxins, possessing an α -helix bundle and a subdomain containing a β-hairpin structure. However, in contrast to the characteristic hydrophobic β-hairpin of HblB and ClyA, NheA has an amphipathic β-hairpin structure resembling a structure of *Staphylococcus aureus* α-hemolysin, which is a β-barrel pore-forming toxin (85). Due to amino acid sequence similarities, the other components of Nhe and Hbl are predicted to share the overall three-dimensional structure with NheA and HblB, and the β-hairpin of NheC has been shown to be essential for binding of NheC to the cell membrane (81). More than 99% of all *B. cereus* strains carry genes encoding Nhe (44, 71).

The last-characterized *B. cereus* toxin associated with food poisoning is CytK. This toxin belongs to a family of β-barrel toxins and is similar to the β-toxin of *C. perfringens*; it was the cause of symptoms in a severe outbreak of *B. cereus* foodborne illness in a nursing home in France in 1998 (12). In this outbreak (*B. cereus* necrotic enteritis), several people developed bloody diarrhea and three patients died. Similar to the other members of this β-barrel toxin family, CytK is inserted into membranes as a heptamer and makes pores 7 Å in diameter in planar lipid bilayers (87).

The *Bacillus* strain that caused the fatal outbreak in France (12) is highly cytotoxic and is now the type strain for *B. cytotoxicus* (19). The CytK produced by this particular strain, CytK-1, differs from CytK produced by most other *B. cereus* strains (12, 88). *cytK* is present in about 40% of *B. cereus* strains (71), and CytK-1 is 89% identical in amino acid sequence to the more commonly occurring CytK (89). The high virulence of the *B. cytotoxicus* type strain is thought to be due to the greater cytotoxic activity of CytK-1 than CytK, and also to a high level of *cytK* expression (88). CytK-1 is about five times more toxic on epithelial cells than the other CytK, although the activities of these two toxins on erythrocytes are very similar (88). CytK-1 is produced by a few strains that are genetically remote from other strains of the *B. cereus* group (89). These strains harbor a novel gene variant encoding Nhe, which is not detected using ordinary *nhe* PCR primers or monoclonal antibodies against the Nhe proteins (89). Although studies have revealed that the total toxicity of *B. cereus* supernatant fluids for most strains is largely due to Nhe (90), Hbl and CytK cannot be excluded as contributing to diarrhea, and CytK can be fatal when produced in large amounts by some strains (12).

Regulation of Enterotoxin Production

The genomes of more than 400 *B. cereus* strains have been sequenced, and database searches reveal that the organization of both the *hbl* and *nhe* operons is very well conserved between strains. All three proteins of the Hbl complex

are transcribed from one operon (*hbl*) in a 5.5-kb polycistronic mRNA, transcribing *hblC* (component L_2), *hblD* (component L_1), and *hblA* (component B) (91). The three genes encoding the Nhe components, *nheA, nheB*, and *nheC*, constitute the *nhe* operon (Fig 20.2) and are transcribed in a 3.7-kb polycistronic mRNA (78). The properties of the three Nhe components are described in Table 20.6..

Regulation of transcription of the enterotoxin encoding genes is very complex, and the 5′ intergenic regions upstream of both the *nhe* and *hbl* operons harbor recognition sites for transcriptional regulators such as PlcR, CcpA, CodY, and SinR (Fig 20.2). The transcriptional activator PlcR was first identified as an activator required for transcription of *plcA* at the onset of stationary phase in *B. thuringiensis* (92) and was later recognized as a major regulator of *B. cereus* virulence (93). The PlcR quorumsensing system regulates transcription of 45 genes, where 22 are secreted proteins (mainly toxins, phospholipases, and proteases), 18 are cell wall proteins, and 5 are cytoplasmic proteins (93). The activity of PlcR depends on activation by PapR, a 48-amino-acid polypeptide with an N-terminal signal peptide sequence. PapR is secreted via the SecA pathway, processed, and then reimported into the bacterial cell via the oligopeptide permease (Opp) system (94). Crystal structure studies have revealed that PlcR is composed of an N-terminal helix-turn-helix DNA-binding domain and a C-terminal regulatory domain composed of five degenerated tetratricopeptide repeats (TPRs) (95). TPRs are structurally conserved helical domains involved in protein-protein or protein-peptide interactions (96), and when PapR binds to the TPR domain, the helix-turn-helix domain is rearranged, allowing binding to DNA (95). PapR-PlcR then binds to a specific DNA sequence called the PlcR box ($TATGNAN_4TNCATA$), located upstream from the controlled genes, resulting in upregulation of expression of *plcR* and *papR* as well as the other genes in the PlcR regulon (92, 93). The PlcR activation is strain specific, and four groups of PlcR-PapR pairs defining four different pherotypes have been identified: PlcRI, PlcRII, PlcRIII, and PlcRIV (97, 98). The strain specificity depends on PapR originating from the same strain or from a member of the same pherogroup. In *B. anthracis*, PlcR is inactivated by a nonsense mutation in the *plcR* gene (99), and consequently, genes regulated by PlcR are expressed at very low levels compared to those of *B. cereus*. Interestingly, most *B. weihenstephanensis* strains also produce enterotoxins, but usually at temperatures below 30°C (100). This temperature regulation is not under the control of the above-described (PlcR-PapR) system and has yet to be elucidated.

Table 20.6 Properties of the Nhe proteins[a]

Protein	Signal peptide size (aa)	Active protein size (aa)	Mol wt (active protein)	pI
NheA	26	360	41,019	5.13
NheB	30	372	39,820	5.61
NheC	30	329	36,481	5.28

[a]Based on reference 110.

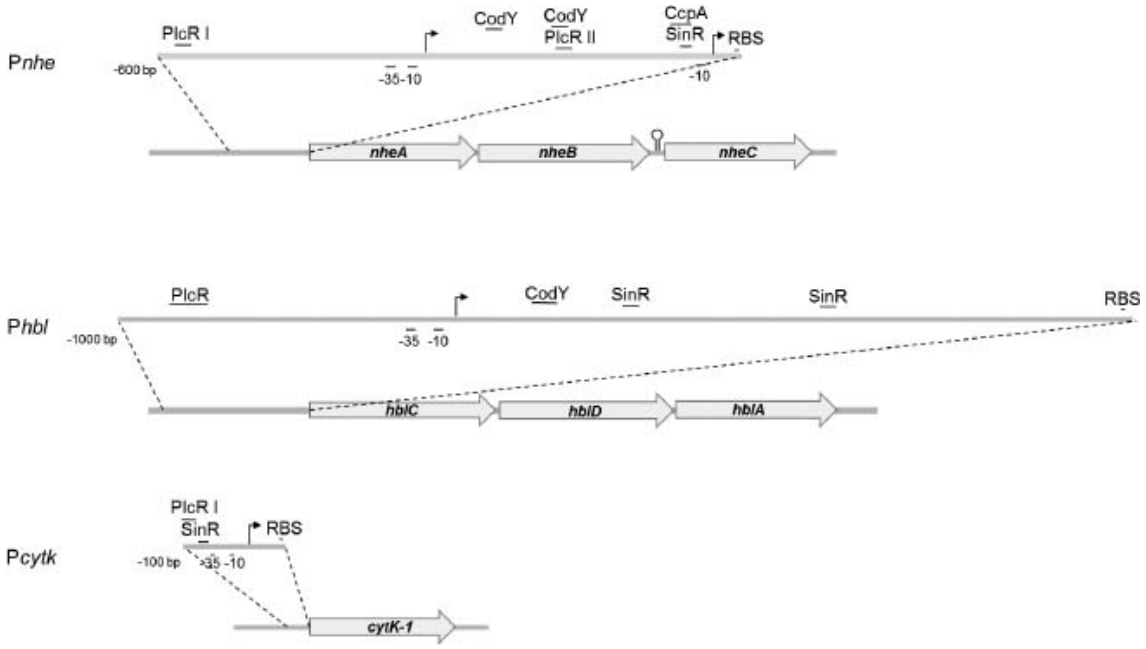

Figure 20.2 Schematic overview of the promoter regions of the three major enterotoxin operons in *B. cereus sensu lato* (109). The −35 and −10 regions and transcriptional start sites (bent arrows) (78, 92, 117, 118), CodY binding sites (109), catabolite-responsive element (Cre) (103), PlcR binding sites (78, 92, 93, 117), SinR binding sites (105, 106), and ribosomal binding sites (RBS) are indicated. The inverted repeat possibly involved in regulation of translation of *nheC* is indicated between *nheB* and *nheC* (78).

Hbl and Nhe have been suggested to be subject to catabolite repression, at least during anaerobiosis, because transcription of *hbl* is repressed by increasing concentrations of glucose (101), and growth on sucrose produces higher levels of Hbl and Nhe than growth on glucose (102). CcpA is a catabolite control protein *B. cereus* described by van der Voort et al., and they suggest that CcpA-mediated glucose sensing is involved in transcription of *nhe* and *hbl* operons (103). The position of the binding site of CcpA in the *nhe* promoter region is indicated in Fig 20.2. CcpA is also possibly involved in expression of Hbl;

however, this binding site is located in the intergenic region between *hblC* and *hblD* (103).

SinR is a master regulator of biofilm formation, and a microarray study on *B. licheniformis* biofilm revealed that SinR also controlled expression of Hbl (104). Putative SinR binding sites in the regulatory regions of the *nhe* and *hbl* operons are indicated in Fig 20.2 (105, 106).

CodY is a nutrient-sensitive regulator of transcription important for efficient production of enterotoxins in *B. cereus* (107). It has been shown that CodY activates production of the proteins of the oligopeptide permease OppABCDF in *B. thuringiensis* (108). Involvement of CodY in the control of the import of PapR allows the PlcR-PapR quorum-sensing system to integrate two types of external signals: the composition of the medium and the accumulation of the peptide. This mechanism adds another layer of complexity to the regulatory circuits which influence the expression of *B. cereus* enterotoxins. In addition, it was recently suggested that CodY may be used for strain-specific fine-tuning of enterotoxin transcription via repression in response to specific environmental conditions (Fig 20.2) (109).

Since a low concentration of NheC is crucial for full activity of the Nhe complex, regulation of *nheC* mRNA translation is of importance. The 109-bp region between *nheB* and *nheC* contains an inverted repeat of 13 bp, which most likely is important for repression of translation of *nheC* mRNA (Fig 20.2) (78, 110).

The *B. cereus* Spore

The *B. cereus* spore is an important factor in foodborne illness. First, *B. cereus* spores are more hydrophobic than spores from any other *Bacillus* sp., which enables them to adhere to several types of surfaces (111). Hence, they are difficult to remove during cleaning and a challenging target for disinfectants. *B. cereus* spores also contain appendages and/or pili (111, 112) that are, at least partly, involved in adhesion (111), although these structures also contribute to spores' ability to stick together in large aggregates. Not only can these properties of *B. cereus* spores enable them to withstand cleaning and disinfection and hence remain present on equipment surfaces to contaminate different foods, but they also contribute to adherence to epithelial cells. Studies have revealed that spores of many strains associated with foodborne outbreaks (112) can adhere to Caco-2 cells in culture and that these properties are associated with hydrophobicity and possibly with the spore's appendages (31).

Food Spoilage

As described above, *B. cereus* contamination is very difficult to avoid in many food products. Spices and other dried components (starch) typically contain from a few to more than 10^3 spores per gram; hence, many food products will be contaminated. If the final product is not sufficiently heat treated (>100°C), the spores will survive, and outgrowth will occur if the food is held at >10°C over time (over 4°C for *B. weihenstephanensis*). This is the reason for outbreaks (mainly emetic) involving heat-treated rice and pasta and even pizza stored at ambient temperatures overnight. Other lightly heattreated products may also be at risk, but most such products (e.g., those packaged sous vide) are usually stored cold and heat treated a second time at home before consumption. A special problem is pasteurized milk, in which the mesophilic strains do not grow if it is stored properly; however, *B. weihenstephanensis* grows in milk at approximately 4°C and reaches high enough cell numbers to cause what is referred to as "sweet curdling" and "bitty cream." Long before reaching this point, the number of *B. cereus* cells is high enough to cause food poisoning. However, milk is rarely associated with outbreaks of *B. cereus* food poisoning, because *B. weihenstephanensis* dominates in milk, and most of these strains (if not all) are unable to produce enterotoxin in the human gut, although they can produce the toxins at lower temperatures (100).

Commercial Methods for Detection of the *B. cereus* Toxins

No commercial kit for detection of the emetic toxin (cereulide) is yet available. However, PCR can be used for detection of the genes encoding the NRPS responsible for cereulide production (113). Screening for cereulide production by *B. cereus* strains can also easily be done by using a boar sperm motility assay (114), and a fully validated liquid chromatography-mass spectrometry detection method was recently published (115).

The Thermo Scientific Oxoid BCET-RPLA toxin detection kit is semiquantitative and measures the presence of the HblC (L_2) component in culture supernatants (116). If the kit reacts positively with the supernatant, it is likely that the strain is enterotoxin positive. If culture supernatants are also toxic for Vero cells in culture, the strains can be regarded as enterotoxin positive. At present, there is no commercial method available for detecting CytK.

CONCLUDING REMARKS

B. cereus is a normal inhabitant of soil but is also well adapted to grow in the gut of warm-blooded animals. *B. cereus* is frequently isolated from a variety of foods, including vegetables, dairy products, and meat. This bacterium causes both emetic and diarrheal food-associated illnesses that occur largely in developed countries. The diarrheal type of illness is most prevalent in the Western Hemisphere, whereas the emetic type is most prevalent in Japan and other Asian countries. Desserts, meat dishes, and dairy products are most frequently associated with diarrheal illness, whereas rice and pasta are the most common vehicles of emetic illness.

Three types of *B. cereus* enterotoxins involved in outbreaks of foodborne illness have been identified. Two of these enterotoxins, Nhe and Hbl, are structurally related three-component toxin complexes, whereas the third is a one-component protein (CytK). Some *B. cereus* strains also produce an emetic toxin, a cyclic dodecadepsipeptide, which is synthesized by a nonribosomal peptide synthetase complex. Both the emetic toxin and CytK have been involved in foodborne outbreaks with fatal outcomes.

Some strains of the *B. cereus* group are able to grow at refrigeration temperature. These variants raise concerns regarding the safety of cooked, refrigerated foods with extended shelf lives. *B. cereus* foodborne illness is likely to be highly underreported because of its relatively mild symptoms and short duration. However, precooked, chilled food products with extended shelf lives can be well suited to *B. cereus* survival and growth, and increased consumer interest in these products may increase the prominence of *B. cereus* as a foodborne pathogen.

Staphylococcus aureus

Staphylococcal food poisoning (SFP) is among the most prevalent causes of gastroenteritis worldwide. It results from ingestion of one or more preformed staphylococcal enterotoxins (SEs) in staphylococcus-contaminated food. The etiologic agents of SFP are members of the genus *Staphylococcus*, predominantly *Staphylococcus aureus*. This form of food poisoning is considered an intoxication and does not involve infection by and growth of the bacteria in the host.

The association of staphylococci with foodborne illness was made more than a century ago. Barber, in 1914, was the first to implicate a toxin in SFP (1). He reported that repeated ingestion of contaminated milk produced symptoms typical of the illness. Barber cultured the milk, demonstrated the presence of a putative causative staphylococcal agent, and provided the first evidence that a soluble toxin was responsible for the disease. The next major advance in understanding SFP etiology was reported in 1930 by Dack et al. (2); Dack voluntarily consumed supernatant fluids from cultures of "a yellow hemolytic staphylococcus" grown from contaminated sponge cake. Upon ingestion of the filtrates, he became ill with vomiting, abdominal cramps, and diarrhea. At that time, the only other foodborne toxin that had been recognized was botulinum toxin. However, staphylococcal toxin, which exerted an effect on the gastrointestinal tract, was the first true enterotoxin described. It was particularly different from botulinum toxin because its activity was "not entirely destroyed by heating even for 30 minutes at 100°C."

S. aureus has been extensively characterized. This bacterium produces a variety of extracellular products. Many of these, including the SEs, are virulence factors which have been implicated in diseases of humans and animals. As a group, the SEs elaborate a set of biological properties that enable staphylococci to cause at least two common human diseases, toxic shock syndrome (TSS) and SFP. This chapter primarily addresses SFP; however, there is significant overlap in the histories of both diseases. Hence, TSS is also discussed in sections in which this overlap is most relevant.

CHARACTERISICS OF THE ORGANISM

Taxonomy

The term "staphylococci" describes a group of small spherical, Gram-positive bacteria. Depending on the species and culture conditions, their cells have diameters ranging from approximately 0.5 to 1.5 μm. They are catalasepositive chemoorganotrophs with a DNA guanine-plus-cytosine content of 30 to 40 mol%. Staphylococci have a typical Gram-positive cell wall containing peptidoglycan and teichoic acids. Except for clinical isolates, such as some community-acquired methicillin-resistant *S. aureus* strains (3) and strains exposed to antimicrobial therapy, most staphylococci are sensitive to β-lactams, tetracyclines, macrolides, lincosamides, novobiocin, and chloramphenicol but are resistant to polymyxin and polyene. Some differential characteristics of *S. aureus* and several other selected species of staphylococci are summarized in Table 21.1.

There have been many useful schemes for classification of the staphylococci. According to *Bergey's Manual of Systematic Bacteriology* (4), staphylococci are classified in the family *Micrococcaceae*. This family includes the genera *Micrococcus*, *Staphylococcus*, *Stomatococcus*, and *Planococcus*. The genus *Staphylococcus* is further subdivided into 53 species. Many of these are present in food as a result of human, animal, or environmental contamination. Several species of *Staphylococcus*, including both coagulase-negative and coagulase-positive isolates, can produce SEs. Although several species, including some coagulase-negative staphylococci, have the potential to cause gastroenteritis (5), nearly

all cases of SFP are attributed to *S. aureus*. This is because of the relatively high prevalence of SE production by *S. aureus* in comparison to other staphylococcal species. Although the reason for this is unknown, the SEs are superantigens (SAgs) and therefore are potential immunomodulating agents (see below). Hence, SE production is proposed to provide a selective advantage to *S. aureus*, a species that is common to both humans and animals, the two most common sources of food contamination.

Enterotoxigenic strains of staphylococci have been well characterized based on a number of genotypic and phenotypic characteristics. An extensive phage-typing system is available for *S. aureus*. Most SE-producing isolates belong to phage group I or III or are nontypeable. Although SE production by other phage groups is less common, it has been documented. Hájek and Marsálek (6) developed a classification scheme based largely on the animal host of origin. They were able to differentiate *S. aureus* into at least six biotypes. By far, SE production was most prevalent among human isolates within biotype A. SE production by other biotypes is rare, except for biotype C bovine and ovine mastitis isolates. SEs may also be produced by *Staphylococcus intermedius* and *S. hyicus* (formerly *S. aureus* biotypes E and F, respectively) and coagulase-negative staphylococci, albeit considerably less frequently than *S. aureus*.

Physiology

Some unique resistance properties of *S. aureus* facilitate its contamination and growth in food. Of the non-sporeforming human pathogens, *S. aureus* is one of the most resistant to environmental stress outside the body and can survive for extended periods in a dry state. Its survival is facilitated by organic material, which is likely to be associated with the staphylococci from an inflammatory lesion. Isolation of staphylococci from air, dust, sewage, and water is relatively easy, and environmental sources of food contamination have been documented in several outbreaks of SFP. The physiological characteristics of *S. aureus* are summarized in Table 21.2.

Table 21.1 General characteristics of selected *Staphylococcus* species[a]

Characteristic	*S. aureus*	*S. chromogenes*	*S. hyicus*	*S. intermedius*	*S. epidermidis*	*S. saprophyticus*
Coagulase	+	–	+	+	–	–
Thermostable nuclease	+	–	+	+	±	–

Mannitol	+	±	–	±	–	±
fermentation Novobiocin resistance	–	–	–	–	–	+

[a] +, positive; –, negative; ±, variable; ND, not determined.

Table 21.2 Physiological limits for the growth of *S. aureus* and SE production (179–183)

Parameter[a]	Growth		SE production		SEs affected	Food products
	Optimal	Limit	Optimal	Limit		
Temp (°C)	35–41	6–48	34–40	10–46	SEA, SEB, SEC, SED	Milk, ham, egg products
pH	6–7	4–10	7–8	5–9.6	SEA, SEB, SEC, SED, SEE	Ham, sausage
a_w	0.99	0.83–0.99	0.99	0.86–0.99	SEA, SEB, SEC, SEH	Bacon, sausage
NaCl (%)	0	0–20	0	<12	SEA, SEB, SEC	Ham, sausage
Oxygen	Aerobic	Facultatively anaerobic	Aerobic	Facultatively anaerobic	SEA, SEB, SEC, SEH	Ham, sausage

[a] a_W, water activity.

The growth temperature for *S. aureus* ranges from 6 to 48°C, with optimum growth at 35 to 41°C. The upper limit of the growth temperature can be extended in the presence of NaCl and monosodium glutamate (7). *S. aureus* is facultatively aerobic and still can grow in the presence of 80% CO_2 (8). The pH tolerance ranges from 4 to 10, with optimal growth at pH 6 to 7. The acid tolerance of *S. aureus* is significantly decreased in the presence of glycerol, sucrose, potassium sorbate, and NaCl (9). *S. aureus* is known for acquiring genetic resistance to heavy metals and antimicrobial agents used in clinical medicine. However, the resistance of this bacterium to common food preservation methods is generally unremarkable. One noteworthy exception is its osmotolerance, which permits growth in media containing the equivalent of 3.5 M NaCl and survival at water activities less than 0.86. This is especially problematic, because other bacteria with which *S. aureus* does not compete effectively are likely to be inhibited under these conditions.

The molecular basis for staphylococcal osmotolerance has been investigated in recent years, although systems for responding to osmotic stress have been more intensively studied in less tolerant bacteria. Considering the unique resistance of staphylococci, it would not be surprising to find that they have developed a highly efficient osmoprotectant system. As in other bacteria, several compounds accumulate in the cell or enhance staphylococcal growth under osmotic stress. Glycine betaine appears to be the most important osmoprotectant for *S. aureus*. To varying degrees, other compounds, including l-proline, proline betaine, choline, and taurine, can also act as compatible solutes for this bacterium. In *S. aureus*, proline and glycine betaine accumulate to very high intracellular levels in response to increased concentrations of NaCl in the environment. Although the signal transduction pathway in staphylococci is not known, in other bacteria it involves a loss in turgor pressure in the cell and activation of required transport systems. High-affinity and low-affinity transport systems operate in *S. aureus* for both proline and glycine betaine (10, 11). The low-affinity systems are primarily stimulated by osmotic stress, have broad substrate specificity, and may be the same transporter shared by both osmoprotectants. By itself, the demonstration of a stress response system in *S. aureus* does not explain the unusual staphylococcal osmotolerance. Other, less tolerant microorganisms possess mechanisms for counteracting osmotic stress. The efficiency of the staphylococcal system may reflect an unusually high endogenous level of intracellular K^+ and lack of need for *de novo* transporter synthesis. For example, in other well-studied systems, such as that of *Escherichia coli*, changes in osmotic stress activate K^+ transport systems. The elevated intracellular K^+ levels that result are required for induction of *proU* and eventually lead to synthesis of transporters for glycine betaine and other osmoprotectants. In *S. aureus*, K^+ levels are high in unstressed cells. Therefore, the transport system is constitutively present in this bacterium and is preformed when high-salt conditions are encountered. The net result is a very rapid and efficient response. *S. aureus* cells accumulate a 21-fold increase in proline after less than 3 minutes of exposure to high salt concentrations (10).

Reservoirs

Humans are the main reservoir for staphylococci involved in human disease, including *S. aureus*. Although most species are normal inhabitants of the external regions of the body, *S. aureus* is also a leading human pathogen. Colonized individuals may be carriers and are an important source for disseminating staphylococci to others and to food. In humans, the anterior nares are the predominant site of colonization, although *S. aureus* can be present on other sites, such as the skin or perineum. Dissemination of *S. aureus* among humans and from humans to food can occur by direct contact, indirectly by skin fragments, or through respiratory tract droplet nuclei.

Today, most sources of SFP are found to be humans who contaminated food during preparation. In addition to contamination by food preparers who are carriers, *S. aureus* may also be introduced into food by contaminated equipment used in food processing, such as meat grinders, knives, storage utensils, cutting blocks, and saw blades. An analysis of more than 700 foodborne disease outbreaks revealed that the following conditions were most often associated with food poisoning: (i) inadequate refrigeration; (ii) preparation of foods far in advance; (iii) poor personal hygiene, e.g., not washing either hands or instruments properly; (iv) inadequate cooking or heating of food; and (v) prolonged use of warming plates when serving foods, a practice that promotes staphylococcal growth and SE production (12).

Animals, also an important source of *S. aureus*, are often heavily colonized with staphylococci. Predisposing factors which facilitate the survival of the bacterium are major concerns in the maintenance and processing of food animals and their products. For example, one very serious problem for the dairy industry is mastitis, an infectious disease of mammary tissue often caused by *S. aureus*. The combined losses and expenses associated with bovine mastitis make it the single most costly disease of animal agriculture in the United States. Colonization of animals by *S. aureus* is also a public health concern because it may result in contamination of milk and dairy products with *S. aureus* prior to or during processing.

It is not always possible to trace the source of staphylococcal food contamination to a human or animal origin. Regardless of its source, many studies have revealed the common presence of *S. aureus* in many different types of food products. In Canada, *S. aureus* was obtained from 10.5% (73/693) of food samples, including 29 meats, 20 prepared foods containing meat, 11 prepared foods not containing meat, 10 dairy products, and three produce samples, between 2007 and 2010 (13). In China, a study of 27,000 retail food items from 203 cities of 24 provinces revealed that 4.3% of the samples (1, 150) were positive for *S. aureus*. From this study, 9.4% of the positive samples were from poultry meats, 7.2% were from red meats, and 3% were from rice and flour products (14). In the European Union, 15.7% (136/868) of food products confiscated from travelers, including antelope, duck, guinea pig, pork, turkey, dairy, and eggs, were positive for *S. aureus* (15). In the United Kingdom, 53% of SFP incidents reported between 1969 and 1990 were associated with meat products, meat-based dishes, and especially ham; 22% of the cases were from poultry and poultry-based meals; 8% were from milk products; 7% were from fish and shellfish; and 3.5% were from eggs (16). In France, 32% of instances of SFP reported in 1999 to 2000 were associated with milk products and especially cheeses, 22% were from meats, 15% were from sausages and pies, 11% were from fish and seafood, 11% were from eggs and egg products, and 9.5% were from poultry (17). In the United States, 36% of SFP cases reported between 1975 and 1982 were associated with red meat, 12.3% with salads, 11.3% with poultry, 5.1% with pastries, and only 1.4% with milk products and seafood (18). The cell numbers of staphylococci in these sources are often low initially. However, their widespread presence provides a potential source of bacteria capable of causing SFP if conditions appropriate for SE production are provided.

CHARACTERISTICS OF SEs

Classification of SEs

Major advances in the characterization of SEs were made approximately 2 decades after Dack and colleagues (2) associated SFP with an exotoxin. Bergdoll and coworkers were the first investigators to

produce purified SE preparations and develop specific antisera. They and others, using purified or partially purified toxins, induced protective antibodies in several species of animals. Immunity was strain specific and did not provide protection against strains other than the one that was used to induce the initial immune response (19). It soon became apparent that *S. aureus* could produce multiple toxins with similar molecular weights as well as biological and physicochemical properties.

Initially, differentiation between antigenic forms of SE was based on the observation that many food isolates produce one common antigenic type of toxin, tentatively designated the F-type toxin. Most other enterotoxigenic strains, such as those from enteritis patients, also produced a second antigenic form that was classified as E toxin. The discovery of additional isolates that did not conform to this pattern prompted adoption of an improved nomenclature system. A committee assembled in 1962 established an alphabetical nomenclature (20) which, with some modification (21), is still recommended. Accordingly, SEs are sequentially assigned a letter of the alphabet in the order of their discovery. The F and E type toxins were designated SEA and SEB, respectively. Between 1962 and 1972, three additional classical SE serotypes (SEC, SED, and SEE) were reported (22). Initially, the term "SEF" was used for an exotoxin commonly produced by isolates of *S. aureus* associated with TSS. This designation was changed when the toxin was confirmed to lack emetic activity. "SEF" was retired from use in the SE nomenclature system, and this toxin is now referred to as toxic shock syndrome toxin 1 (TSST-1) (23).

Designation of SEs based on serological typing has been useful. However, sequence analysis and detailed immunological studies have produced some examples in which the antigenic characteristics of the proteins do not reflect their molecular or biological uniqueness. The best-documented examples are with SEC. It had been observed for some time that the SEC serological variant can be further divided into at least three subtypes (SEC1, SEC2, and SEC3) based on minor differences in immunological reactivity. However, within each subtype, significant sequence variability may occur. For example, the SECs produced by strains FRI-909 and FRI-913 were both designated SEC3 according to their immunological reactivity. However, it was later determined that the sequences of these toxins differ by nine residues (24). The SEC variants produced by bovine and ovine isolates of *S. aureus* have very similar sequences and are apparently indistinguishable from SEC1 in immunological assays. In contrast, they behave differently from SEC1 in biological assays. For example, although SEC-bovine differs from SEC1 by only three residues, the potencies of the two toxins differ by several orders of magnitude in lymphocyte proliferation assays (24). Examples of heterogeneity among both the classical SEs and newly described toxins are becoming more common with the rapid rate of sequence determinations.

Designation of SEs based on serological typing has been useful. However, sequence analysis and detailed immunological studies have produced some examples in which the antigenic characteristics of the proteins do not reflect their molecular or biological uniqueness. The best-documented examples are with SEC. It had been observed for some time that the SEC serological variant can be further divided into at least three subtypes (SEC1, SEC2, and SEC3) based on minor differences in immunological reactivity. However, within each subtype, significant sequence variability may occur. For example, the SECs produced by strains FRI-909 and FRI-913 were both designated SEC3 according to their immunological reactivity. However, it was later determined that the sequences of these toxins differ by nine residues (24). The SEC variants produced by bovine and ovine isolates of *S. aureus* have very similar sequences and are apparently indistinguishable from SEC1 in immunological assays. In contrast, they behave differently from SEC1 in biological assays. For example, although SEC-bovine differs from SEC1 by only three residues, the potencies of the two toxins differ by several orders of magnitude in lymphocyte proliferation assays (24). Examples of heterogeneity among both the classical SEs and newly described toxins are becoming more common with the rapid rate of sequence determinations.

Compared to the rate of identification of the classical SEs (SEA through SEE), modern genomic analysis has greatly increased the rate at which previously unrecognized SEs and related proteins are discovered. As a result, classification based solely on antigenic properties is not practical. Instead, nomenclature is now based predominantly on molecular relatedness of the primary sequences.

Furthermore, it is not common to confirm the enterotoxigenic activities of putative SEs prior to publication. As a result, some toxins originally reported to be SEs were later determined to lack emetic activity. To ensure an orderly assignment for newly identified confirmed or putative toxins, investigators should contact the International Nomenclature Committee for Staphylococcal SAgs (INCSS) for guidance prior to publication (21). The INCSS also recommends that proteins related to the SEs but not confirmed to exhibit emetic activity in the monkey feeding assay (see below) be designated SE-like (SEl) until their enterotoxic activity can be confirmed. Thus far, 25 SEs and SEl proteins have been reported and designated SEA through SEZ except SEF. The primary sequences and other properties of currently reported SEs and SEl proteins are summarized in Fig. 21.1 and Table 21.3 (24–34).

Based on amino acid sequence alignment, currently known members of the SE family are divided into four groups (Fig. 21.2). Group 1 comprises the closely related toxins SEA, SEP, and SEE, as well as SEIJ, SED, SElW, SEH, SES, SEN, and SEO, which are more distantly related. Group 2 contains SEB, the SEC subtypes, and the molecular variants SEG, SER, SElU, and SElZ. Group 3 contains SEI, SEL, SEK, SEM, SElV, and SEQ. Group 4 contains SET, SElY, SElX, and TSST-1, which are smaller than the other SEs.

Most SEs, SEl proteins, and TSST-1 contain four highly conserved stretches of primary sequence (35). This suggests that there is a selective advantage in host-pathogen interactions for these bacteria to maintain certain toxin characteristics. At the same time, modification of selected regions of the proteins could allow the bacteria to broaden their host range. This molecular diversity may explain how a group of toxins with the same function but different host specificities could have arisen for the purpose of exploiting a broader repertoire of receptors.

Sequence comparisons of members within the SAg family have provided several examples where diversity among the toxins appears to have arisen through gene duplication and/or homologous recombination. For example, SEC1 is most related to SEC2 and SEC3. However, residues 14 through 26 of SEC1 (Fig. 21.1) are identical to the analogous region of SEB but substantially different from the same region in the other SEC subtypes (30). Genetic recombination between *seb* and *sec* in a strain producing both SEB and SEC2 (or SEC3) could explain the generation of SEC1.

Additional minor variabilities have resulted from point mutations; even closely related SEs display some sequence differences. This may reflect fine-tuning of the toxin sequences for interacting with cells from a variety of hosts, as observed for the SEC subtype variants. The sequences of SEC toxins produced by strains of *S. aureus* isolated from humans differ slightly (>95% identity) from sequences of SEC variants produced by bovine and ovine isolates (24).

Locations of SE Genes

Most SE and SEl-protein genes are located on accessory genetic elements, such as prophages, plasmids, staphylococcal pathogenicity islands (SaPIs), genomic islands, or staphylococcal chromosomal cassettes (Table 21.3). Most of these are mobile genetic elements which can be horizontally transferred among *S. aureus* isolates, thereby modifying their virulence and contributing to pathogenic evolution (36, 37).

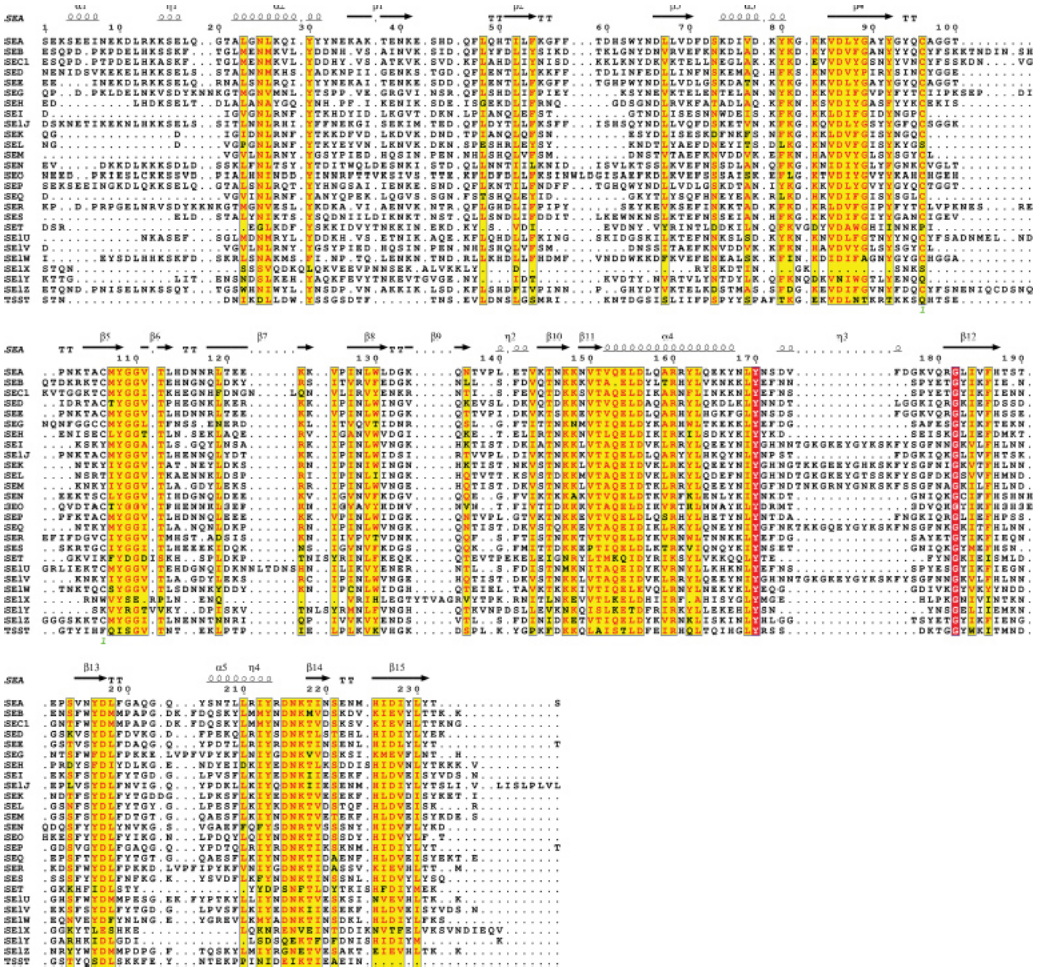

Figure 21.1 Alignment of primary sequences of mature SEs and SEl proteins in the current literature. Sequence alignment and output were conducted using the ClustalW program (177). The secondary structure was aligned to SEA (66).

Most *S. aureus* prophages carrying SEs belong to the family *Siphoviridae*, whose members have an integrase that inserts the phage genome at a specific site (the *att* site) in the bacterial chromosome. To date, at least six fully sequenced *S. aureus* strains carrying different temperate phages harboring the SE genes have been identified (38). The genes *sea*, *sek*, and *sek* are carried in ϕSa3ms and ϕSa3mw, whereas other phages carry the *sea* (ϕMu50a) or *sep* (ϕSa3n) gene alone. Plasmids are one of the main mechanisms for spreading virulence genes by bacteria. The *sed* gene was the first SE gene to be identified as plasmid encoded. Bayles and Iandolo reported that in more than 20 characterized *sed*$^+$ isolates, the *sed* structural gene is localized to a stable 27.6-kb plasmid (pIB485), which also encodes penicillin and cadmium resistance (25). Subsequent studies also revealed that pIB485-related plasmids harbor the genes for SElJ, SER, SES, and SET (39, 40).

Table 21.3 Biochemical and functional properties of SEs, SEl proteins, and TSST-1[a]

SE or SEl Protein[b]	Mol mass (kDa)	Genetic locations	Zinc site(s)	Binding to MHC α/β chain	Human TCR interactions[c]	Emesis tested animal	Emetic dose (μg/kg)	No. positive/no. tested	Referenc

[a] ND, not determined; NA, not available.

[b] Nomenclature used in this table follows the new nomenclature rule of the INCSS (75).

[c] Unless otherwise indicated, numbers indicate TCR Vβ elements.

[d] Toxins were prepared from *E. coli*.

The SEC and SEB genes are also associated with transmissible penicillin resistance plasmids (41). However, it is now generally agreed that both of these toxins are chromosomally encoded and harbored on SaPIs in most strains. The SaPIs are widely distributed in *S. aureus* and have a highly conserved genetic structure. Each SaPI has a single copy of the integrase gene and a module for excision and replication in the presence of helper phages which induce excision and packaging of SaPIs into transducing phage particles, resulting in a high frequency of horizontal transfer (36, 37). Genome sequencing revealed more than 20 SaPIs, with many of them carrying SE genes. The *seb* gene is carried on SaPI3 (42), whereas the *sec*, *sel*, and *tst* genes are carried on SaPI4 and SaPIbov (43). SaPI1 carries the *sek*, *sel*, and *tst1* genes (41).

Uniquely present in the *S. aureus* chromosome are genomic islands that occupy specific loci and carry various combinations of virulence factors with either intact or remnant DNA recombinases (44, 45). Two genomic islands, vSaα and vSaβ, are present in all *S. aureus* genomes sequenced to date. vSaα carries a cluster of lipoprotein genes (*lpl* cluster) and the staphylococcal SAg-like cluster (*ssl* cluster) (46). The *ssl* cluster comprises a series of related genes (7 to 11) encoding SAglike proteins which are not superantigenic but are capable of modulating the host immune system by interaction with IgA, C5, or neutrophils (47). vSaβ carries a serine protease gene (*spl*) cluster, leucocidin D and E genes, lantibiotic biosynthesis genes (*bsa*), and/or an enterotoxin gene cluster (*egc*), which includes various

combinations of five or six SE genes (*seg*, *sei*, *sem*, *sen*, *seo*, and *selu*) (43, 48). The *egc* cluster has been proposed to be a nursery of new toxin genes that has created variant SEs, such as those encoded by *selv* and *selw*, by gene recombination (33, 49). It has long been postulated that genomic islands are not mobile; however, recent studies revealed that a temperate phage, ϕSaBov, in *S. aureus* strain RF122 induces specific excision of vSaα, vSaβ, and vSaγ genomic islands, packages them to transducing phage particles, and horizontally transfers them to other *S. aureus* strains at high frequency (50, 51). Importantly, the *egc* cluster proteins have become the most prevalent SEs in *S. aureus* isolates, suggesting an important role for phage-mediated transfer of *egc* in the pathogenic evolution of *S. aureus*.

Basic Biophysical and Structural Features

SEs and SEl proteins are globular proteins of approximately 25 kDa. SE sequence analysis, relatedness, and diversity are discussed above (Fig. 21.1 and 21.2 and Table 21,3). Although detailed studies have not been performed with every toxin, as a group they are stable molecules in many respects. Their recognition as heatstable toxins arose from early studies in which enterotoxicity and antigenicity were not completely destroyed upon boiling of crude preparations. Furthermore, less extreme temperature treatments, such as those used for the pasteurization of milk, had little or no effect on SE toxicity. The heat resistance of the SEs has been extensively studied. The general conclusion from this combined work is that SEs are difficult to inactivate by heating and have increased stability when present in high concentrations or in crude states, such as in the environment of food. Since temperatures required to inactivate SEs are much higher than those needed to kill *S. aureus* under the same environmental conditions, toxic food involved in many cases of SFP is devoid of viable staphylococci at the time of serving. One additional property of SEs that has potential significance with regard to development of SFP is their resistance to inactivation by proteases present in the gastrointestinal tract. Resistance to pepsin, especially in a relatively low-pH environment, is a key requirement for SE activity *in vivo*. Each of the SEs tested has some resistance to pepsin, a property not shared by at least one nonemetic staphylococcal pyrogenic toxin (PT), TSST-1. SEB is susceptible to degradation by pepsin at very low pH, but partial neutralization of gastric acidity by ingested food is presumed to temporarily provide a protective environment for the toxin (1).

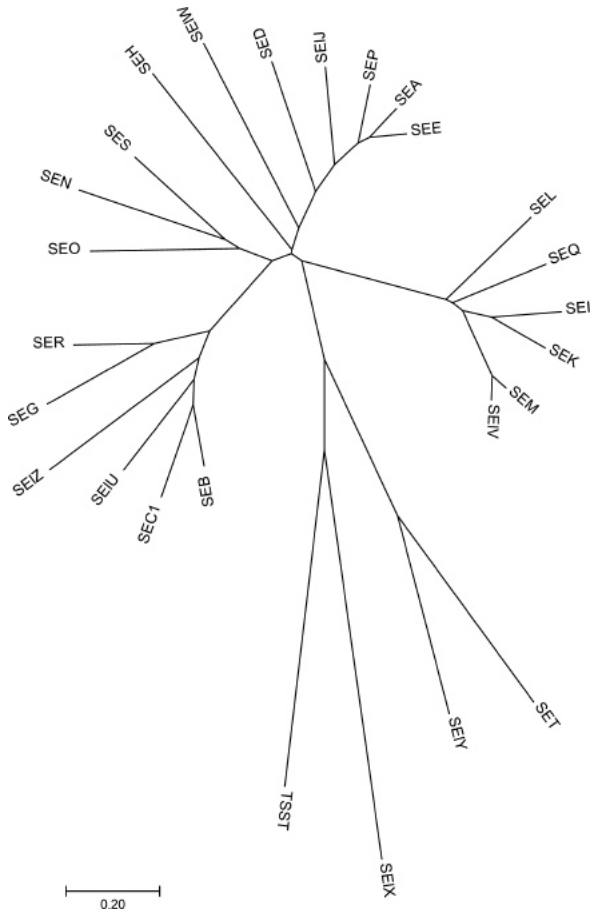

Figure 21.2 Neighbor-joining tree based on the sequences of currently known SEs, SEl proteins, and TSST-1. This tree was created with the clustering feature of Clustal W using MEGA 4.0.1 software (178).

SEs may be cleaved by other common proteases; however, unless the fragments generated are separated in the presence of denaturing agents, proteolysis alone may not be sufficient to cause a loss of biological activity. This is apparently representative of inherent SE molecular stability, which can be demonstrated by renaturing studies. For example, denaturation occurs only under strong denaturing conditions employing high concentrations of urea or guanidine hydrochloride. If the denaturing conditions are removed, SEs may spontaneously renature and regain biological activity (52). Differences in stability exist among the toxins. For example, SEB and SEC1 are approximately 50-fold more stable under denaturing conditions than SEA (53). It has been suggested that the SE disulfide bond is responsible for its inherent molecular stability. Several investigators have determined that the closed disulfide bond does contribute at least some degree of conformational stabilization but that its disruption has only minimal effects on the overall stability and activity of the molecule (54) (see below).

SEs Are SAgs and Belong to a Large PT Family

In discussing the genetics and evolution of the SEs, one must also consider other staphylococcal toxins, plus some toxins produced by other bacteria, especially group A streptococci. SEs are part of a large family of related PTs produced by *S. aureus* and *Streptococcus pyogenes* (55). Members of this family are grouped together based on shared biological and biochemical properties. The one feature common to all PTs, including SEs, is their unique ability to act as SAgs (56). SAgs are molecules that stimulate an exceptionally high percentage of T cells. The mechanism by which this occurs distinguishes them from mitogens and conventional antigens (Ags). Regarding T-cell stimulation, SAgs are bifunctional

molecules that interact with major histocompatibility complex class II (MHCII) molecules on Ag-presenting cells (APCs). Unlike with conventional Ags, this interaction does not require processing and occurs outside of the MHCII peptide-binding groove (Fig. 21.3). The MHCIISAg complex interacts with the T-cell receptor (TCR). The interaction with the TCR is also nonconventional and relatively nonspecific; for most SAgs, binding occurs at a variable location on the TCR β chain (the Vβ region). Since SAgs bind outside the area on the TCR used for Ag recognition, they activate a much higher percentage of T cells than can be activated by conventional Ags. However, compared to mitogens, which stimulate T cells in an indiscriminate manner, there is some degree of specificity in SAg action, because only certain Vβ (or rarely Vα) sequences are recognized. Hence, not all T cells are stimulated. The binding of SAgs with the TCRCD3 complex activates the Src family of protein kinases, including Lck and ZAP-70, which subsequently activates phospholipase C gamma, resulting in the activation of diacylglycerol and protein kinase C (57, 58). Protein kinase C activates downstream signaling pathways, including the mitogen-activated protein kinase, NF-κB, p38, extracellular signal-regulated kinase, and Jun N-terminal protein kinase, which induce expression of many proinflammatory cytokines and chemokines, such as interleukin 1 (IL-1), tumor necrosis factor alpha, gamma interferon, IL-2, IL-6, and monocyte chemoattractant protein 1 (59). Recent studies revealed that SAgs also directly bind to CD28, thus activating phosphatidylinositol 3-kinase–Akt–mTOR pathways, which modulate many biological processes, including cell growth, differentiation, proliferation, survival, migration, and metabolism (60–62).

The staphylococcal and streptococcal PTs are prototype microbial SAgs that exert a variety of immunomodulatory effects leading to shock, immunosuppression, and other systemic abnormalities associated with TSS. While SEs are included with the PTs, they have the unique distinction of possessing an additional ability to induce an emetic response upon oral ingestion and are thus solely responsible for SFP. It is generally agreed that many of the toxins in this family, including members of the SE family, arose from a common ancestral gene which crossed the genus barrier and became stably introduced in both the genera *Staphylococcus* and *Streptococcus*. This idea is strongly supported by the observation that the structural genes for some SEs and related streptococcal PTs are carried on discrete genetic elements (see below).

Three-Dimensional Structure

Despite their sequence diversity with only partial sequence conservation, structural studies revealed that threedimensional topology of the SEs is remarkably similar (63). The molecule has an overall ellipsoidal shape and is folded into two domains of amino- and carboxy-terminal domains which are connected by α-helices in the center (Fig. 21.4). The amino-terminal domain, domain 1, contains residues near the N terminus but not the N-terminal residues themselves. The folding conformation of this domain may have potential significance for the function of the toxin. Its topology, in which a β-barrel structure is capped at one end by an α-helix, is known as the oligonucleotide/oligosaccharide-binding (OB) fold. The internal portion of its β-barrel is rich in hydrophobic residues, and the potential oligomer binding surface is covered with mainly hydrophilic residues. This OB folding pattern is found in staphylococcal nuclease and the B subunit of AB_5 heat-labile enterotoxins, such as cholera toxin, pertussis toxin, and Shiga toxin (64), which share the feature of exerting their activity by interacting with either oligosaccharides or oligonucleotides. The other prominent feature of domain 1 is that in most toxins of this family it contains two cysteine residues responsible for forming the disulfide linkage characteristic of most SEs. This bond and the cysteine loop are located at the end of the domain opposite its α-helix cap. Crystallographic data for SEA, SEB, and SEC3 indicate that the loop regions of all three toxins are quite flexible (63, 65, 66).

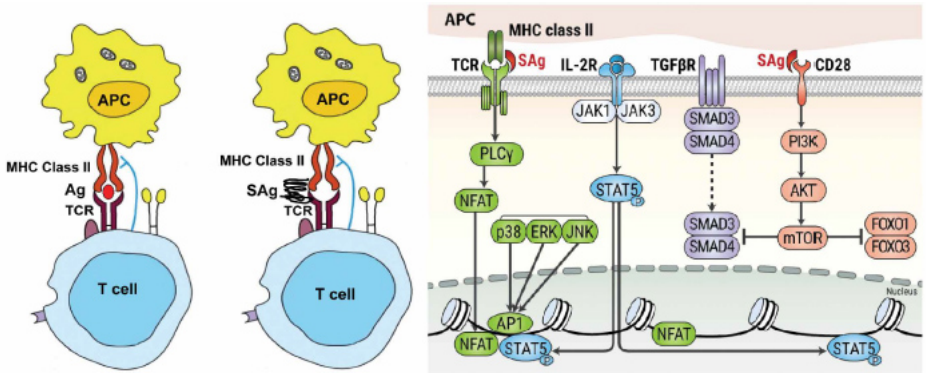

Figure 21.3 Interactions between APCs and T cells facilitated by conventional Ags and SAgs. The binding of SAg with TCR-MHCII triggers activation of signaling cascades through Lck-dependent and Lck-independent pathways, leading to the activation of transcriptional factors that induce T-cell proliferation, cytokine production, and proinflammation. TGFβR, transforming growth factor beta receptor; PLCγ, phospholipase Cγ; ERK, extracellular signal-regulated kinase; JNK, Jun N-terminal protein kinase; NFAT, nuclear factor of activated T cells; PI3K, phosphatidylinositol 3-kinase; mTOR, the mechanistic target of rapamycin; AKT, protein kinase B.

The larger carboxy-terminal domain (domain 2) can be described as a five-strand antiparallel β-sheet wall overlaid with a group of α-helices forming a β-grasp motif. It has structural similarity to the immunoglobulin-binding motifs of streptococcal proteins G and L, ubiquitin, $2F_2$-2S ferredoxin, and the Ras-binding domains of the Ser/Thr-specific protein kinase Raf-1 (67, 68). The structural similarities among SEs and other bacterial proteins suggest that SEs evolved through the recombination of these proteins (69).

Zinc Binding

Biochemical and structural studies on SEs have revealed that some SEs are dependent on zinc ions to be functional and to be able to properly bind MHCII. Fraser et al. (70) determined that SEA and SEE bind zinc via a single site, with a dissociation constant of 1 to 2 μM. The binding site was subsequently predicted by mutagenesis of SEA to be composed of a nonlinear stretch of residues (H187, H225, and D227) in the concave β-sheet within the C-terminal domain and an N-terminal serine in the metal coordination (Fig. 21.4) (66). Crystallographic analysis of SEA crystals soaked in 10 mM $ZnCl_2$ revealed a second zinc-binding site, which is similar to the SEC2 site (see below). It is coordinated by D86 and H114 (corresponding to D83 and H118 in SEC2), a water molecule replaces the second histidine residue in SEC2 (H122), and E39 is analogous to D9 in SEC2 (Fig. 21.4) (71).

SEC2 and SEC3 bind zinc through a low-affinity mechanism (65, 72). The zinc ion is tetrahedrally coordinated by D83, H118, and H122 from one molecule and D9 from a neighboring molecule. The zinc-binding site is located in a classical motif (H-E-X-X-H) at the cleft in the α5 groove of SEC3 between the two domains. This zincbinding motif is typically in the catalytic site of metalloenzymes such as thermolysin (73) and in certain other bacterial protease-dependent toxins, such as botulinum and tetanus neurotoxins (74). However, none of the SEs is known to possess protease activity. Although the function of zinc in SEC is not certain, it has been suggested that it plays a minor role in stabilizing the toxin structure.

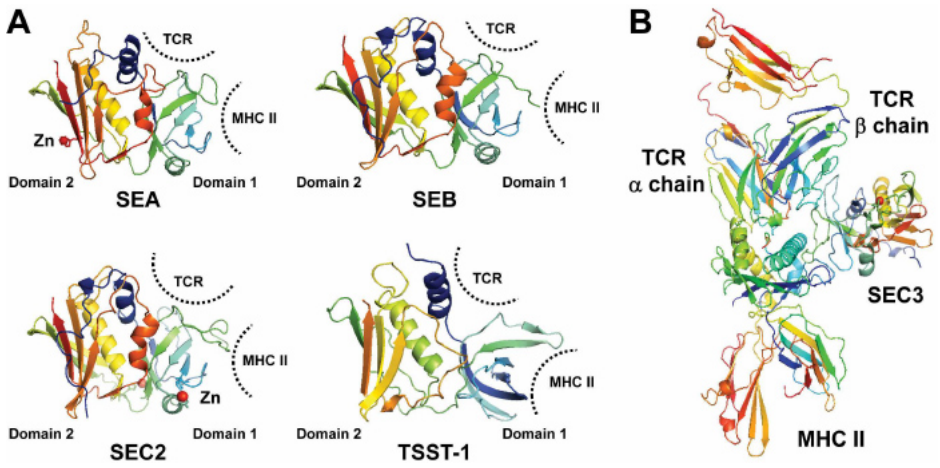

Figure 21.4 (A) Schematic diagrams of SEA, SEB, SEC2, and TSST-1 crystal structures. Domain 1 contains highly conserved, low-affinity binding sites for TCR Vβ and MHCII at generic sites. (B) Hypothetical model of the MHCII-SEC3-TCR complex based on modeling predicted from the crystal structures of the SEC3-HLA-DR1 and SEC3-Vβ complexes.

Crystallographic studies revealed that SED binds two zinc ions and forms a homodimer in a zinc-dependent manner (75). One zinc ion is tetrahedrally coordinated by D182, H220, and D222 from one molecule and H218 from the other molecule, which allows it to bind both MHCII α and β chains (see below). The second zincbinding site is similar to that in SEC2.

Binding to MHCII Molecules

Despite their structural similarities, the mechanisms by which various SEs bind MHCII are diverse. SEs interact with MHCII in three ways: (i) binding a single α chain of MHCII, (ii) binding a single β chain of MHCII, or (iii) cross-linking two MHCII molecules.

The first type of SE binding is to the α chain of MHCII. SEB, SEC1, SEC2, SEC3, and TSST-1 bind in this manner and share a common MHCII-binding site at domain 1 (referred to as the generic site), with a comparatively low affinity (0.4 to 0.7 μM) (Fig. 21.4). The crystal structure of the SEB-HLA-DR1 complex revealed that one major interaction is mediated by a salt bridge provided by Glu67 of SEB and Lys39 on HLA-DR1 (76). Although SEC2 and SEC3 are able to bind zinc, crystal structure data and site-directed mutagenesis studies revealed that the zinc ion is not involved in the MHCII interaction (77).

The second type of interaction is with the β chain of MHCII. A crystal structure of SEH complexed with HLA-DR1 revealed that toxin interacts with the β chain of the receptor, and binding requires its bound zinc ion (78). The cross-linking of the zinc ion plays an important role in the interaction of SEH and HLA-DR1 by providing a cross-link through His81 on HLA-DR1 and through His206 and Asp208 on SEH.

The third type of interaction involves SE cross-linking of two MHCII molecules. SEA has a low-affinity MHCII α-chain-binding site which overlaps that of SEB and TSST-1, plus a high-affinity site on the outside of domain 2 near the N terminus (79). The SEA highaffinity site involves coordination of zinc through three toxin residues (His187, His225, and Asp227) and His81 of the MHCII β chain. Two MHCII-binding sites per toxin allow two MHCII molecules to be cross-linked (80) (Fig. 21.4). Similar modes of action, including formation of homodimers by some toxins, have been proposed for other SEs with high-affinity zinc-binding sites on the outer face of domain 2 (SED and SEE) (75, 81).

Binding to TCRs

SEs and other SAgs interact with a characteristic repertoire of TCR sequences (Table 21.3). The TCR specificity of each SE is determined by toxin residues in the shallow cavity at the top of the molecule (82). Crystallographic analysis of a molecular complex between SEC3 and a portion of the murine TCR

β chain (83) revealed that the toxin binds to the CDR1, CDR2, and HV4 loops of Vβ. Modeling permitted the deduction of a trimolecular complex model containing the SAg bridging the T cell and APC. Using SEC3 and SEB, this model shows that these toxins form a "wedge" between the TCR and the MHCII, orienting the peptide-binding cleft away from the TCR (Fig. 21.4B). Although different SAgs are predicted to bind with variations of this theme, in general, SAg-binding results in receptor interactions significantly different from that in typical Ag presentation. The overall affinity of the entire complex determines the effectiveness of the stimulation (84), and binding by toxins with low affinity for the TCR can be compensated for by stronger binding to MHCII, and vice versa. SEH appears to have the most divergent mechanism of binding and T-cell stimulation. This toxin binds to MHCII with a mechanism that does not allow efficient interactions between SEH and the TCR Vβ, or between MHCII and Vβ. In one study (85), SEH stimulated T cells by interacting with TCR Vα (Vα10), and Vβ-specific expansion was not observed.

SE Mode of Action in Induction of Emesis and Related Symptoms in SFP

Molecular Regions of SEs Responsible for Enterotoxicity

The structural aspects of SEs that enable them to survive degradation by pepsin and other enzymes in the gastrointestinal tract are required for the toxins to induce SFP. However, stability alone is not sufficient. SEs must also be able to interact with the appropriate target, leading to emesis, diarrhea, and other gastrointestinal tract symptoms. Initial attempts to define molecular regions responsible for enterotoxicity involved testing biological activity of protease-generated fragments derived from SEA, SEB, or SEC1 (52). Three main conclusions were drawn from this work. First, only large toxin fragments containing central and C-terminal portions of the SEs retained enough of the native structure to cause emesis. Second, N-terminal residues of the SEs were not required for emesis. A form of SEC1 with the 59 N-terminal residues removed retains the ability to cause emesis in monkeys. Smaller toxin fragments from SEC1 and other SEs were inactive. The third conclusion was that emesis seemed to require preservation of structure in the conserved SE disulfide loop.

The disulfide bond is a structural feature that is characteristic of most, but not all, SEs. The disulfide bond has long been associated with emesis and is not present uniformly in nonemetic staphylococcal and streptococcal exotoxins. With a few known exceptions, SEs contain exactly two cysteine residues which could potentially form an intramolecular linkage and a spacer disulfide loop. SEG and the SEC molecular variant produced by isolates from sheep (SEC-ovine) deviate from this pattern and possess an additional third cysteine (Fig. 21.5). There is speculation regarding the importance in emesis of the disulfide bond, which is located near the center of every classical SE and most other SEs. Data from analyses of recently identified SEs and SEl proteins in the monkey feeding assay suggest that a stable disulfide bond facilitates an emetic response *in vivo*. Specifically, toxins lacking one or both cysteine residues are generally nonemetic or weakly emetic (86–91). Potential structural contributions from the Cys-Cys bond that could contribute to the SE conformation necessary for emetic activity include one or more of the following features: (i) proper positioning of cysteine residues upon formation of the disulfide bond, (ii) exposure and/orientation of crucial residues in the loop formed between the two linked cysteines, (iii) exposure and/or orientation of residues immediately adjacent to the disulfide linkage but not contained within the cysteine loop, and (iv) contributions to the overall SE conformation by the linkage of the two cysteine residues.

Each of these possibilities has been considered. The cysteine residues and the loop probably do not play a direct role in the emetic response. It has been found to be possible to replace the cysteine residues in several SEs by site-directed mutagenesis and show that neither of these two residues is required. Although most of the SEs have a cysteine loop or analogous feature, the lengths and composition of residues within the loops of different SE types vary greatly. This lack of consistency among SE loop properties suggests that they are unlikely to have a shared enterotoxigenic function (Fig. 21.5). Furthermore, proteolytic nicking of toxins in their loops has no effect on their ability to cause emesis (52). Warren et al. (92) determined that the disulfide bond contributes only minimally to overall protein conformation. Presumably, then, if the disulfide linkage is important in emesis, the

effect is likely to provide a specific orientation of residues near the disulfide linkage, but not in the loop. The most convincing evidence in support of this possibility has been provided by mutagenesis of SEC1 in which its cysteine residues were replaced by either serine or alanine (54). It was determined that mutants with serine substitutions were emetic, whereas the analogous mutants with alanine substitutions were nonemetic. Although serine and alanine are both considered conservative substitutions for cysteine, one difference between them is that serine can form hydrogen bonds. Thus, hydrogen bonding by serine may be able to replace the disulfide linkage stabilization of local structure.

Figure 21.5 Comparison of the cysteine loop and adjacent sequences between highly emetic and weakly emetic SEs in the monkey feeding assay.

Which critical local residues require proper orientation by the disulfide bond (or hydrogen bonding at the same positions) for the SEs to induce emesis is unknown. Possible candidates are those within a highly conserved stretch of residues directly adjacent to, and downstream from, the disulfide loop (Fig. 21.5). In SEC3, these residues are located on the β5 strand. An attractive hypothesis is that in addition to stability in the gut, two other structural requirements need to be met for enterotoxicity. First, the appropriate conserved residues must be present in the toxin. Many PTs, emetic and nonemetic, have a similar set of highly conserved residues in a location analogous to the β5 strand of SEC3. Second, they must be positioned properly for interacting with their target in the gut. The unique SE disulfide bond may serve this function. Of the entire PT family, two non-SE toxins produced by *Streptococcus pyogenes* (streptococcal pyrogenic exotoxin and streptococcal SAg) could potentially form a disulfide linkage (93). However, the presence of more than two cysteines in these toxins suggests that the structure in this area and degree of local stabilization by their putative disulfide linkage may not be identical to those of the SEs.

Additional studies on SEA revealed that single-site substitutions of residues close to the N terminus also influence emesis (94). This was especially the case for mutants constructed by substitution with glycine. For example, mutagenesis of residues 25, 47, and 48 cause significant reduction in the emetic potency of SEA. Although these residues are far from the disulfide bond in the SEA primary sequence, they are located near or within domain 1 of SEA and could potentially influence the area near the disulfide bond.

Recently, the emetic activity of newly discovered SEs has been determined in monkey feeding assays using the cynomolgus monkey (*Macaca fascicularis*) (95). All of the SEs tested were emetic but required a very high dose (100 μg/kg of body weight). Some SEs induced emesis in one of six animals tested. It is noteworthy that these SEs were prepared from *E. coli* protein expression systems. One of the prominent features of SEs is the enhancement of the toxic effect of lipopolysaccharide (96), which is very difficult to remove from proteins expressed by *E. coli*. Additionally, for the safety of animal handlers, animals may be sedated with ketamine-HCl. Previous studies revealed that 10 of 41 cynomolgus monkeys had an emetic response to an intramuscular injection of 2.5 to 20 mg/kg of ketamine-HCl (97), whereas the rhesus monkey (*Macaca mulatta*) did not have this response even at doses of 7.5 to 15 mg/kg, and sedation did not inhibit the emetic activity of subsequent oral administration of SEB (98). The SEs have the potential to be used as biological weapons; hence, the

SEs with confirmed emesis are classified as select agents (99). Thus, the results from recent cynomolgus monkey feeding assays need to be carefully interpreted.

SE-Induced Emesis Requires Nerve Stimulation

Except for rare SFP cases, in which massive doses of SEs are consumed, systemic dissemination of the toxins does not contribute significantly to illness. When fed to rodents, SEs do enter the circulatory system but are rapidly removed by the kidneys (100). Most studies using the simian model indicate that the SE site of action following ingestion is the abdominal viscera. Early studies into the mechanism of action of SEs tested the emetic responsiveness of animals to the toxins after disruption of well-defined neural systems or after visceral deafferentation. The characteristic emetic response resulted from stimulation of local neural receptors in the abdomen (101), which transmit impulses through the vagus and sympathetic nerves, ultimately stimulating the medullary emetic center.

Cellular Histopathology in the Gastrointestinal Tract

Information on the histological effects of oral doses of SEs in humans is extremely limited. Most of it was obtained from experiments in rhesus monkeys. Upon ingestion of the toxin, pathological changes compatible with a definition of gastroenteritis were observed in several parts of the gastrointestinal tract (102).

The primate stomach becomes hyperemic and is marked by lesions which begin with the influx of neutrophils into the lamina propria and epithelium. A mucopurulent exudate in the gastric lumen is typically observed. Also characteristic are mucus-filled surface cells, which eventually release their contents. Later in the illness, neutrophils are replaced by macrophages. Eventually, upon resolution of the symptoms, the cellular infiltrate clears.

A similar cellular infiltrate and lumen exudate occur in the small intestine, although they are less severe in sections from lower portions of the intestine than in those from upper portions. Clearly evident in the jejunum are an extension of crypts, disruption or loss of the brush border, and an extensive infiltration of neutrophils and macrophages into the lamina propria. Changes in the colon are minimal in the monkey model; only a mild cellular exudate and mucus depletion are evident. The only other significant effect in monkeys is acute lymphadenitis in the mesenteric lymph nodes.

Search for the Gastrointestinal Tract Target

The specific cells with which SEs interact in the abdomen have not been clearly identified, nor has their receptor. Evidence suggests that interaction of SEs with their target directly or indirectly causes production of inflammatory mediators that induce SFP symptoms. Jett et al. (103) determined that oral administration of SEB produced elevated levels of arachidonic acid cascade products. Specifically, they observed significant increases in prostaglandin E_2, leukotriene B4, and 5-hydroxyeicosatetraenoic acid. These three compounds are potent vasoactive inflammatory mediators that can also act as chemoattractants for neutrophils. Both of these activities are consistent with the histopathology described above for the SFP monkey model.

Scheuber et al. (104) could not demonstrate an effect of prostanoid inhibitors on SEB-induced emesis but were able to correlate gastrointestinal symptoms with cysteinyl leukotriene generation. Intoxication of animals with SEB resulted in a 10-fold increase in the levels of leukotriene E4 in bile, plus an unidentified leukotriene in the urine. These investigators suggested a role for mast cells in the pathogenesis of SFP. Although induction of histamine production by SEB was responsible for some secondary nonenteric immediate hypersensitivity skin reactions, it did not correlate with emesis.

Evidence suggests that ingestion of SEs causes a stimulation of mast cells and possibly other inflammatory cells in the abdomen. Thus far, the abdominal receptor has not been identified. Experiments using anti-idiotype antibodies in binding assays and protection assays have provided circumstantial evidence for its existence on monkey mast cells (105). Komisar et al. determined that SEB stimulates rodent peritoneal mast cells as well and provided evidence for a protein receptor (106).

It is possible that SEs act directly on their receptor and circumvent the typical two-stage mast cell IgE antibody-Ag interaction (104).

Despite these observations, Alber et al. (107) were unable to directly stimulate monkey or human skin and intestinal mast cells with SEB to release inflammatory mediators. It was suggested that stimulation of mast cells *in vivo* occurs through a nonimmunological mechanism requiring the generation of neuropeptides released from peripheral terminals of primary sensory nerves. At least one putative mast cell-stimulating peptide, substance P, was implicated in SEB-induced toxicity by use of antibodies and a variety of inhibitors. This explanation is consistent with earlier predictions of a neural involvement in the pathogenesis of SFP.

A recent study using the house musk shrew (*Suncus murinus*) revealed that SEA induces 5-hydroxytryptamine (5-HT) release in the intestine (108). Pretreatment with a 5-HT synthesis inhibitor or a 5-HT_3 receptor, or with surgical vagatomy, inhibited SEA-induced emesis. Furthermore, cannabinoid receptor agonists significantly decreased the release of 5-HT and SEA-induced emesis. These results suggested that, in this model, SEA-induced emesis is mediated by the release of 5-HT and 5-HT_3 receptors on vagal afferent neurons and is downregulated by the cannabinoid receptor system by decreasing the release of 5-HT. However, results with other animal models, including kittens, piglets, house musk shrews, and ferrets, particularly those that require systemic administration rather than oral feeding, must be interpreted with caution, since they may mimic TSS rather than SFP.

Is There a Relationship Between Superantigenicity, TSS, and SFP?

The discovery of the mechanism of SAg action and the unique properties of this class of proteins provided an explanation for the multiple systemic effects observed in TSS patients. The massive cellular stimulation induced by superantigenic PTs explained the long-recognized fact that TSS patients had elevated levels of serum cytokines and other factors which mediate many symptoms of the disease. The realization that at least some of the pathogenesis of TSS could be attributed to immune cell stimulation led to the prediction by some investigators that SFP could also be a function of SAgs. Consistent with this prediction was the fact that TSS often has a gastrointestinal tract component characterized by vomiting and diarrhea. Also, patients with endotoxin shock have elevated cytokine levels and similarly display vomiting and diarrhea. If superantigenicity is responsible for SFP, the SEs presumably act directly on T cells and APCs in the gut. Although some SEs enter the circulation, they appear to be rapidly cleared by the kidneys, so that significant systemic concentrations are unlikely to be achieved (100). This, plus the fact that TSS-associated symptoms (i.e., shock and fever) are not observed in SFP patients, suggests that SEs do not mediate SFP through systemic cytokines.

Despite their similarities and the evidence cited above, several lines of evidence suggest that the partial overlap between SFP and TSS symptoms is likely coincidental and that superantigenicity is not directly responsible for SFP. First, as discussed above, nonimmunological mast cell stimulation has been linked to the release of the inflammatory mediator affecting nerve interactions. The second line of evidence was obtained via mutagenesis of several SEs. Studies have revealed that T-cell stimulation and induction of emesis are separable functions and are determined by distinct portions of the SE molecules (54, 94, 109). It has been possible to construct SEA, SEB, or SEC1 mutants which are deficient in T-cell-stimulatory activity but which retain the ability to induce emesis and vice versa. Finally, although all PTs have been reported to have SAg function, only the SEs are emetic when ingested. The lack of emesis-inducing ability of some nonenterotoxic PTs has been attributed to instability in the gastrointestinal tract. However, at least one nonemetic PT, streptococcal pyrogenic exotoxin A, is very stable in gastric fluid (110).

If superantigenicity does not explain SFP, how do PTs cause vomiting and diarrhea in TSS? Several possibilities could explain how SEs and other PTs act on the gastrointestinal tract if they are not consumed by the oral route. First, the toxins' ability to induce TSS symptoms may be limited to the systemic circulation. If so, cytokines would need to enter the abdomen or gain access to the central nervous system from the circulatory system and mediate gastroenteritis pathogenesis. Alternatively, the PTs could enter the gut from the circulation and act directly at the local level as SAgs or through

other mechanisms, as proposed for SFP. The latter possibility is less likely, since even nonenterotoxic PTs, including those that are susceptible to degradation in the gut, are known to cause gastrointestinal symptoms when they are associated with TSS.

These complex and unresolved issues are relevant to interpreting models for studying the enterotoxic activity of SEs. Oral administration of SEs, culture filtrates, or suspected food to monkeys is the preferred method for detecting enterotoxic properties of the SEs. However, intravenous administration of SEs to primates and other animals such as cats has been used as an alternative to feeding (89, 111). Considering that systemic exposure to SEs mimics the situation leading to TSS symptoms, intravenous administration may not accurately reflect the pathogenesis and toxin properties required to induce emesis in SFP. Recently, other models that demonstrate emesis following administration of toxins to shrews and piglets have been proposed as alternatives to the gold standard, the monkey feeding assay (86, 112). Additional studies will be required to determine whether these alternatives can replace the primate feeding assay.

SE Antigenic Epitopes

The need for reagents that can detect SEs in food and clinical samples, plus a desire to differentiate antigenically different toxins in the toxin family, has been the impetus for considerable effort directed toward epitope characterization and mapping. Although the increased number of identified SEs and putative SEs is beginning to make immunological detection of SEs obsolete, several commercial reagents relying on this technique are still widely used. However, detection based on antigenicity is gradually being replaced by molecular techniques, especially multiplex PCR (113, 114).

Individually, each classical SE type and subtype has a sufficient degree of antigenic distinctness to allow its differentiation from other PTs using highly specific polyclonal antisera and monoclonal antibodies. However, some degree of cross-reactivity can often occur between several SEs. The level of cross-reactivity generally correlates with shared primary sequences. The type C SE subtypes and their molecular variants exhibit a substantial amount of cross-reactivity, as do SEA and SEE, the two major serological types with the greatest sequence relatedness. For these toxins, cross-reactivity can even be demonstrated in relatively insensitive assays, such as immunodiffusion assays, in which these two toxins produce lines of partial identity with the heterologous antiserum. SEB and the SEC subtypes and molecular variants (see above) are also closely related at the amino acid level. Cross-reactivity between SEB and SEC may be demonstrated occasionally by immunodiffusion but is shown more consistently by using sensitive methods, such as radioimmunoassays or immunoblotting. Generally, it has not been possible to produce useful antibodies that cross-react among less closely related SEs. Although one investigator has produced a monoclonal antibody that cross-reacts with all five major SE antigenic types (SEA through SEE), this antibody has low affinity and cross-reacts with other staphylococcal proteins (115). The two most distantly related SEs determined to be recognized by a common epitope are SEA and SED (22).

The mapping of conserved and specific antigenic epitopes on SEs and their differentiation from potentially toxic regions have potential applications in the rational development of nontoxic vaccines. Considering the array of SE antigenic types, the most efficient toxoid would presumably contain one or more epitopes that are shared by multiple toxins. Several approaches have been used to partially localize antigenic epitopes on the SEs and differentiate them from toxic regions. One of the earlier methods used for this purpose was to identify protease-generated toxin fragments from several SEs that bind to cross-reactive antibodies (116). These studies revealed that both N- and C-terminal toxin fragments contain cross-reactive epitopes, but they were unable to define shorter stretches of residues.

There is some evidence that immunization with short, highly conserved peptides could have merit. For example, the use of synthetic peptides from highly conserved stretches of primary sequence has resulted in the production of neutralizing antibody to several of the SEs. Immunization with synthetic peptides corresponding to residues 130 to 160 of SEB or the same region of SEC1 (residues 148 to 162) induced antibodies that neutralized both native toxins (35, 103). The highly conserved SE sequence K-K-X-V-T-X-Q-E-L-D (Fig. 21.1), encompassed by both peptides, may represent part of an epitope that

could be useful for protective immunity. It is yet to be determined if major epitopes identified on other toxins, such as SEA, also show promise (117).

FOODBORNE ILLNESS OUTBREAKS

Incidence of SFP

SFP occurs as either isolated cases or outbreaks affecting many people. Since SFP is usually self-limiting, the incentive to report cases is not as great as for other foodborne illnesses. Although there is a national surveillance system for SFP, SFP is not an officially reportable disease. It has been estimated that only 1 to 5% of all SFP cases are reported in the United States, usually at the state health department level. Most of these occur during highly publicized outbreaks. Isolated cases occurring in the home are not usually reported. Staphylococci account for an estimated 14% of the total of foodborne illness outbreaks within the United States (118). According to a study conducted by the Economic Research Service of the U.S. Department of Agriculture, more than an estimated 1.5 million cases of SFP occurred in a single year (1993), resulting in 1,210 deaths and a cost of $1.2 billion (119).

According to the Centers for Disease Control and Prevention (CDC), an average of approximately 20 major outbreaks of SFP are reported annually within the United States (https://www.cdc.gov/foodsafety/outbreaks/index.html). The occurrence of SFP is cyclical, with the highest incidence typically occurring in the late summer, when temperatures are warm and food is more likely to be stored improperly (54). A second peak occurs in November and December. Approximately one-third of these are associated with leftover holiday food.

SFP may be a leading cause of foodborne illness worldwide, although reporting in other countries is even less complete than in the United States. In one study, 40% of outbreaks of foodborne gastroenteritis in Hungary were due to SFP (1). In Brazil, *S. aureus* was the second most common cause of foodborne disease between 1999 and 2011 (120). The percentage is slightly lower in Japan (approximately 20 to 25%), where contamination of rice balls during preparation is a potential problem (1). Outbreaks due to improper manufacturing of canned corned beef have been reported in England, Argentina, Malta, northern Europe, and Australia. Cases in Great Britain have been attributed to contaminated milk and cheese produced from milk from mastitic sheep (121). In some countries, ice cream has been a major vehicle of SFP. Despite increased knowledge of the epidemiology of SFP and attempts to educate the public, large outbreaks continue to represent a significant health hazard. For example, in 1998, approximately 4,000 individuals acquired SFP at a church event in Brazil (122). More recently, a massive outbreak in Osaka, Japan, in 2000 resulted in more than 10,000 cases from SEA and SEH in reconstituted milk (123).

Characteristics of a Recent Large Typical SFP Outbreak

The following is a summary of an outbreak of SFP reported by the U.S. Food and Drug Administration (124). Many of the aspects of this outbreak, such as type of food involved, mechanism of contamination, inadequate safety measures in food handling, and clinical manifestations of illness, are typical. This outbreak originated from one meal that was fed to 5,824 elementary school children at 16 sites in Texas. Of all the children exposed, a total of 1,364 developed clinical signs of SFP. Investigation into the source of the illness revealed that 95% of the children who became ill had eaten chicken salad from which large numbers of *S. aureus* were cultured.

The series of events leading up to the outbreak were as follows. Preparation of the meals was performed in a centralized kitchen facility and began on the day before the food was to be eaten. Frozen chickens used for the salad were boiled for 3 hours. After cooking, the chickens were deboned, cooled to room temperature with a fan, ground into small pieces, placed in 30.5-cm-deep aluminum pans, and stored overnight in a walk-in refrigerator at 5.6 to 7.2°C. The following morning, the remaining ingredients of the salad were added and the mixture was blended with an electric mixer. The food was placed in thermal containers and transported by truck to the various schools between 9:30 and 10:30 a.m. It was held at room temperature until served between 11:30 a.m. and noon. It is believed that the

chicken became contaminated after cooking when it was deboned. Most likely, the storage of the warm chicken in the deep aluminum pans did not permit rapid cooling and provided an environment favorable for staphylococcal growth and SE production. Further growth of the bacteria probably occurred during the period when the food was kept in the warm classrooms. Prevention of the incident would have entailed more rapid cooling of the chicken and refrigeration of the salad after preparation.

CHARACTERISTICS OF DISEASE IN HUMANS

SFP is usually a self-limiting illness presenting with emesis following a short incubation period. However, vomiting is not the only symptom that is commonly observed. In fact, many patients with SFP do not vomit. Other common symptoms include nausea, abdominal cramps, diarrhea, headaches, muscular cramping, and/or prostration. In a summary of clinical symptoms involving 2,992 patients diagnosed with SFP, 82% complained of vomiting, 74% felt nauseated, 68% had diarrhea, and 64% exhibited abdominal pain (118). In all cases of diarrhea, vomiting was always present. Diarrhea is usually watery but may contain blood as well. The absence of high fever is consistent with a lack of infection or significant toxemia in this type of food poisoning, although some patients present with low-grade fever. Other symptoms can include general weakness, dizziness, chills, and perspiration.

Symptoms typically develop within 6 hours after ingestion of contaminated food. In one report, 75% of the exposed individuals exhibited symptoms of SFP within 6 to 10 hours postingestion (118). The mean incubation rate is 4.4 hours, although incubation periods as short as 1 hour have been reported. In another outbreak, symptoms lasted for 1 to 88 hours, with a mean of 26.3 hours. Death, usually from severe dehydration or electrolyte imbalance, occurs in a small percentage of patients, with the fatality rate ranging from 0.03% for the general public to 4.4% for more susceptible populations, such as children and the elderly (118). Approximately 10% of patients with confirmed SFP seek medical attention. Treatment is minimal in most cases, although administration of fluids is indicated when diarrhea and vomiting are severe.

TOXIC DOSE AND SUSCEPTIBLE POPULATIONS

Numbers of Staphylococci Required for Sufficient Toxin Production

Since many variables affect the amount of SE produced, one cannot determine with certainty the number of *S. aureus* organisms in food required to produce sufficient amounts of SE to cause SFP. Factors contributing to the amounts of toxin produced have been extensively studied and include environmental conditions (such as food composition and temperature), other physical and chemical parameters, and the presence of antimicrobial growth inhibitors. In addition, bacterial factors to be considered include potential differences in the types, amounts, and numbers of different SEs the strain involved has the physiological ability to produce. It is likely that these combined conditions are unique for each isolated case or outbreak of SFP. Despite this variability, there are several general guidelines that are useful for assessing general risk. According to the U.S. Food and Drug Administration, doses of SE causing illness result when populations greater than 10^5 *S. aureus* organisms per gram of contaminated food are present (124). In other studies, 10^5 to 10^8 *S. aureus* organisms were observed to represent the typical range, despite the fact that lower levels were sometimes implicated (118).

Toxin Dose Required for Illness

Many investigations have been conducted to assess SE potency and the amount of toxin in food required to initiate SFP symptoms. Some of the most useful information has come from analysis of food recovered from outbreaks of the illness. Although SEs are quite potent, the amount of SE required to induce symptoms is relatively large compared to that of many other exotoxins that are acquired through contaminated food. A basal level of approximately 1 ng of SE per gram of contaminated food is sufficient to cause symptoms associated with SFP. Although 1 to 5 μg of ingested toxin is typically associated with many outbreaks, the actual levels of detectable SE were considerably less (<0.01 μg) in

16 SFP outbreaks (125). One of the most useful studies for predicting the minimal oral dose of SE required to induce SFP in humans was a well-documented investigation of an outbreak associated with ingestion of contaminated chocolate milk (126). In that study, the minimum dose of SEA required to cause SFP in school children was 144 ± 50 ng. Another massive SFP outbreak in Japan caused by low-fat milk contaminated with SEA revealed that the total intake of SEA per capita was 20 to 100 ng (127).

The minimal number of *S. aureus* organisms required to produce the toxic level of SE in food has also been investigated. Noleto et al. (128) determined that an *S. aureus* strain harboring *sea*, *seb*, and *sed* produced detectable levels of SEB and SED (1 ng/ml) at a cell population of 6×10^6 CFU/ml and SEA (4 ng/ml) at a cell population of 3×10^7 CFU/ml under nutrient-enriched conditions. However, when grown in milk, this strain produced detectable levels of SEA and SED at populations as low as 10^4 and 10^7 CFU/ml, respectively. Considering the variability in strains, culture conditions, and genetic regulation of SE production, this information needs to be interpreted with caution.

Many factors contribute to the likelihood of developing SFP symptoms and to their severity. The most important include susceptibility of the individual to the toxin, the total amount of food ingested, and the overall health of the affected person. The toxin type may also influence the likelihood and severity of disease. Though SFP outbreaks attributed to ingestion of SEA are much more common, individuals exposed to SEB exhibit more severe symptoms. Of 2,291 individuals exposed to SEB, 46% experienced SFP symptoms severe enough for them to be admitted to the hospital (118). Only 5% of 1,813 individuals exposed to SEA required such treatment. It is possible that these observations reflect differences in levels of toxin present, because SEB is generally produced at higher concentrations than SEA.

Human volunteers and several species of macaque monkeys have been used to determine the minimal amount of purified SEs required to induce emesis when administered orally. Generally, monkeys are less susceptible to SE-induced enterotoxicity than humans. A study with purified SEs provided useful comparative information that has important research applications, but its direct relevance to SFP is uncertain, because potential stabilization of unpurified SEs by food is an important consideration. Based on a study in which human volunteers ingested partially purified toxin, Raj and Bergdoll estimated that 20 to 25 μg of SEB (0.4 μg/kg) is sufficient to cause vomiting in humans (129). In the rhesus monkey model, the 50% emetic dose is between 5 and 20 μg per animal (or approximately 1 μ4g/kg) when administered intragastrically. In our investigations, the minimal emetic dose of SEC1 for pigtail monkeys (*Macaca nemestrina*) is consistently between 0.1 and 1.0 μg/kg.

Regulation of Toxin Expression

S. aureus is a widely distributed bacterium. It can exist in harsh environments as well as on various animals and humans. This versatile survival ability relies on a complex network of virulence factors and adaptability. More than 50 genes involved in pathogenesis produce proteins that are either cell free or expressed on the bacterial surface. These enable the bacterium to evade host defenses, adhere to cells and the tissue matrix, propagate within the host, and destroy cells and tissues. Expression of virulence factors is temporarily controlled in response to cell density, nutrient availability, and environmental signals so that these factors are produced when required. During growth, expression of surface proteins is upregulated early, whereas that of cell-free secreted proteins is upregulated post-exponential growth phase. These changes in expression are regulated by a complex network of regulatory genes described below. In addition, several environmental signals also affect the production of extracellular proteins, such as salt concentration, pH, and subinhibitory concentrations of antibiotics or glycerol monolaurate (130).

Regulation of SE Production by a Global Regulatory System

SEs are produced in extremely low quantities throughout most of the exponential growth phase (131, 132). There is generally a large increase in expression during the late exponential or early stationary phase of growth, with SEA and SED accumulating somewhat earlier than other SEs (30). The ability of *S. aureus* to respond to changes in the growth phase involves the density-sensing *agr* system (133),

which has some properties typical of bacterial two-component sensors and regulators (134). *agr* expression coincides temporally with expression of most SEs during the bacterial growth cycle. All are maximally expressed during late-exponential-phase and postexponential-phase growth. SEA, which is not regulated by *agr*, is produced earlier (30). The *agr* locus maps at approximately 4 o'clock on the staphylococcal genome, near *purA*, *bla*, and *sea*, on the standard map of *S. aureus*. It contains two divergent operons separated by approximately 120 bp (Fig. 21.6).

Transcription can be initiated from three promoters (P1, P2, and P3). P1 is weakly constitutive and transcribes *agrA*. P2 and P3 are induced strongly during late exponential and early stationary phase but are only weakly expressed earlier. The P2 transcript, RNA II, encodes four proteins, designated AgrA, AgrB, AgrC, and AgrD.

A model for signal transduction through the *agr* system is shown in Fig. 21.4. Together, these four proteins form a quorum-sensing system, enabling the bacterium to respond to its environment. A unique cyclic thiolactone pheromone peptide (autoinducing peptide [AIP]) derived from AgrD residues 46 to 53 is the activating molecule for the *agr* system. AIP is processed from AgrD by AgrB (135). Increased levels of AIP are recognized by the membrane-bound receptor AgrC, which in turn initiates a signal transduction pathway (135). Its homology to conserved domains of histidine protein kinases, in particular, a conserved histidine autophosphorylation site (134), further suggests that the 423-residue *agrC* gene product is likely to be the sensor. Autophosphorylation of the *agrC* product at the end of the exponential phase is thought to allow it to phosphorylate AgrA, the response regulator, by phosphorylation of aspartic acid residue, thereby activating expression of both RNA II and RNA III (136). AgrA has homology to activator proteins in other systems, such as OmpR. AgrA and other typical response regulators exhibit a highly conserved N terminus approximately 120 residues in length. Three amino acids, two aspartic acids and a lysine, are conserved among all response regulators.

Mutations in the *agr* locus result in substantially reduced transcription of the *seb*, *sec*, and *sed* genes (25, 137, 138), whereas transcription of *sea* is not affected (139). Regulation of gene expression by *agr* can be transcriptional or translational. It regulates α-hemolysin at both the transcriptional and translational levels, whereas SEB and SEC are regulated at the transcriptional level. Transcriptional regulation of the *seb* and *sed* genes is dependent on the presence of Rot (repressor of toxin), which is a member of the Sar family of transcription factors. Rot negatively regulates expression of SEB by binding to the promoter of the *seb* gene (140). Even though the transcription of *rot* is not affected by *agr*, its activity is negatively regulated by *agr*. During the postexponential growth phase, the Agr system induces transcription of RNA III, which is base-paired with the *rot* mRNA and subsequently causes mRNA degradation, resulting in transcriptional activation of the *seb* gene (141). It is not clear whether transcription of *sec* is also regulated by Rot-RNA III interference (Fig. 21.6).

The SarA protein family is a family of proteins homologous to SarA. Included in this family are SarA homologs (SarA, -R, -S, -T, -U, and -V), MgrA (a global regulator of autolysis and virulence), and Rot (the repressor of toxin) (142–144). Sequence alignment and crystal structure studies revealed that SarA, -R, and -S are typical winged-helix DNA-binding proteins with helix-turn-helix motifs (145–147). SarA binds to several target promoters, including *agr*, *hla*, *spa*, and *fnbA*. SarA binds to an intergenic region between *agr* promoters P2 and P3, which upregulates expression of RNA III, hence influencing the expression of *agr*-regulated genes (148) (Fig. 21.6). Transcriptional gene fusion analysis revealed that *sarA* upregulates both *tst* and *seb* (149). Mutation of the *sar* locus causes increased expression of α toxin and decreased expression of δ and β toxins (150).

The two-component regulatory system SrrAB is involved in anaerobic growth and inhibits transcription of RNA III by binding to the P2 and P3 promoters (Fig. 21.6). The two-component regulatory system SaeRS is a positive effector of cell-free β- and α-hemolysins, coagulase, nuclease, and protein A but apparently does not affect SEA, protease, lipase, staphylokinase, or cell-bound protein A. A recent study revealed that mutations affecting SaeRS completely abolished expression of TSST-1, whereas there was no effect on the production of RNA III (133, 151). Furthermore, SaeR, a transcriptional regulator, was able to directly bind to a region of the *tst* promoter containing two SaeR binding sites (151) (Fig. 21.6).

These results suggest that the *sae* locus is distinct from other previously identified regulatory loci and that the presence of SaeR binding consensus sequence is important for its regulation.

Expression of the alternative sigma factor (σ^B) is the major response of *S. aureus* to environmental stimuli. The *sigB* operon is constitutively transcribed under the control of σ^A and encodes SigB (σ^B) and the anti-*sigB* factor RsbW, the antirepressor RsbV, and RsbU. RsbW usually binds to σ^B, which phosphorylates RsbV (152). Under environmental stresses such as high temperature, alkaline pH, high levels of NaCl, and the presence of certain catabolites (e.g., glucose, galactose, sucrose, glycerol, and maltose), phosphorylated RsbV is dephosphorylated by RsbU or RsbP and then binds RsbW, subsequently releasing and activating σ^B (30, 153). σ^B recognizes a unique promoter ($GTTTN_{14-17}GGGTAT$), which has been identified for 23 different *S. aureus* genes, including the *sar* locus (154). This suggests that environmental signals activate σ^B, which, in turn, activates global virulence regulation. SEB expression is negatively regulated by σ^B. When σ^B is activated by stress-induced conditions, expression of SEB is reduced (155). In contrast, expression of SEB is increased in a *sigB* mutant; however, the promoter of *seb* differs from the unique promoter for σ^B. This suggests that expression of SEB is not directly regulated by σ^B.

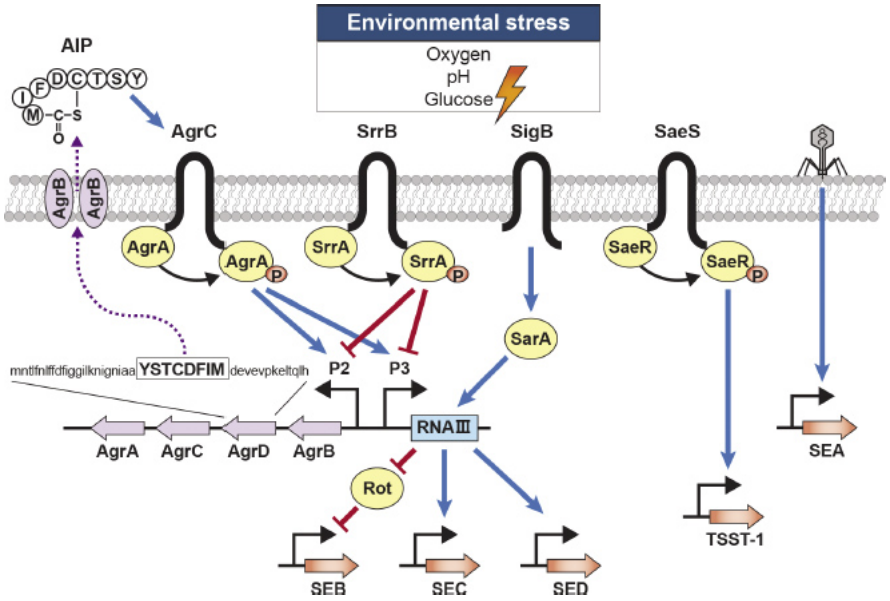

Figure 21.6 Regulation of SE expression by the *agr* locus and other interacting regulatory genes and gene products (not drawn to scale) in *S. aureus*. The blue arrow indicates activation, and the red line indicates inhibition. A letter "P" in a red dot indicates phosphorylation.

Regulation of SE Production by Environmental Factors

SFP is often associated with the growth of *S. aureus* in protein-rich foods, such as meats and dairy products, in which nutrients, salt, pH, oxygen availability, and temperature conditions are different from laboratory medium culture conditions.

Glucose affects expression of SEs through at least two different mechanisms. First, metabolism of glucose lowers pH, which negatively affects transcription of *agr*, because *agr* is maximally transcribed at neutral pH (138). Consequently, expression of *seb*, *sec*, and *sed* and other *agr* target genes is affected correspondingly (138). Second, low pH can cause induction of prophages which activate transcription of SEs associated with prophages. A recent study revealed that expression of SEA is linked to the life cycle of temperate phages (156). Sequence analysis of the *sea* gene revealed two promoters, one immediately upstream of the *sea* gene and the other at the phage-related latent promoter (Fig. 21.6). During stressinduced phage induction, both promoters are activated, resulting in the production of large amounts of SEA.

The regulatory effect of glucose described above cannot be attributed entirely to lower pH levels in cultures grown on glucose, because cultures containing glucose produce less SE, even when the pH is stably maintained. Although this effect has some attributes of catabolite repression, there are major differences between the glucose inhibitory effect in *S. aureus* and catabolite repression in *E. coli*. For example, inhibition by glucose cannot be reversed by adding cyclic AMP to staphylococcal cultures. The significance of these differences is still unclear. Even the catabolite-repressible staphylococcal *lac* operon has features that are significantly different from those of the analogous operon in *E. coli* and is apparently unresponsive to cyclic AMP.

While *S. aureus* can survive and grow in environments with low water activity, production of some SEs, especially SEB and SEC, is reduced when the bacteria are grown under osmotic stress. In experiments performed with SEC-producing strains, levels of *sec* mRNA and SEC protein are both reduced in response to high NaCl concentrations. However, addition of osmoprotectants reverses the effect. This reduced expression was also observed in *agr*$^{-}$strains (strains lacking *agr*), indicating that the signal transduction pathway used in this mechanism occurs by an alternative pathway.

Low concentrations of the commonly used emulsifier glycerol monolaurate (GML) inhibit transcription of many exoprotein genes, including *sea*, without inhibiting *S. aureus* growth (157). Inhibition of SE production is not associated with a simultaneous effect on *agr* transcription and occurs in *agr*$^{-}$strains as well as wild-type strains. These results, plus the finding that constitutive expression of some genes is not affected, suggest that GML interferes with non-*agr*-mediated signal transduction. It has been proposed that GML and a variety of related food additives exert this effect by insertion into the staphylococcal membrane, altering the membrane protein conformation and thereby interfering with signal transduction.

METHODS FOR DETECTING TOXINS

As *S. aureus* is a natural colonizer in both humans and animals, the incidence of SFP is typically associated with meats and dairy products. Approximately 2.1% of SFP reported between 1998 and 2012 in the United States was associated with dairy products (158). Surveys from 15 European countries revealed that 19% of SFP was linked to milk and dairy products (159, 160). In contrast, there was only one report of SFP associated with dairy products in Japan during the past 10 years. The most frequently detected SEs in SFP outbreaks are SEA, SED, SEH, SEE, and SEC. In the United States, 77.8% of all SFP outbreaks were linked to SEA, followed by SED (37.5%) and SEB (10%) (17, 161). Similarly, 56.9% of SFP outbreaks in the United Kingdom were attributed to SEA alone or in combination with SED (15.4%), SEB (3.4%), SEC (2.5%), or both SEB and SED (1.1%) (16). SEA was the most common SE implicated in SFP outbreaks in Japan (69.7%), France (90%), and Korea (68%) (162–164).

Bioassays

Bioassays are based on clinical symptoms such as vomiting and gastroenteritis in monkey and kitten models. Historically, the kitten was used for the detection of SEs in staphylococcal filtrates, but this model has been retired due to low sensitivity and specificity (165). Recently, the house musk shrew model has been used to characterize newly discovered SEs; however, with this animal model, the vomiting response requires considerably greater amounts of toxins than those involved in human SFP (112). Thus, this model is not truly representative of human implications. As mentioned above, the monkey feeding assay is the gold standard for confirming enterotoxigenicity.

Immunological Assays

Antienterotoxin antibodies are commonly used to detect SEs in food samples. Currently, commercial kits are available to detect the classical SEs (SEA to SEE) using enzyme-linked immunoassays (ELISAs) and enzymelinked fluorescent assays such as SET (Denka Seiken), VIA (Tecra), BTA (Alexeter Technologies), Transia tube (Diffchamb AB), and Ridascreen (rBiopharma). ELISA detection of SEA using ABTS [2,2′-azino-di(3-ethyl-benzthiazoline-6-sulfonate)] was able to detect 0.4 ng/ml

(with a 20-hour incubation period) and 3 ng/ml (with a 3-hour incubation period) (166). Other ELISA systems using a streptavidin-biotin interaction were able to detect SEB at concentrations ranging from 0.5 to 1 ng/ml (167).

The fluorescent immunoassay has become more commonly used to detect SEs in food samples. Using anti-SEB as a capture antibody and anti-SEB antibody conjugated with the cyanine dye Cy5 for detection, investigators were able to detect SEB at 0.1 ng/ml (168). However, many organic fluorochromes are susceptible to photodegradation, which limits their use. To overcome this limitation, luminescent nanoparticles such as quantum dots (QDs) and lanthanide ion chelate-doped nanoparticles have been used. Anti-SEB antibody bioconjugated with cadmium telluride QDs (QD523 and QD601) and used in a fluorescence resonance energy transfer-based immunoassay was able to detect 8.15 ng and 1 to 0.05 ng of SEB from samples (169, 170). Timeresolved fluorescence from lanthanide ion chelate-doped nanoparticles had good stability against photobleaching, low cytotoxicity, and biocompatibility. By using these new technologies, a method to simultaneously detect SEA, SEB, SEC, SED, SEE, SEG, and SEI applying hydrogelbased microarrays (biochips) has been developed and successfully used to detect these SEs at 0.1 to 0.5 ng/ml (171).

A chemiluminescence-based assay has also become popular because of its high sensitivity, low background, and simple instrumentation needs. The use of a luminol–H_2O_2–HRP (horseradish peroxidase)–*p*-iodophenolenhanced chemiluminescence system greatly improved the detection limit of SEB to as little as 0.01 ng/ml from roast beef, peanut butter, cured ham, milk, and orange juice (172). The sensitivity was further enhanced by the use of poly-HRP40, which comprises five identical covalent HRP homopolymer blocks covalently coupled to streptavidin molecules, resulting in a large number of signal-generating enzyme molecules per one bound analyte molecule (173).

The surface plasmon resonance (SPR) immunoassay offers several unique benefits, such as surface-sensitive response, label-free detection, and real-time monitoring capacity. With the SPR immunoassay, the sensor chip is coated with the appropriate antibodies and binding of the target to antibodies changes the reflection intensity which is detected through thin metal layers at the sensor chip. A sandwich SPR immunoassay detected as little as 10 to 100 ng/g of SEA in milk, hot dogs, mushrooms, and potato salad (174).

Aptamer-Based Bioassays

Aptamers are short single-stranded DNA or RNA molecules with high affinity and selectivity for target molecules. Aptamers can be selected through *in vitro* selection or the systematic evolution of ligands by exponential enrichment. Aptamers can be easily synthesized to higher purity and are amenable to modification for various detection modules, which makes them ideal flat forms for biosensors (175). A screening of aptamer sequences using SEB conjugated to tosyl-activated magnetic beads identified a panel of aptamers capable of selectively binding to SEB and other SEs. The gold nanoparticlebased colorimetric assay successfully detected SEB at concentrations as low as 10 ng/ml (175). The sensitivity of aptamers was greatly improved by fluorescence resonance energy transfer technology in which an aptamer affinity method was coupled with upconversion nanoparticle (UCNP) sensors composed of fluorescence donor probes (cDNA 1-UCNPs) and fluorescence quencher probes (cDNA 2-Black Hole Quencher 3). The formation of an aptamer-SEB complex causes the dissociation of the aptamer from the duplex of fluorescence donor probes and fluorescence quencher probes, which restores UCNP fluorescence. The addition of exonuclease I selectively degrades the single-stranded DNA in the aptamer-SEB complex, which further amplifies the fluorescence of UCNPs. This approach improves the detection limit to 0.3 pg/ml of SEB. Using multicolor lanthanide-doped time-resolved fluorescence-labeled aptamers and graphene oxide as a resonance energy acceptor, a method to simultaneously detect multiplex SEs (SEA, SEB, and SEC1) was developed and successfully detected these SEs at concentrations below 1 ng/ml in milk (176).

CONCLUDING REMARKS

Advances in genome sequencing have expanded the list of identified SEs expressed by *S. aureus*. Recent monkey feeding assays have confirmed the emetic activity of these newly discovered SEs. However, the methods used for toxin preparation and the species of test animals applied need to be considered to properly evaluate the enterotoxigenic potential of SEs. The implementation of Hazard Analysis and Critical Control Points systems and active foodborne illness outbreak surveillance programs have greatly reduced the incidence of SFP, but SFP still causes an estimated 5% of all foodborne illnesses. Recent progress in developing better detection methods using biosensors will greatly contribute to the effective control of SFP. Additional knowledge of the molecular aspects of staphylococcal survival, growth, and SE production in food will enable further development of effective ways to prevent SFP.

One issue that continues to puzzle the scientific community is the questionable benefit to staphylococci of producing an emetic toxin. Unlike the case of enteric pathogens, which inhabit the gut, the ability to induce emesis and diarrhea as a mechanism to promote exit from the host and dissemination does not appear to be important for staphylococci. Also, the lack of knowledge about the receptors for SEs in enterocytes is a significant bottleneck for developing effective therapeutics.

Based on what is now known regarding the superantigenic properties and proposed host-specific molecular adaptation of the SEs, one might suggest that SEs are produced to modulate host immune responses. Exposure of animals and peripheral blood mononuclear cell cultures to SEs and other SAgs has repeatedly been shown to induce at least a transient immunosuppression. Similarly, TSS patients often fail to produce a significant immune response to causative superantigenic PTs, and they remain susceptible to subsequent toxigenic illnesses. Hence, one could speculate that the harmful effects on the host (SFP and TSS) are merely secondary effects of the staphylococci's attempts to affect immune cell function, thereby allowing the bacteria to survive and persistently colonize their many human and animal hosts.

Our efforts to prepare this chapter were supported by grants from the Center for Biomedical Research Excellence in Pathogen-Host Interactions, National Institute of General Medical Sciences, NIH (1P20GM103646-01A1) and the Animal and Plant Quarantine Agency, South Korea (grant I-1543081-2015-17-01). We thank Moyim Kim for drawing the illustrations for this chapter. We also thank Justin Thornton for an editorial review.

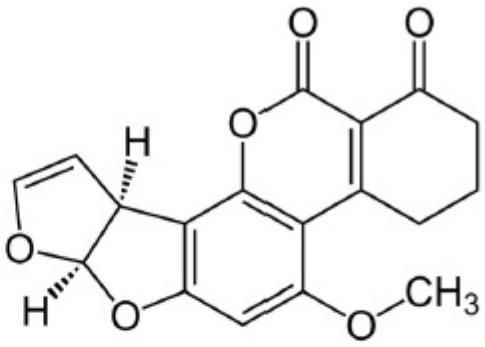
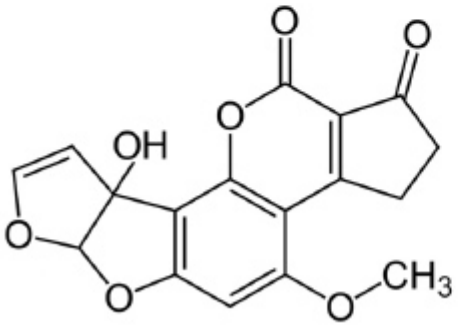
Mycotoxins

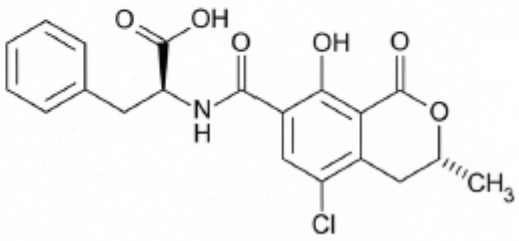


The term “mycotoxin” is derived from the Greek word “*mykes*,” which means fungi, and from the Latin word “*toxican*,” meaning toxin. Mycotoxins have been defined as “fungal metabolites which when ingested, inhaled or absorbed through the skin, can cause disease or death in man and domestic animals, including birds” (1). By general agreement, this definition excludes the toxins produced by macrofungi (mushrooms) and compounds that cause disease only in lower animals or plants. Fungi produce a vast number of secondary metabolites. Only a small number of these compounds are classified as mycotoxins; i.e., they have been demonstrated to cause illness in humans or domestic animals. Specific mycotoxins are produced only by specific fungi, usually by only a few species. A particular species of fungus may produce more than one mycotoxin, though very rarely more than one of the major compounds described here.

Mycotoxin production occurs only as a result of fungal growth: the presence of spores of a particular fungus on a foodstuff is not a good guide to mycotoxin production. However, if environmental conditions, particularly temperature and water activity (a_w), are conducive to fungal growth, toxin production may occur at any period during growing, harvesting, drying, or storage of food commodities. Mycotoxins may occur in processed foods but are much less important in such foods than when they occur in commodities such as grains or nuts. Mycotoxins are typically chemically stable once formed and persist in food even after the destruction of the fungi that produced them.



Molecular structures of mycotoxins vary widely (Fig. 22.1), so their effects on human and animal health also vary widely: they may be neurotoxins, teratogens, nephrotoxins, hepatotoxins, immunosuppressive agents, or carcinogens. The International Agency for Research on Cancer (IARC) (2, 3) has evaluated important mycotoxins according to the risk of carcinogenicity to humans (Table 22.1). Perhaps the most important point is that toxicity due to mycotoxins is almost always insidious, with no overt indication of effects on health in the short term. For this reason, the health effects of mycotoxins are among the more neglected areas of medical science.



Aflatoxin B_1

Aflatoxin G_1

Aflatoxin M_1

Ochratoxin A

Figure 22.1 Structures of aflatoxin B_1, aflatoxin G_1, aflatoxin M_1, and OTA.

Table 22.1 Evaluation of mycotoxins in humans[a]

Mycotoxin	IARC classification
Aflatoxins B and G	Group 1, carcinogenic to humans
Aflatoxin M_1	Group 2B, possibly carcinogenic to humans
OTA	Group 2B, possibly carcinogenic to humans
Fumonisins	Group 2B, possibly carcinogenic to humans
DON	Group 3, not classifiable as to carcinogenicity
ZEA	Group 3, not classifiable as to carcinogenicity

[a] Data from references 2 and 3.

Many fungal secondary metabolites are toxic, but only a few are significant in relation to food safety. Most are of little concern, either because their toxicity is limited or because they are produced by species that are uncommon in foods. The most important mycotoxins are aflatoxins, ochratoxin A (OTA), fumonisins, deoxynivalenol (DON), and zearalenone (ZEA) (4). Each of these is discussed below.

AFLATOXINS

Chemical Characterization

Aflatoxins are highly substituted coumarins, with a fused dihydrofurofuran moiety. Four naturally occurring aflatoxins are important: aflatoxins B_1 and B_2, named because of their blue fluorescence under UV light, and aflatoxins G_1 and G_2, which fluoresce greenish yellow (Fig. 22.1). When aflatoxins B_1 and G_1 are ingested by lactating animals, small proportions (1 to 2%) are excreted in milk as aflatoxins M_1 and M_2, which are hydroxylated derivatives of the parent compounds (5).

Fungal Sources

Aflatoxins are produced in foods primarily by *Aspergillus flavus* and the closely related species *Aspergillus parasiticus*. On standard identification media, i.e., Czapek yeast extract agar (CYA) (6) and malt extract agar (MEA) (6), both species produce rapidly growing colonies characterized by green conidia (asexual spores) borne on typical *Aspergillus* fruiting structures (Fig. 22.2). The two species differ in small details: *A. flavus* usually bears conidia on two sets of supporting cells (metulae and phialides), while *A. parasiticus* spores are borne on phialides alone. Conidia of *A. parasiticus* exhibit rougher walls than those of *A. flavus*.

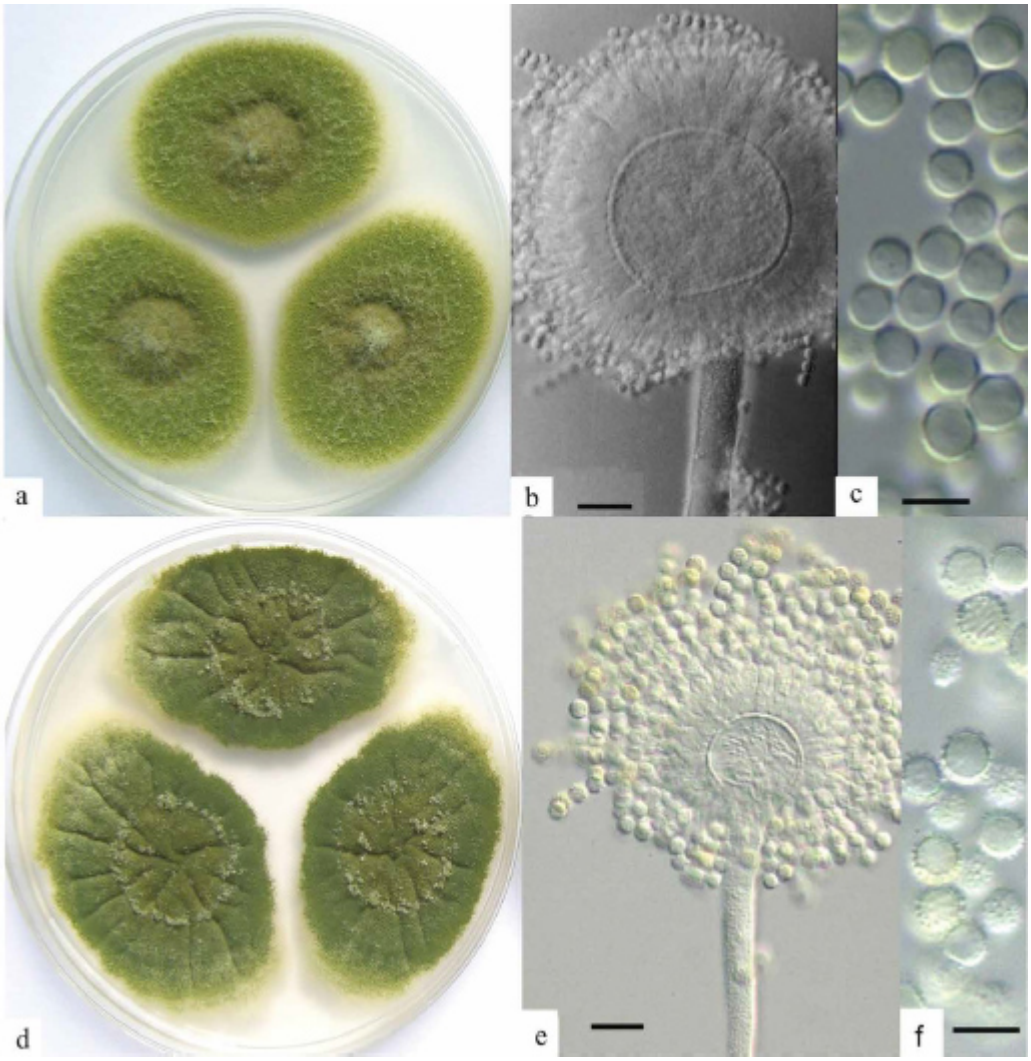


Figure 22.2 (a) *A. flavus*, CYA, 7 days at 25°C; (b) *A. flavus* fruiting structure (bar, 20 mm); (c) *A. flavus* conidia (bar, 5 mm); (d) *A. parasiticus*, CYA, 7 days at 25°C; (e) *A. parasiticus* fruiting structure (bar, 10 mm); (f) *A. parasiticus* conidia (bar, 5 mm).

A. flavus isolates produce B aflatoxins, and some also produce cyclopiazonic acid. On a worldwide basis, about 40% of *A. flavus* isolates produce aflatoxins (7), though percentages of toxin-producing isolates may vary with land use (7). Isolates of *A. parasiticus* produce both B and G aflatoxins but not cyclopiazonic acid, and almost all isolates are toxigenic.

At least 14 *Aspergillus* species are known to produce aflatoxins (8–10). Besides *A. flavus* and *A. parasiticus*, two others are of some

importance in foods: *Aspergillus nomius* and *Aspergillus minisclerotigenes*. Both resemble *A. flavus* in culture, but *A. nomius* produces bullet-shaped sclerotia, in contrast to the large spherical sclerotia produced by many *A. flavus* isolates, while *A. minisclerotigenes* produces small spherical sclerotia. Both of these species produce B and G aflatoxins.

Detection of these species from foods or soils is facilitated by the use of *Aspergillus flavus* and *A. parasiticus* agar (11). After 42 to 48 h of incubation on this agar at 30°C, colonies of *A. flavus* and *A. parasiticus* exhibit a brilliant orange-yellow reverse coloration.

A. flavus grows at temperatures from a minimum of 10 to 12°C to a maximum of 43 to 48°C, and optimally at about 33°C. It has been shown to grow at minimum a_w of 0.82 at 25°C, 0.81 at 30°C, and 0.80 at 37°C (12). Growth of *A. flavus* occurs over the pH range 2.1 to 11.2 at 25, 30, and 37°C, with optimal growth over a broad range from pH 3.4 to 10 (6). Atmospheres of 20% CO_2 and <0.5% O_2 or 80% CO_2 with 20% O_2 did not inhibit *A. flavus* growth on CYA (6, 13). However, CO_2 levels of >40% and O_2 levels of <0.5% inhibited *A. flavus* (14).

The most reliable figures for heat resistance of *A. flavus* conidia indicate a D_{45} value of >160 h, a D_{50} of 16 h, a D_{52} of 40 to 45 min, and a D_{60} of 1 min, at neutral pH and high a_w, with z values from 3.3 to 4.1°C (6). These values indicate ready destruction at pasteurization temperatures. The physiology of *A. parasiticus*, *A. nomius*, and *A. minisclerotigenes* is similar to that of *A. flavus*.

Genetics

The aflatoxin-biosynthetic pathway in *A. flavus* has been studied extensively and is now quite well understood. The pathway is encoded by a single unit on a chromosome within linkage group VII and includes more than 20 enzymes and gene products. Many of these have now been isolated and characterized (15). Two regulatory genes, *AflR* and *AflJ*, are known. The gene products of *AflR* regulate

the biosynthetic pathway at the transcription level. The function of *AflJ* is not known, but its disruption prevents aflatoxin accumulation (15). The production of aflatoxin by toxigenic *Aspergillus* species is affected by environmental and nutritional factors, including temperature, a_w, pH, carbon and nitrogen sources, stress factors, lipids, and certain metal salts (16, 17).

Ecology

A. flavus occurs universally in food crops in the tropical and warm temperate zones of the world. It is associated with peanuts, maize, and cottonseed and frequently produces aflatoxins in these commodities. It also occurs in tree nuts, especially pistachios (18) and Brazil nuts (19, 20) and less commonly in hazelnuts, walnuts, cashew nuts, coconut, copra, and pecans (6, 18, 21–23). Evidence indicates that *A. parasiticus* has a more limited ecological and geographical range than *A. flavus*. It is common in peanuts wherever they are grown but uncommon in most other foodstuffs. It occurs in the same climatic regions as *A. flavus* except that it is uncommon in Southeast Asia (24). *A. nomius* has been shown to be a common cause of aflatoxin production in Brazil nuts (19, 20). *A. minisclerotigenes* was originally detected in peanuts (25) but has been found to be widespread (26, 27). The occurrence of *A. flavus* and related species in foods has been reviewed extensively elsewhere (6, 23).

Toxicity of Aflatoxins

Aflatoxins have likely involvement in five toxic effects: acute toxicity, liver carcinogenicity, liver cirrhosis, immunosuppression, and growth retardation in children.

Acute Toxicity—Aflatoxicosis

An outbreak of hepatitis due to aflatoxin ingestion from maize occurred in India in 1974: almost 400 cases were identified, and 106 deaths were reported. Clinical features were jaundice preceded by

fever, vomiting, and anorexia, with ascites and edema in the lower limbs in extreme cases. Levels in analyzed foods were often extremely high, with estimated daily ingestion of up to 6 mg of aflatoxins (28). Two outbreaks of aflatoxicosis were documented in Kenya in 1981 and 2004. In the latter outbreak, 317 cases and 125 deaths were reported (8, 29, 30). A smaller outbreak occurred in Malaysia in 1988, where 13 children died from acute hepatic encephalopathy from consumption of commercially prepared noodles contaminated with aflatoxin (31).

With the exception of the Malaysian incident, aflatoxicosis occurs only when drought or famine causes exceptionally high levels of aflatoxins in the diet or forces the eating of substandard food.

Liver Carcinogenicity

More insidious and more frequent is the development of liver cancer from consumption of much lower levels of aflatoxin over longer periods. IARC recognizes aflatoxin B_1 and naturally occurring mixtures of aflatoxins as group 1 carcinogens; i.e., they are recognized as carcinogenic to humans (2). Studies in the past 20 years have determined that hepatitis B virus also causes human liver cancer; the two agents are causal and synergistic. In its risk assessment of aflatoxins, the Joint FAO/WHO Expert Committee on Food Additives (JECFA) has derived two potency factors for cancer formation by aflatoxins: for aflatoxin alone, 0.01 case per 100,000 people per annum per ng per kg of body weight per day and for individuals carrying hepatitis B infection, 0.30 case. Thus, the two agents together are about 30 times as potent as aflatoxin alone (3). It has been estimated that aflatoxin is responsible for between 25,000 and 155,000 of the approximately 600,000 deaths from liver cancer in the world each year (32, 33).

In the liver, aflatoxin B_1 is converted by cytochrome P450 enzymes to the 8,9-epoxide. This is capable of binding to liver proteins, leading to liver failure and potentially to aflatoxicosis. This epoxide

is also able to bind to DNA, a precursor to the development of liver cancer.

Stunting in Children

A number of studies have now provided evidence that aflatoxin exposure before birth and in early childhood is associated with stunted growth, defined by the World Health Organization (WHO) as height for age being more than two standard deviations below average height for age in a given population. It is apparent, from the high numbers of people believed to be consuming uncontrolled levels of aflatoxin, that stunting is an important disease burden that has only recently been recognized (34, 35). Growth suppression has also been observed in a number of mammals and avian species.

Immunosuppression

Aflatoxins have been shown to suppress the cell-mediated immune response in both cell lines and domestic animals. Effects include the impairment of delayed-type hypersensitivity, decreases in the phagocytic activity of macrophages, increased susceptibility to infection, and reduced response to vaccines (3, 23). Few studies in humans have been reported, but it is apparent that if the effects in humans mirror those in animals even approximately, then the immunosuppressive effects of aflatoxins probably have very broad implications for human health.

Liver Cirrhosis

Direct evidence that aflatoxins are involved in liver cirrhosis is limited, but as death from cirrhosis of the liver is an important cause of mortality, any enhancement by aflatoxin of other factors in causing cirrhosis will have important consequences.

Analysis of Aflatoxins

Aflatoxins are usually very unevenly distributed in commodities, especially peanuts, where few nuts are contaminated but

contamination levels in individual nuts are often high, up to 1 mg kg^{-1}. For that reason, sampling is considered the largest source of error in aflatoxin assays (36). Sampling plans have been developed for continuous lines, for 10-metric-ton lots, and for bag stacks (37–39). The Food and Agriculture Organization (FAO) recently released an online system for calculating the efficacy of sampling plans over a range of mycotoxins and commodities (40). All of the recommended methods use samples sizes of 8 kg or more. Entire samples should be comminuted in a vertical chopper or similar mill. Subsamples, ideally of 500 g or more, may be extracted by a variety of mixed polar and nonpolar solvents, depending on the food matrix being analyzed. Methanol-water (80:20) is recommended for commodities such as maize, peanuts, and cottonseed (41).

The traditional method for aflatoxin assays is thinlayer chromatography (TLC), and as this is inexpensive and reliable, it is recommended for less developed economies. For "acceptable/not-acceptable" testing, immunochemical methods are most frequently used. For advanced users, such as high-volume analytical laboratories or regulatory authorities, high-pressure liquid chromatography (HPLC), preferably coupled with tandem mass spectrometry (HPLC-MS/MS), for determination of aflatoxins alone or in combination with other mycotoxins has been widely used. Limits of detection are now well below 0.1 μg/kg (42, 43).

Occurrence and Regulation of Aflatoxins in Foods

Levels of aflatoxins in foods are highly variable. Only a few commodities are at serious risk if good agricultural and manufacturing practices are observed. Peanuts, maize, and cottonseed frequently contain unacceptable levels of aflatoxins, and assays are usually carried out at wholesale intakes and frequently in finished products as well. In developed countries, regulations are generally stringently applied to human foods and animal feeds that contain appreciable amounts of these commodities. Other closely watched commodities are tree nuts, especially pistachios and Brazil

nuts, figs, and spices. Although levels in these commodities may exceed regulatory limits from time to time, such levels seldom pose a long-term risk to human health.

Under inadequate storage conditions, other grains including sorghum and rice may also permit growth of *A. flavus* and aflatoxin production. These commodities have very high consumption levels in many communities, so careful storage is of great importance.

Regulation of aflatoxin levels in foods commenced about 1970, using what was then the limit of detection, 5 μg kg^{-1}, as the permitted limit. However, as peanut producers could not reach that limit, higher limits were set in peanut-exporting countries, including the United States and Australia. As analytical techniques improved, with the introduction of liquid chromatography, lower limits were frequently set by importing countries, especially in Europe. The understanding of aflatoxin toxicology has produced a compromise safe limit for human consumption of 15 μg kg^{-1} in peanuts. Levels in most foodstuffs, where aflatoxin is less likely to occur, remain lower, usually 5 μg kg^{-1} or less. Although safe levels of aflatoxins have now been established and aflatoxin levels are closely controlled in developed countries, it has been estimated that up to 5 billion people worldwide are at risk from exposure to uncontrolled levels of aflatoxins in their diets (44).

Control of Aflatoxins in Foods

Control of aflatoxins has proved very difficult, as invasion by *A. flavus* (and *A. parasiticus* in peanuts) occurs before harvest in all of the major crops affected (6). In peanuts, it appears likely that infection by *A. flavus* while nuts are still in the ground is a prerequisite for high levels of aflatoxins to be formed after harvest (45). In the absence of high preharvest infection levels, and with rapid and effective drying, peanuts can be produced free of any appreciable level of aflatoxin. The major causes of preharvest infection are high spore numbers in soil and plant stress induced by drought and/or high soil temperatures (23, 46). *A. parasiticus* and

A. flavus are commensals in peanuts, as both fungi are able to grow in peanut plants and developing peanuts (47).

Partial control of spore numbers can be achieved by crop rotation, as numbers of *A. flavus* in soil decrease under small-grain cultivation or pasture. Irrigation, which eliminates drought stress, is regarded as the most effective method for reducing aflatoxin formation in peanuts (48). However, peanuts throughout the world are recognized as a drought-resistant crop and are mostly grown under dry culture, with irrigation being reserved for crops that are more sensitive to drought, such as rice or vegetables. In many areas where peanuts are grown, irrigation is not an option. Under these circumstances, reduction in drought stress by good agricultural practices can be a beneficial approach; for example, by weed control and wider spacing between rows. Harvesting early when drought stress occurs can help reduce contamination. Rapid drying of peanuts using mechanical dryers as soon as possible after pulling has a major effect in reducing the levels of aflatoxins in peanuts. Maintaining dryness during storage is also essential (49).

A. flavus is also a commensal in maize and cottonseed (50, 51), so preharvest infection is common in these crops. In maize, the infection route is usually through insect damage and, in cotton, through the nectaries. For maize, irrigation and improved farm management practices have a beneficial effect on aflatoxin formation (52). However, as maize is usually dried in the field, rapid drying techniques are not commonly practiced. Control of insect damage in maize (53) and a number of practices including good storage conditions (54) and genetically modified crops (55) are used to control aflatoxin levels. Cottonseed is a by-product of cotton production, and seed often accumulates in heaps at cotton factories before drying. Breeding of cotton without nectaries has been proposed as one means of limiting *A. flavus* access to cotton bolls (51).

In tree nuts, cultivar selection, harvest timing, and irrigation rate are important factors in efforts to reduce aflatoxin formation. Insect

control is also of great importance (56). Entry of *A. flavus* into pistachio nuts depends on the time of splitting of hulls. Nuts in which hull splitting occurs early are much more susceptible to *A. flavus* invasion (57). Some cultivars are more prone to early splitting than others, so where nuts are harvested from the ground, cultivar selection is important.

Figs are sometimes infected by *A. flavus*, both because of their unique structure developed for insect fertilization and because they are harvested from the ground in some countries. Immature figs are not colonized by *A. flavus*, but once they are ripe, infection occurs readily and fungal growth continues during drying (58, 59). The proportion of figs infected is usually very low (60).

Good agricultural practice has been the standard method in developed countries for attempting to control aflatoxin levels in commodities, particularly maize and peanuts. Good agricultural practice involves good farm management, including weed control, optimal row and plant spacing, insect control, adequate water supplies, rapid and complete drying, removal of defects, and effective control of storage conditions. By themselves, these approaches are often inadequate; too often, drought stress and/or insect damage results in aflatoxin formation before harvest, out of farmer control, even in developed countries. The only effective hazard analysis and critical control point plan for aflatoxins remains end product testing.

Reducing Aflatoxin Levels in Foods

In peanuts, reduction in aflatoxin levels is accomplished by color sorting of individual kernels after shelling. The process was developed originally to reject commercially unacceptable discolored nuts, regardless of cause, but as fungal growth is a prime cause of discoloration, the process is also an effective nondestructive means of removing most nuts containing aflatoxins. In crops under severe drought stress, peanuts begin to dry in the ground, and under these conditions, luxuriant growth of *A. flavus* can occur, with high

aflatoxin production. In this case, blanching to remove skins and roasting to increase discoloration permits effective color sorting to be carried out(61). Manual or mechanical sorting of Brazil nuts, and drying at 60°C for 30 to 36 h, eliminated more than 98% of aflatoxins (20).

Maize and fig samples are screened for the presence of aflatoxin by the examination of cracked kernels or fruit by UV light. No effective nonchemical testing techniques exist for cottonseed or pistachios, and, as with other commodities, nondestructive chemical assays are not available.

In developed producing countries, it is standard practice to assay aflatoxin levels, often repeatedly, in consignments of peanuts and maize from intake to shellers to final product. Such controls rarely exist in less developed countries. Other commodities are similarly screened according to needs and markets.

The extent to which aflatoxins are destroyed during heating is largely dependent on the process used. Dry roasting of peanuts at 160, 180, and 200°C resulted in aflatoxin reduction of 62, 84, and 90%, respectively (62). Microwave roasting at 140°C for 4.5 min and at 185°C for 7 min reduced aflatoxins by 21% and 100%, respectively, but both temperature and time conditions resulted in excessively dark nuts (63).

Nixtamalization, the processing of corn for making tortillas, reduces aflatoxin in maize by >90% (64). The alkali process used to produce refined table oil completely removes aflatoxin (65).

Interventions to Reduce Aflatoxins

Several approaches have been put forward to reduce aflatoxin levels in foods and feeds in recent years. The most advanced preharvest approach for limiting aflatoxin formation in peanut, maize, and cotton crops is biocontrol by competitive exclusion. This technique relies on the fact that only about 40% of *A. flavus* strains produce aflatoxins. Spores of selected nontoxigenic strains that are both

competitive in the field and unlikely to revert to toxicity are added to carrier seed (rice or sterilized sorghum) and introduced into soils during late stages of crop growth, where spores multiply rapidly (47, 66–68). The nontoxigenic spores compete with the existing toxin-producing spores in the soil for infection sites on developing nuts, kernels, or seeds. If the fungus grows to sufficiently high numbers, control can be very effective. This process was developed independently in Australia (47, 66) and in the United States (67), where it is used commercially for peanut and cotton crops (68, 69). Studies on biocontrol for maize in Africa have reported the method to be very successful (68, 70), and biocontrol is now in use on a large scale in several African countries (71). Experiments in Thailand have been less successful (72).

Other reported experimental studies have aimed to improve farm efficiency by providing advice and improved management for farmers in less developed countries (73). Some success has been achieved. Another approach has been to use weather and soil data to forecast when drought stress and aflatoxin production are about to occur. Such forecasting has been very well developed and successful in Queensland, Australia, for both peanut (74) and maize crops (75).

The discovery that certain montmorillonite clays adsorb aflatoxins very strongly has led to experiments where such clay is added at concentrations of a few percent to animal feeds, where it has been very effective. Trials with clay added to human food have also showed promise, but this approach is likely to be reserved for emergency remedial use (23, 76).

OCHRATOXIN A

Chemical Characterization

Ochratoxins are mycotoxins containing a dihydroisocoumarin ring linked to phenylalanine through a 7-carboxy group (Fig. 22.1). Several ochratoxins are known: OTA; its ethyl ester, ochratoxin C; and dechlorinated analogues, i.e., ochratoxin B and its methyl and

ethyl esters. Ochratoxins A and B are the only ones so far detected in naturally contaminated foods or feeds. OTA is the most toxic compound and the only one discussed here.

Fungal Sources

OTA is produced by three well-defined groups of fungi: (i) the ochre-colored aspergilli, including *Aspergillus ochraceus*, *A. westerdijkiae*, *A. steynii*, and a few other much less important, closely related species; (ii) the black aspergilli, including *A. carbonarius* and *A. niger* (which produces OTA only infrequently); and (iii) *Penicillium* species, including *Penicillium verrucosum* plus the closely related species *Penicillium nordicum* (6, 77, 78).

A. ochraceus and Related Species

After 1 week at 25°C on the standard growth medium CYA, *A. ochraceus* and closely related species produce colonies 40 to 55 mm in diameter with ochre (light yellow brown) conidia, characteristics distinctive for this group of species. *A. westerdijkiae* and *A. steynii* are distinguished from *A. ochraceus* by their inability to grow on CYA at 37°C. *A. westerdijkiae* produces finely roughened, spherical conidia, and *A. steynii* produces smoothwalled, ellipsoidal conidia, while those of *A. ochraceus* are smooth-walled and spherical (6) (Fig. 22.3a to c).

These three species have similar growth requirements so far as is known apart from the difference in maximum growth temperature, ca. 40°C for *A. ochraceus* and about 5°C lower for the other species.

Although *A. ochraceus* was the species first recognized as producing OTA, advances in molecular and fungal metabolite techniques have resulted in the separation of *A. westerdijkiae* and *A. steynii* from *A. ochraceus* (79). Studies reporting *A. ochraceus* before 2005 were likely to include all three species under the name *A. ochraceus* (80–82). *A. westerdijkiae* is now recognized as the main source of OTA in coffee (79, 83). These three species are xerophilic, growing at an

a_w of 0.8 or below, and so have been isolated from stored dry foods on occasion.

A. carbonarius and *A. niger*

A. carbonarius and *A. niger* produce rapidly growing, black or deep reddish-brown colonies on CYA, usually 60 mm or more after 7 days at 25°C. *A. carbonarius* produces much larger conidia (6 to 7 μm in diameter) than *A. niger* (4 to 5 μm). *A. carbonarius* grows at from 10 to 40°C and at an a_w as low as 0.85 (6) (Fig. 22.3d to f).

A. carbonarius has a major habitat in vineyards and grape-drying yards, where its ability to tolerate high temperatures and strong sunlight (as a result of its dark hyphae and spores) provides a competitive advantage. It has been recognized as the primary source of OTA contamination in grapes and grape products, including wines, throughout the world (84–86). Grapes are usually sun dried without preservatives, so raisins and sultanas sometimes contain unacceptable levels of OTA (87–89). OTA can also result from growth of *A. carbonarius* in coffee beans (82, 90, 91) and cocoa beans (92, 93). Other sources, including figs (59, 94), peanuts and maize (95, 96), and paprika (97), are less important.

Figure 22.3 (a) *A. ochraceus*, CYA, 7 days at 25°C; (b) *A. ochraceus* fruiting structure (bar, 20 mm); (c) *A. ochraceus* conidia (bar, 5 mm); (d) *A. carbonarius*, CYA, 7 days at 25°C; (e) *A. carbonarius* fruiting structure (bar, 40 mm); (f) *A. carbonarius* conidia (bar, 5 mm); (g) *P. verrucosum*, CYA, 7 days at 25°C; (h) *P. verrucosum* fruiting structure (bar, 10 mm); (i) *P. verrucosum* conidia (bar, 5 mm).

A. niger has usually been regarded as a benign fungus and has been widely used in enzyme production and ingredients for food processing. It holds GRAS (generally regarded as safe) status from the U.S. Food and Drug Administration. Usually, only a low percentage of *A. niger* isolates are able to produce OTA. Although *A. niger* is very frequently isolated, it is not a significant source of OTA as a rule.

P. verrucosum and *P. nordicum*

P. verrucosum and *P. nordicum* are very similar, slowly growing species, with colonies reaching only 15 to 25 mm in diameter on CYA after 7 days at 25°C and being colored dull green to dark green. Both grow from about 0 to 30°C and at an a_w as low as 0.80 (6) (Fig. 22.3g to i).

P. verrucosum is the major OTA producer in cereals grown in cool temperate climates, ranging across northern and central Europe, Canada, and northern Asia (98). In these regions, OTA is frequently present in cereal products, especially bread and flour-based foods, and in the meat of animals which eat cereals as a major dietary component (99). *P. verrucosum* is not found in warmer climates, so small grains from the tropics and warm temperate zones do not contain OTA (6). *P. nordicum* is closely related to *P. verrucosum* (100) but occurs in manufactured meat products such as salami and ham, not in cereals. This species does not appear to be a major problem.

Toxicity of OTA

OTA is a chronic nephrotoxin, affecting kidney function in all animal species tested. OTA is readily absorbed through the intestines and, once it enters the bloodstream, has a long half-life, up to 3 weeks in monkeys. As a result, the blood of healthy humans regularly contains detectable amounts of OTA in areas where it is frequently part of the diet, i.e., northern Europe, northern North America, and northern Asia (101). Recent indications of OTA in human blood from other parts of the world are almost certainly due to the presence of *Aspergillus* species producing OTA in foods.

OTA also has carcinogenic properties, but the mechanism of carcinogenicity remains unclear. The carcinogenic effects in animals are considered to be of less importance than the nephrotoxicity (101, 102). Although OTA is demonstrably toxic to animals of all kinds, its effects in humans remain unclear and the subject of debate. Both genotoxic and nongenotoxic modes of action have been proposed (102, 103). IARC has classified OTA as a possible human carcinogen (group 2B), based on sufficient evidence of carcinogenicity in experimental animal studies and inadequate evidence in humans (2). The target organ of toxicity in all mammalian species tested is the kidneys, in which lesions can be produced by both acute and chronic exposure (103).

Although the mechanism of action of OTA is unclear, its structural similarity to phenylalanine and the fact that it inhibits many enzymes and processes that are dependent on phenylalanine strongly suggest that it acts by disrupting phenylalanine metabolism (104). As it is a phenylalanine analogue, OTA toxicity in animals can be reduced by treatment with phenylalanine (105).

Exposure Assessment

Assessment of OTA exposure has proved to be very difficult. People in Europe and northern North America are exposed to OTA in barley and wheat and their products, especially bread, and also to that in meat, especially pork, from animals fed contaminated feed (23). Low levels also occur in beer, wines, coffee, cocoa, chocolate, and

dried vine fruits. However, as wheat and barley crops from warmer climates are not infected by *P. verrucosum*, OTA intake is much lower in tropical and subtropical regions (106).

Risk Characterization

JECFA set the provisional tolerable weekly intake (PTWI) of OTA at 100 ng/kg of body weight in 2001 (101) and confirmed that value more recently (103). This PTWI is based on the lowest observed level of acute toxicity in pigs, as risk assessments have indicated that the acute toxicity occurs at lower intake levels than any carcinogenic effect (101). However, a Canadian reevaluation of the risk associated with OTA has reduced the PTWI to 21 ng/kg of body weight, by applying a larger uncertainty factor to available toxicity data (102). Despite this evaluated high toxicity, the fact remains that although OTA is commonly found in blood from persons in some regions, OTA has not been correlated with any known human syndrome.

Dietary exposure to OTA is based primarily on data from Europe, where processed cereal foods sometimes contain high OTA levels (102, 103). JECFA (103) has assessed the dietary exposure to OTA from processed cereals in Europe as 8 to 17 ng/kg of body weight per week, well below the PTWI. However, in a previous evaluation, JECFA had determined that the 95th percentile for OTA consumption was about 90 ng/kg body weight, approaching the PTWI (101). Even with some additional intake from wines and coffee, the hazard from intake of OTA in Europe appears low. Intake in other parts of the world is likely to be much lower, in the absence of appreciable levels in cereals.

Analysis of OTA

The introduction of monoclonal immunoaffinity columns as a cleanup step for the analysis of OTA was a major improvement in assessment of OTA contamination in foods (43). These columns selectively separate OTA from interfering compounds, and this

effective separation is usually followed by analysis by HPLC with fluorescence detection (43). Other methods for quantification of OTA in foods include TLC and immunoassays such as enzymelinked immunosorbent assays. LC-MS/MS allows accurate determination of OTA without any need for cleanup in several types of matrices (43).

Occurrence and Control of OTA in Crops

None of the fungi producing OTA are known to be systemic invaders or pathogens of food crops, so the occurrence of OTA in foods is usually due to postharvest contamination (107). In consequence, control of OTA relies on good practice. For cereal grains, coffee cherries (dry process), and grapes, rapid drying ensures low production of OTA. However, climatic conditions often make that difficult to achieve.

A. carbonarius occurs in vineyards and can infect grapes before harvest, as the result of damage by plant-pathogenic fungi, including powdery mildews and *Rhizopus* and *Botrytis* species, or skin splitting due to rain damage. The resulting *Aspergillus* bunch rots generally occur near harvest, when the sugar content of berries is highest (86, 108), resulting in the prevalence of OTA in grape juice and wines. OTA mostly occurs in wines from the warmer growing areas throughout the world, but levels are usually low (109). If grapes for wine production are substantially sound, i.e., free from rotting fruit, and are crushed quickly after harvest, leading rapidly to anaerobic conditions, OTA can be held to low levels (110), as the fermentation process stops growth of the fungus.

When grapes are dried, mechanical damage during harvesting and the time in the drying yard increase the probability of OTA formation. The population of *A. carbonarius* in vineyards can be reduced by good management practices, including irrigation, pruning to improve air flow through vines, use of cover crops between rows, and appropriate fungicide applications (108, 111, 112).

Fungi capable of producing OTA are rarely present on coffee cherries (mature fruit) at harvest (82). Harvested coffee cherries are processed via two basic systems: (i) the dry system, where the whole fruit remains intact, producing what is called natural coffee or dried coffee, and (ii) the wet processing system, where the seed is enclosed only in the inner integument or endocarp, producing what is called parchment coffee (113). Slow drying in either system can potentially lead to OTA formation. Effective sun drying or a combination of sun drying and mechanical dehydration provides effective control (82).

If grains are stored under safe conditions, OTA formation will also be minimal (46, 114). However, in cool temperate climates, *P. verrucosum* has the potential to produce OTA during slow drying or in storage (98).

Effect of Processing on OTA

OTA is largely removed during the winemaking process, as it is bound to solid fractions and sediment. Use of some fining agents can also reduce OTA levels in wine. Red wines retain slightly more OTA than white wines, but overall, the carryover from grapes into finished wine is <10% (110, 115, 116).

When the kinetics of OTA destruction during coffee roasting was studied at four temperatures (180, 200, 220, and 240°C) over three time periods, a reduction from 8% to 98% was observed, with reduction depending directly on the degree of roasting (117). Although thorough roasting of coffee beans may destroy OTA effectively, the use of highly contaminated beans in coffee blends is not recommended, as beverage quality may be affected. The effects of processes such as roasting, drink preparation, and instant coffee production on OTA destruction have been reviewed elsewhere (118, 119).

Bran and germ removal reduces OTA levels in flour and flour-based products, with the degree of loss being influenced by the process used (120). Milling hard wheat to produce white flour produces an

approximately 65% reduction in OTA, and a further 10% decrease occurs during baking. Whole-meal flour and bread showed much less reduction in OTA during processing, as might be expected, because less of the grain is discarded (120).

Dry and moistened samples of wheat contaminated with OTA were heated at several temperatures and times, and the times to 50% destruction of OTA under various heating conditions were calculated. A 50% inactivation of OTA at 100, 153, 200, and 250°C required 707, 201, 12, and 6 min, respectively, for dry wheat. For moist wheat, the corresponding inactivation times at 100, 150, and 200°C were 145, 64, and 19 min, respectively. Complete destruction did not occur even at 250°C (121).

FUSARIUM MYCOTOXINS

The most important general observation to be made about the production of mycotoxins by *Fusarium* species is that they all grow only at high a_ws (>0.9) (6), so toxin production in crops occurs only before harvest or during early stages of drying (107). Production of mycotoxins ceases long before the crops are fully dried and occurs only during storage under catastrophic conditions, such as flooding. Production of *Fusarium* mycotoxins occurs as the result of growth of the causal fungus in the living plant and seed.

FUMONISINS

Chemical Characterization

Fumonisins are a family of compounds comprising longchain aliphatic acids with esterified carboxylic acid side chains. Fumonisins are large molecules: the most important, fumonisin B_1 (CAS [Chemical Abstract Service] registry no. 116355-30-0), has the molecular formula $C_{34}H_{59}NO_{15}$, with a molecular weight of 721. Fumonisins are structurally similar to the sphingoid base backbone

of sphingolipids, which are important membrane constituents (122) (Fig. 22.4).

Fungal Sources

Fumonisins are produced by *Fusarium verticillioides* (referred to in older literature as *Fusarium moniliforme)* and some closely related species, in particular, *Fusarium proliferatum*. These species are systemic in maize worldwide, being always present in the plants, even in healthy kernels (123). Surprisingly, fumonisins are also produced by *A. niger* (124, 125).

F. verticillioides grows rapidly at 25°C on any standard mycological medium, including CYA, MEA, and potato dextrose agar (PDA) (6, 126). Colonies are white to pale salmon, with low and often ropy mycelium and a powdery texture due to production of chains of microconidia. The reverse color on PDA is variable and can be pale salmon, grayish violet, brownish violet, or deep violet. Slow growth occurs at 37°C on these media.

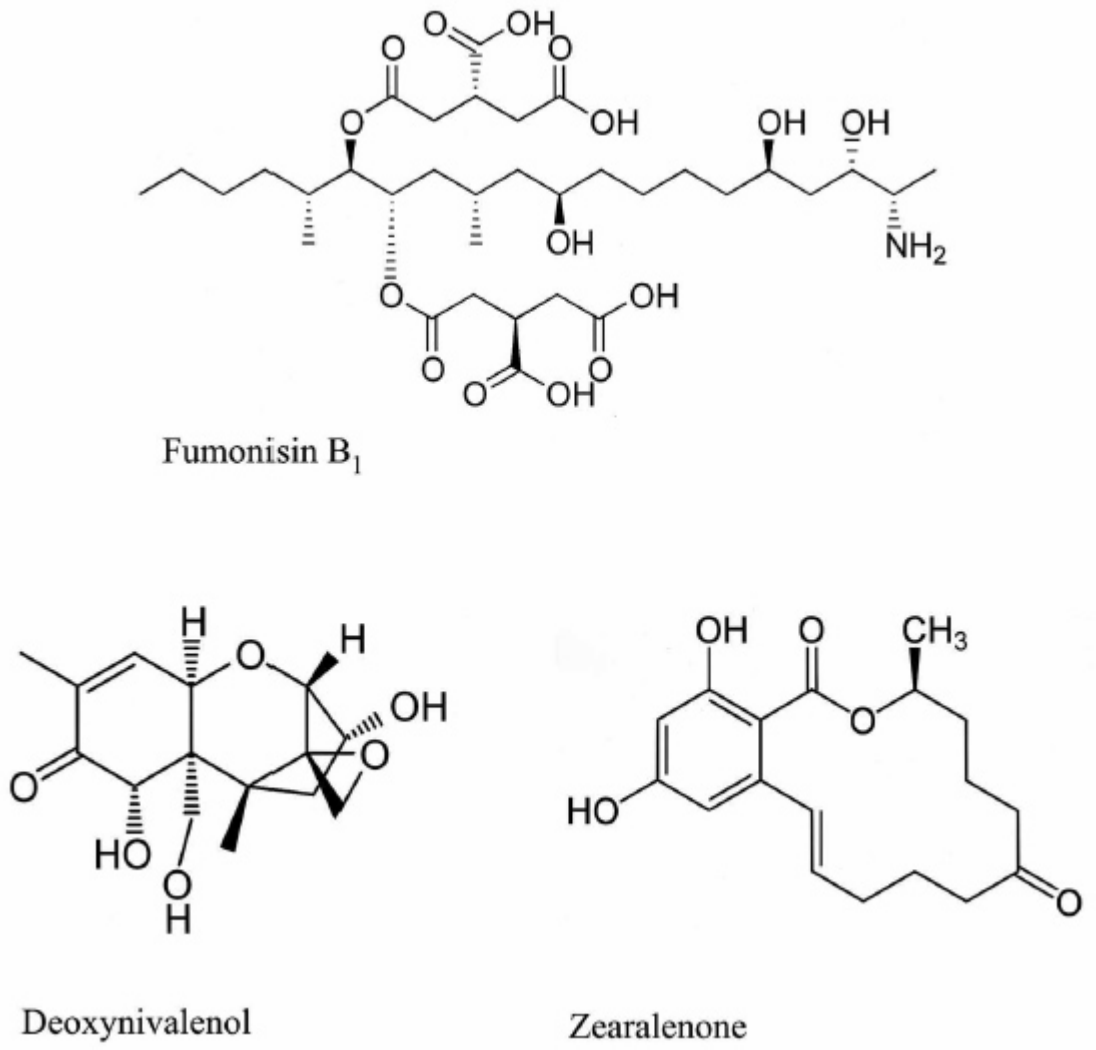

Figure 22.4 Structures of fumonisin B_1, DON, and ZEA.

Characteristic *Fusarium* spores, macroconidia, are produced on dichloran chloramphenicol peptone agar (6) or other specialist media. Macroconidia are long (40 to 50 µm) and slender, almost straight, and thin walled, with foot-shaped basal cells. Microconidia are pointed at both ends or club shaped, are 7 to 10 µm long, and are produced in chains from long single phialides (fruiting cells) (6, 126) (Fig. 22.5a and b).

F. proliferatum is very similar, but colonies on PDA lack purple colors in the reverse, and microconidia are produced from phialides with more than one fertile neck (126).

Fumonisin production in maize is favored by relatively high temperatures (127). Fumonisins are found primarily in maize and sorghum, as *F. verticillioides* and *F. proliferatum* rarely infect other crops. Levels are mainly influenced by local climatic conditions near harvest. Under plant stress, the normally symptomless endophytic relationship may change to a disease- and/or mycotoxin-producing interaction (128–130). It is likely that water stress and insect predation, factors related to the onset of this change in the fungus-plant interaction, may be involved in this conversion (131). Biological interactions between the maize plant and the fungus are complex (132). Endophytic growth of *F. verticillioides* within the maize plant may be of benefit to plant growth, as observed in other members of the *Gramineae* (133). *F. verticillioides* has been reported to suppress the growth of *Fusarium* species which cause *Gibberella* ear rot (134).

The production of fumonisin B_2 by *A. niger* was reported quite recently (124). Previously, production of fumonisins was believed to be exclusive to species of *Fusarium*. *A. niger* has been shown to produce fumonisin B_2 and fumonisin B_4 on grapes and raisins (135), while only fumonisin B_2 has been found in coffee (136). *A. niger* is among the fungi most commonly detected in foods, raising the possibility of co-occurrence of OTA and fumonisin B_2 in foods.

Besides *A. niger*, the very closely related species *Aspergillus welwitschiae* (also known as *Aspergillus awamori*) has been shown to produce OTA and fumonisin B_2 (136, 137). Of 175 Brazilian isolates collected from dried fruits, Brazil nuts, coffee beans, grapes, cocoa, and onions and previously identified as *A. niger*, about one-half have now been reidentified as *A. welwitschiae*. Among *A. niger* isolates, approximately 74% were fumonisin B_2 producers, compared to 34% of *A. welwitschiae* isolates (137).

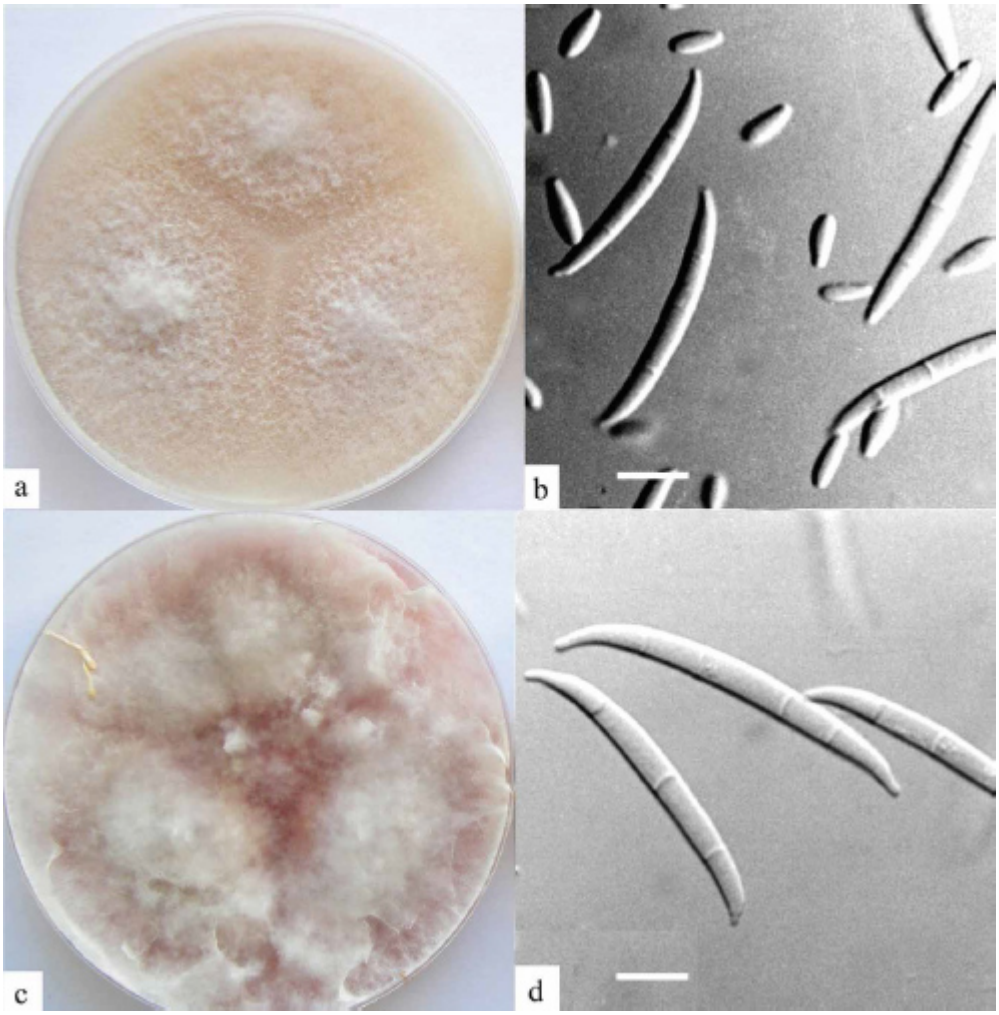

Figure 22.5 (a) *F. verticillioides*, PDA, 7 days at 25°C; (b) *F. verticillioides* macroconidia (bar, 10 mm); (c) *F. graminearum*, PDA, 7 days at 25°C; (d) *F. graminearum* macroconidia (bar, 10 mm).

Toxicology

Fumonisins are remarkable for their wide range of effects in animals and humans. Fumonisins act by inhibiting ceramide synthase, causing accumulation of intermediates of sphingolipid metabolism and also causing depletion of complex sphingolipids. These effects interfere with the functions of some membrane proteins, including folate binding. The most dramatic effect occurs in horses, in which it causes equine leukoencephalomalacia. This is a rapidly progressing disease that turns equine brains to mush. For

horses, consumption of feed containing >10 mg/kg fumonisin B_1 in the diet (equivalent to 0.2 mg/kg of body weight per day) was associated with increased risk of developing this disease (103). In pigs, fumonisins cause pulmonary edema due to left ventricle heart failure (103). In rats, the primary effect is liver cancer (138), but fumonisins also cause programmed cell death (apoptosis) (139). It is unusual for a single toxin to have such diverse effects in different animal species, and the reasons for that remain unknown (140).

In humans, fumonisins and *F. verticillioides* are associated with esophageal cancer. Extensive studies in areas of low and high maize consumption in South Africa have established this connection (103, 141). This disease is also prevalent in areas of China (142) and also occurs at significantly higher levels than background in parts of Iran, northern Italy, Kenya, and a small area of the southern United States (103). In all those areas, consumption of maize and maize products is very high.

Some evidence exists that a high intake of fumonisins from maize may be associated with neural tube defects such as spinal bifida in areas of Guatemala, South Africa, and China and a population along the Texas-Mexico border (143). In animal models, folate supplementation has been shown to reduce the incidence of neural tube defects (144). Numerous studies have shown that antioxidants can prevent some of the cytotoxic effects of fumonisins and other mycotoxins (103, 145).

Analysis of Fumonisins

The most effective solvent for extraction of fumonisins is methanol-water (146). The most satisfactory cleanup method is the use of a solid-phase extraction cartridge (146).

The traditional TLC method is still in use and is recommended for less developed economies, as it is inexpensive and reliable (146). Enzyme-linked immunosorbent assay techniques are also effective for fumonisin analysis. Although antibodies are raised against fumonisin B_1, crossreactivity usually occurs with fumonisins B_2 and

B_3 as well. Commercial kits are available from several manufacturers, and a range of methods has been described (147).

Detection of fumonisins by HPLC continues to be widely used, although ultra-high-pressure liquid chromatography (UHPLC) is in increasing use, as it has the potential to reduce separation times. As the fumonisins lack a good chromophore, chromatographic methods generally rely on MS or derivatization and detection by fluorescence or UV absorbance. A large number of such methods for fumonisins have been published, either singly or in combination with other mycotoxins (43).

Occurrence and Regulation in Foods

The major source of fumonisins in foods is maize, though other small grains may have low levels at times. With the discovery that *A. niger* may produce fumonisins, the range of foodstuffs where fumonisins may be found has become much wider. The toxicological implications of this discovery have not yet been assessed, but it is unlikely to have a major impact on food safety.

The United States has established guidelines for fumonisin levels: dry milled grain products should contain no more than 2 mg/kg of total fumonisins (148). In the European Union, the limits are 1 mg/kg for maize flour, semolina, germ, and oil and 0.4 mg/kg for products that are ready for consumption, except that for babies and children the limit is 0.2 mg/kg (149).

Control

Fumonisins occur in maize preharvest. It is known that drought stress and insect damage are major factors inducing production, so good agricultural practices, rain, irrigation, and the cultivation of cultivars carrying genes from *Bacillus thuringiensis* (Bt maize genotypes) are all important in limiting fumonisin formation. Some progress has been made in breeding cultivars resistant to *Fusarium* ear rot (107, 123, 127).

As insect damage and fumonisin levels correlate, transgenic Bt maize genotypes can lower levels of *F. verticillioides* infection and fumonisin formation (127).

Freshly harvested maize should be rapidly dried to a stable moisture level as soon as possible (150, 151), but this is important only in the initial stages of drying because *Fusarium* species do not grow below an a_w of about 0.9, so once the kernel moisture content has been reduced below that figure, fumonisin accumulation ceases (107). Moreover, fumonisins are not produced in storage. Even if very high moisture occurs due to water ingress, competition with other microorganisms at such high water activities will prevent any significant increase in fumonisin levels (107).

In most geographical areas, the main methods for controlling fumonisin levels are visual inspection of lots for fungal damage, followed by fumonisin analyses and rejection of lots that do not meet specifications. Visible sorting of maize grain as a technique to reduce fumonisin levels by subsistence farmers has been proposed (152) and optimized (153, 154).

In Central America, the process of nixtamalization removes almost all fumonisins, so tortillas and other maizebased foods are substantially free of these mycotoxins in that region (155).

Effect of Processing on Fumonisins

Wet milling of maize produces maize starch, germ, and fiber, while dry milling produces bran, germ, and fractions of decreasing particle size—grits, corn meal, and corn flour (156). Fumonisins are not destroyed during these processes and are found in all fractions, with higher concentrations in bran and germ (157–159).

Fumonisin levels are reduced by processing at temperatures above 150°C, including frying (160), baking, roasting, and extrusion (158, 161, 162). Extrusion is used extensively in the production of breakfast cereal, snack foods, and textured foods. The highest

reduction in fumonisin levels occurs at extrusion temperatures of 160°C or higher and in the presence of glucose (163, 164).

DEOXYNIVALENOL

Chemical Characterization

DON belongs to the family of chemicals known as the trichothecenes, sesquiterpenoid compounds that are characterized by a 12,13-epoxy ring. At least 100 trichothecene molecules are known, differentiated by hydroxyl or acetyl groups and side chains. DON, still sometimes known as vomitoxin in the United States, is 12,13-epoxy-3,7,15-trihydroxy-trichothec-9-en-8-one, CAS registry no. 51481-10-8 (165) (Fig. 22.4). It is the most commonly produced trichothecene. Nivalenol differs from DON by the substitution of a hydroxyl group for the hydrogen atom at the 4 position. The most toxic of these molecules is known as T-2 toxin, but it is not commonly produced in foodstuffs.

Fungal Sources

DON is produced by *Fusarium graminearum* (often listed as *Gibberella zeae*, its sexual stage), *Fusarium culmorum*, and, less commonly, some related species.

F. graminearum grows rapidly on any standard mycological medium, including CYA, MEA, and PDA (6). Colonies on CYA and MEA are grayish rose, grayish yellow, or paler, with reverses being orange red to yellowish brown. On PDA, colonies are yellowish brown to reddish brown, sometimes with a central mass of red-brown to orange areas bearing macroconidia, with the reverse being dark red.

Characteristic *Fusarium* conidia, macroconidia, are produced on dichloran chloramphenicol peptone agar or other specialist media, usually with five septa, and are thick walled and straight to

moderately curved, with a distinctly foot-shaped basal cell; microconidia are not produced (6, 126) (Fig. 22.5c and d).

Colonies of *F. culmorum* are similar to those of *F. graminearum* but are pale red to pastel red on CYA, MEA, and PDA; the reverse on CYA and PDA is pastel red to deep red, and that on MEA is brown to reddish brown. Macroconidia are relatively short, wide, and only slightly curved, with four or five septa; they are 30 to 45 μm long, with basal cells having a slight to definite notch. Microconidia are not produced (126).

F. graminearum occurs in maize, and both *F. graminearum* and *F. culmorum* occur in small grains, especially wheat and barley. These species are rank pathogens, invading plants and grains by causing diseases, known as *Gibberella* ear rot in maize and *Fusarium* head blight in wheat, barley, and triticale. Epidemics of *Gibberella* ear rot require the congruence of three factors: airborne or insect-borne spores, inoculation at the time of susceptibility, and appropriate moisture and temperature (123, 127). This disease is prevalent in north temperate climates, especially in wet years, and much less common in the tropics.

Fusarium head blight affects all commercial cultivars of wheat and barley. The formation of DON or nivalenol by *F. graminearum* depends on the geographical origin of the fungal strain (165, 166), while *F. culmorum* always produces DON (166, 167).

Toxicology

Like all trichothecenes, DON and nivalenol are inhibitors of protein synthesis (168). Nivalenol is much more toxic than DON but is produced in much lower quantities in grains and is not considered a significant mycotoxin (168). Trichothecene toxicoses in humans appear to be rare (169), but DON has been known to cause gastrointestinal problems and immunotoxicity in humans (170). DON causes feed refusal by pigs at quite low concentrations, resulting in retarded growth and economic losses (171, 172). Apart

from a general effect on protein synthesis, the mechanism of action of DON remains unclear (103).

Analysis of DON

Analysis for DON requires solvent extraction followed by cleanup by filtering through a C_{18} or silica gel column. HPLC with UV or UV plus diode array detection is the most common assay method; the more sophisticated UHPLC-MS/MS is also used (43). A multimycotoxin immunoaffinity column for the simultaneous determination of DON, ZEA, and T-2 and HT-2 trichothecenes is available commercially (173). The authors claim that the advantages of combining an immunoaffinity column with HPLC-MS/MS include efficient removal of matrix interferences, clean chromatograms, high selectivity, low limit of detection, and separation of a wide range of molecules with different physicochemical properties in a single run (173). A number of publications have reported methods to detect the so-called "masked" mycotoxins, such as DON-3-glucoside (43, 174). Such compounds are not assayed by the usual techniques.

Occurrence and Regulations

DON is found in maize and small grains in all areas where these crops are grown. It is especially prevalent in cooler areas where rainfall is high, such as Canada (175, 176) and Argentina (177), and less common in drier, hotter areas, such as Australia (178).

A number of studies have shown that fungal infection rates are higher in crops planted in fields previously planted with maize, particularly when residues from those crops are left in the field (123).

Favorable weather conditions are critical for infection by *F. graminearum* to occur in wheat heads. Researchbased field observations have confirmed that temperature and moist conditions during heading and anthesis are the major factors of importance (179).

The U.S. Food and Drug Administration has issued guidelines for DON in foods and feeds as follows: for finished wheat products that may be consumed by humans, 1 mg kg^{-1}; for grains and by-products for feedlot and dairy cattle, 10 mg kg^{-1}, except that for dairy cattle the total DON content in feed should not exceed 5 mg kg^{-1}; in feed for pigs, 5 mg kg^{-1}, with the added recommendation that these ingredients not exceed 20% of their diet; and for all other animals, 5 mg kg^{-1}, with the same recommendation that these ingredients not exceed 40% of the total diet (180).

Control

Some success has been achieved in controlling DON formation in wheat by the use of azole fungicides at anthesis (181, 182). Forecasting systems to advise farmers of the likelihood of DON formation have been developed in Canada (183) and Europe (184, 185). Otherwise, control relies on reducing levels of *Fusarium* species in the field by good management and crop rotation (103, 107).

ZEARALENONE

Chemical Characterization

ZEA is an estrogenic mycotoxin, described as belonging to the resorcylic acid lactone group. Its molecular formula is $C_{18}H_{22}O_5$, and its CAS registry number is 17924-92-4 (5) (Fig. 22.4).

Fungal Sources

ZEA is produced by the *Fusarium* species that produce DON and nivalenol, and generally speaking, it is produced under the same conditions, the main sources being maize and small grains (186).

Toxicology

ZEA has a low acute toxicity, but it and its metabolites, the zearalenols, possess estrogenic activity in pigs, cattle, and sheep. The most obvious problems are seen in pigs: doses of ZEA as low as 1 mg/kg can induce vulvovaginitis and vaginal and rectal prolapse in young female pigs (171). ZEA is also considered to be hepatotoxic, hematotoxic, immunotoxic, and genotoxic, but no studies of human carcinogenicity have been reported. The nature of its toxicity is not completely understood (186). IARC has classified ZEA as group 3, noncarcinogenic for humans (2). Estimates of human exposure from dietary sources are generally in the range of 1 to 30 ng/kg of body weight per day (183).

The metabolism of ZEA involves reduction of the 6-keto group, resulting in the formation of α- and β-zearalenol. α-Zearalenol has greater estrogenic activity than ZEA (187). ZEA has been implicated in early puberty and advanced growth of girls in Hungary and Italy (188). Its importance in human health is still poorly understood.

Analysis

The use of the immunoaffinity column method for the simultaneous detection of major trichothecenes in cereals is also effective for analysis of ZEA (173). Methods coupling MS to HPLC or UHPLC are also in use (43). UHPLC-MS/MS methods have also been developed for the quantification of ZEA and its derivatives α-zearalenol and β-zearalenol (43). A novel immunoassay using a magnetic bead electrochemical immunoassay on microfluidic chips for the determination of ZEA has also been reported (43).

Occurrence and Regulation

ZEA occurs in the same grains as DON, i.e., maize and small grains, and it occurs in all regions of the world (186).

No internationally recognized limits for ZEA exist, and specific regulations vary from 20 to 1,000 μg/kg or more (186). JECFA has established a provisional maximum tolerable daily intake of ZEA and its metabolites of 0.5 μg/kg of body weight per day (101).

Control

Control of ZEA in crops is similar to that of DON.

GENOMICS

Genomics, the study of entire genomes, provides basic information to build the knowledge base of gene functions, which will assist in understanding mycotoxin formation and reduction in crops. Understanding the molecular basis of plant resistance, where it exists, will hopefully lead to identification of biochemical factors for use in plant breeding or genetic engineering (56). Studies on economically important fungi at the genomic level will assist in understanding mycotoxin biosynthesis and also in understanding the biology, evolution, biochemical function, and genetic regulation of the genes in these fungal systems. "-Omics" studies, including genomics, transcriptomics, metagenomics, proteomics, and metabolomics, have been carried out on several toxigenic fungi, including *A. flavus*, *A. niger*, *F. graminearum*, and *F. verticillioides* (189, 190). Genome sequences have been determined for some toxigenic fungi, notably *A. niger*, *F. graminearum*, *F. verticillioides*, and *Fusarium solani*. The availability of large amounts of genomic and expressed sequence tag data has provided tools for large-scale functional analysis of gene expression in *F. graminearum* and *F. verticillioides*.

The sequencing of the *A. niger* genome led to a most unexpected result. Searches for biochemically active genes showed the presence of the genes for fumonisin (191), which was independently verified (192). It was soon confirmed that this gene cluster (consisting of at least 15 genes) was complete and active, and the ability of at least some strains of *A. niger* to produce fumonisins was confirmed (124). Indeed, recent information indicates that fumonisin production by *A. niger* is common. In one study on *A. niger* strains from a sample of Californian raisins, 50 of 66 strains (77%) produced fumonisins (135). In a second study, where isolates were

taken from 13 samples of dried vine fruits from several countries, 20 of 30 (67%) were producers (193).

Research on *Fusarium* head blight has used fungal genomics to determine the role of DON in pathogenicity and the effect of accumulation of this toxin on crop production. The information may be useful in developing resistant germplasm (56).

The availability of modern "-omics" techniques has facilitated a rapid expansion of data on the biology of toxigenic fungi, increasing significant knowledge of the biological, biochemical, and biophysical molecular processes regulating the production of mycotoxins and the adaptation of these fungi to environmental stresses (189).

Foodborne Viral Pathogens

Human enteric viruses are responsible for substantial morbidity worldwide. Transmitted predominantly by the fecal-oral route and exclusively in association with human feces and/or vomitus, these viruses come into contact with humans by a variety of routes, including the consumption of contaminated foods. A functional rather than taxonomic group, the human enteric viruses are represented by many different virus families and genera (Table 23.1). From an epidemiologic perspective, the most significant of these are human noroviruses (hNoVs), which are the most common cause of acute gastroenteritis worldwide and are now recognized as the leading causes of foodborne illness (1). For example, in the United States, hNoVs are estimated to be responsible for about 58% of all domestically acquired foodborne illnesses of known etiology, causing more than 5 million estimated foodborne cases annually (2). Additionally, epidemiologic surveillance demonstrates that they were the cause of 48% of all foodborne disease outbreaks of confi rmed etiology reported to the U.S. Centers for Disease Control and Prevention (CDC) via the National Outbreak Reporting System (NORS) in 2015 (3). Furthermore, hNoVs were estimated to be responsible for ~ 15,000 (range, 8,097 to 23,323) foodborne diseaserelated hospitalizations every year, second only to *Salmonella enterica* as the leading cause of hospitalizations due to foodborne disease. Human noroviruses also cause an estimated 150 foodborne-disease-related deaths annually in the United States (2). Enteric viruses in general may also be responsible for a large proportion of foodborne diseases of unknown etiology, the burden of which is substantial (4).

Enteric viruses can be transmitted directly by personto-person contact or indirectly by consumption of contaminated food or water or contact with fomites. The usual source of enteric virus contamination is human fecal matter, which can easily harbor up to 10_{10} genomic RNA copies per gram when shed by infected individuals—both symptomatic and asymptomatic (5). However, the role of vomitus cannot be overlooked, particularly for hNoVs, as virus particles can be shed during a vomiting episode (e.g., up to 10_5 viruses per ml), and this is likely a significant factor contributing to transmissibility (6). Aerosolization of vomitus can result in infection of exposed subjects who inhale and subsequently swallow the aerosolized virus (7); it can also provide a source of virus to be deposited on and contaminate nearby surfaces.

Table 23.1 Human enteric viruses

Family	Genus (type species)	Disease syndrome(s)	Role of foodborne transmission
Adenoviridae	*Mastadenovirus* (human adenovirus C)	Six subgroups (A–F); serotypes 40 and 41 in group F are the major causes of gastroenteritis in young children; second in prevalence to rotavirus	Credible but not documented
Astroviridae	*Mamastrovirus* (human astrovirus)	Two genogroups (A and B); human astroviruses cause acute gastroenteritis in children, elderly, and the immunocompromised	Credible but not well documented
Caliciviridae	*Norovirus* (Norwalk virus)	Seven genogroups (I–VII); I, II, and IV cause disease in humans with II being the most common; hNoVs cause acute gastroenteritis that is usually self-limiting	Well documented
	Sapovirus (Sapporo virus)	Five genogroups (I–V), four infect humans; causes sporadic outbreaks and cases of gastroenteritis that is usually self-limiting	Documented but rarely causes Outbreaks

Family	Genus (type species)	Disease syndrome(s)	Role of foodborne transmission
Hepeviridae	*Orthohepevirus* (hepatitis E virus Burma)	Causes outbreaks and cases of enterically transmitted acute hepatitis that are usually self-limiting; pregnant women are at increased risk for mortality	Travel-related transmission via waterborne routes; zoonotic transmission documented in developed countries
Picornaviridae	*Enterovirus* (poliovirus)	Cause asymptomatic or mild forms of gastroenteritis, meningitis, encephalitis, myelitis, myocarditis, and conjunctivitis	Credible but not well documented
	Hepatovirus (hepatitis A virus)	Causes relatively mild form of acute hepatitis, usually self-limiting; symptoms and severity increase with age	Well documented
	Parechovirus (human parechovirus)	Respiratory and gastrointestinal symptoms in young children; occasionally infection of the central nervous system	Credible but not well documented

Family	Genus (type species)	Disease syndrome(s)	Role of foodborne transmission
	Kobuvirus (Aichi virus)	Three species (A–C); species A type 1 causes gastroenteritis in humans	Documented
Reoviridae	*Rotavirus* (rotavirus A)	Five groups (A–E); type A causes gastroenteritis and dehydration in children <24 mo, milder disease in older children; major cause of child mortality worldwide	Documented but rare

Human enteric viruses have properties that are distinct from those of bacterial foodborne pathogens. Viruses are usually species specific and tissue tropic, meaning that the human enteric viruses are believed to infect only humans. Since they must resist the enzymatic conditions and pH extremes encountered in the gastrointestinal tract, enteric viruses are also resistant to a wide range of commonly used food-processing, preservation, and storage treatments (8). In addition, human enteric viruses are notably persistent in foods and the environment, frequently surviving for days to weeks and even months without significant loss in infectivity. Although frequently present in low numbers in contaminated foods, their infectious doses are also low (9), meaning that very low levels of contamination may pose a human health risk.

HUMAN ENTERIC VIRUSES OF EPIDEMIOLOGIC SIGNIFICANCE AND THEIR DISEASES

Virus groups that can be transmitted by foodborne routes include the human enteroviruses (poliovirus, coxsackievirus, and echovirus), enteric adenoviruses, astroviruses, hepatitis A and E viruses, rotavirus, hNoVs, and sapoviruses, among others. From an epidemiologic perspective, hNoV and hepatitis A virus (HAV) are the two most important foodborne viruses. The former is most significant by virtue of the sheer numbers of cases, the latter because it causes a more severe disease.

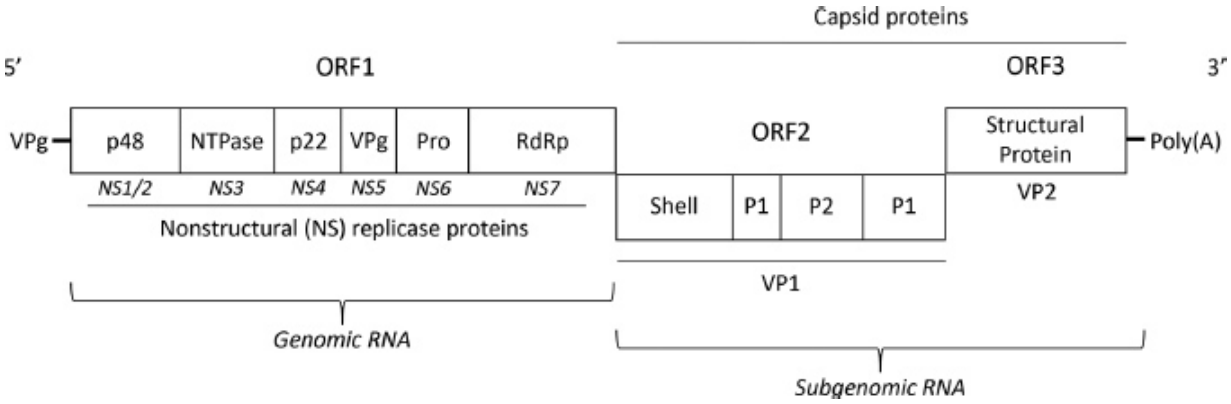

Figure 23.1 Norwalk virus genome organization (adapted from reference 10). VPg, genomelinked virion protein. ORF1 encodes a polyprotein that is posttranslationally cleaved into the nonstructural proteins helicase (with a predicted nucleotide triphosphate-binding domain [NTPase]), proteinase (Pro), and RNA-dependent RNA polymerase (Pol). ORF2 encodes capsid protein, which is translated into major and minor structural proteins consisting of shell and protruding domains. N, NH_2-terminal arm. ORF3 encodes a basic protein of unknown function.

Norovirus

The Norwalk virus was first reported in 1972 by Kapikian and colleagues, who identifi ed a small, roundstructured virus 27 nm in diameter by electron microscopy when viewing fecal material obtained from a 1968 gastroenteritis outbreak (10). Since that time, many similar so-called small, round-structured viruses have been reported. Virtually all of these viruses are now considered members of the family *Caliciviridae* (from the Greek word *calyx*, which means “cup”). Research over the past 4 decades has resulted in significant advances in

Caliciviridae taxonomy, and current classifications include five genera: (i) *Vesivirus*; (ii) *Lagovirus*; (iii) *Norovirus*, with Norwalk virus as the prototype strain; (iv) *Sapovirus*, represented by the Sapporo virus; and (v) *Nebovirus* (11). There are additionally six unclassified caliciviruses that may represent new genera; these are tentatively named *Bavovirus*, *Nacovirus*, *Recovirus*, *Salovirus*, *Sanovirus*, and *Valovirus* (11). Members of the genera *Nebovirus*, *Vesivirus*, and *Lagovirus* infect animals, posing no known human disease risk, whereas the genera *Sapovirus* and *Norovirus* are responsible for epidemic gastroenteritis in humans.

The genomes of viruses within the family *Caliciviridae* consist of a single strand of positive-sense RNA ranging in size from 7.4 to 8.3 kb. For example, the Norwalk virus genome sequence is 7,642 base pairs (bp) in length, excluding the 3′ poly(A) tail, and has a base composition of 48% guanine plus cytosine (G+C). The genome contains three open reading frames (ORFs): ORF1 (~5 kb) is the largest (corresponding to ~1,700 amino acids) and encodes a nonstructural polyprotein that is posttranslationally cleaved into p48, NTPase, p22, VPg (genome-linked virion protein), protease, and RNA polymerase; ORF2 (1.8 kb) encodes the primary viral capsid protein (VP1; 550 amino acids; molecular weight, ~56,600); and ORF3 (~0.6 kb) encodes a minor structural capsid protein (VP2) that is associated with the interior surface of the capsid formed by the shell (S) domain of VP1 (12) (Fig. 23.1).

The genus *Norovirus* consists of more than 40 genotypes, which are subdivided into seven genogroups (GI to GVII) based on RNA genome sequence analysis (13). There is only 51 to 56% nucleic acid sequence similarity across genogroups. Each genogroup can be further subdivided into several genotypes. Strains within a genotype share 69 to 97% nucleic acid sequence homology; there are 9 distinct genotypes of GI NoVs and 22 genotypes of GII NoVs (13). Genogroups I, II, and occasionally IV can cause human disease, with GII strains being responsible for the vast majority of human illness (13). Over the last 2 decades, the epidemic variants of the GII.4 genotype have been of particular interest, with multiple successive pandemic strains causing the majority of hNoV outbreaks worldwide (14, 15). Interestingly, GII.4 strains tend to be transmitted more commonly by person-to-person

spread rather than by food or waterborne mechanisms, although this observation may be confounded by their propensity to cause outbreaks in health care settings (16).

Hepatitis A Virus

First visualized by immune electron microscopy in 1972, HAV is classifi ed as a member of the genus *Hepatovirus* within the family *Picornaviridae* (17). The virus is a nonenveloped, round particle with a diameter of 27 to 32 nm. It has a linear, single-stranded, 7.5-kb, positive-sense RNA genome with a single ORF that is enclosed in an icosahedral capsid composed of three structural proteins, designated VP1-px, VP2, and VP3, as well as the viral capsid protein (VP4). The genome can be subdivided into three regions: a long 5′-terminal untranslated region (5′UTR) of about 735 bp, a large ORF (~7 kb) encoding a polyprotein of 2,227 amino acids, and a short 3′UTR with a poly(A) tail (Fig. 23.2). The single ORF is divided into three regions, designated P1, P2, and P3. P1 codes for the capsid proteins and is co- and posttranslationally cleaved into the four smaller capsid proteins (VP1-px, VP2, VP3, and VP4). P3 encodes the viral protease 3C, which cleaves the structural proteins of the capsid. Additional nonstructural proteins (2A, 2B, 2C, 3A, 3B [viral genome-linked protein], and 3D) are processed from the P2 and P3 regions of the ORF, and these are required for RNA synthesis and virus particle assembly (17). The approximate genome locations of these various proteins have been defined (17).

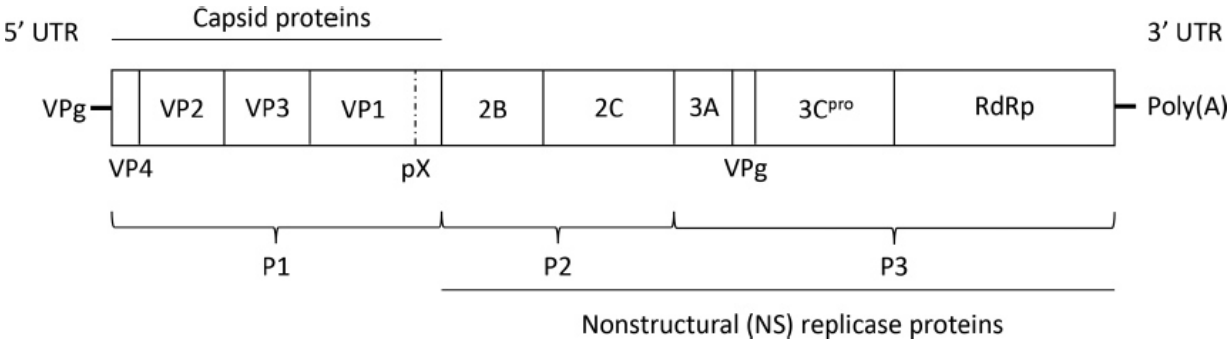

Figure 23.2 HAV genome organization (adapted from reference 121; see also reference 114). The 5′UTR is 624 to 1,199 nt long. VPg, genome-linked virion protein, 22 to 24 amino acids. The single ORF encodes a polyprotein that posttranslationally cleaved into VP1, VP2, and VP3, which form the capsid; VP4 is the inner surface capsid protein. 2A, unknown function; 2B, RNA synthesis and cell membrane permeability; 2C, RNA replication; 3A and 3B, RNA replication proteins, cofactor for 3D; 3C, viral proteinases; 3D, RNA-dependent RNA polymerase. The poly(A) tail is about 35 to 100 nt long; the 3′UTR is 47 to 125 nt long.

Human isolates of HAV constitute a single serotype, and monoclonal antibodies targeting different isolates fail to distinguish them from one another. Nonetheless, there is substantial sequence heterogeneity within certain genome regions that encode the putative VP1-P2A junction of HAV. When this region is used as the basis for typing, HAV isolates can be differentiated into six unique genotypes such that a genotype is defined as a group of viruses that differ from each other in sequence homology by no more than 15% (18). Of these six genotypes (designated I to VI), only genotypes I, II, and III are associated with human disease, and these are additionally subdivided into subtypes A and B, whereas genotypes IV, V, and VI have been isolated from non-human primates (17).

Other Foodborne Human Enteric Viruses

There are other human enteric viruses that can be transmitted by contaminated foods, although their epidemiologic significance is not as well understood. The human enteroviruses, for example, are smooth, round, nonenveloped particles 27 nm in diameter with singlestranded,

positive-sense RNA. These viruses are members of the family *Picornaviridae* (poliovirus is the type species) and historically have been transmitted through the consumption of contaminated water and unpasteurized milk (19). Although the disease can occasionally be problematic in developing countries, outbreaks of foodborne poliomyelitis usually do not occur in developed countries due to effective vaccination. Other human enteroviruses, such as the coxsackie- and echoviruses, have also been associated occasionally with foodborne disease (20, 21). The symptoms of enteroviral infection are diverse and virus specific but may include gastrointestinal, respiratory, neurological, and skin manifestations.

Rotaviruses usually are transmitted by the person-to-person route, but occasionally foodborne outbreaks occur (19). This virus group is the leading cause of infantile diarrhea worldwide (22) and is responsible for significant morbidity and an estimated 197,000 deaths per year; the vast majority of these deaths occur in developing countries. Rotaviruses are 70 to 75 nm in diameter and appear roughly spherical in electron micrographs. They consist of 11 segmented, double-stranded RNA molecules encased in a double-layered protein coat. The 5′ and 3′ ends of the double-stranded RNA are highly conserved, with sizes ranging from 667 bp (segment 11) to 3,302 bp (segment 1) and totaling 6,120 kDa, or 18,500 bp (23). All rotavirus genes are monocistronic (i.e., coding for only one polypeptide) except segments 9 and 11. There are six structural viral proteins (termed VP1, VP2, VP3, VP4, VP6, and VP7) and five nonstructural proteins (termed NSP1 through NSP5). Based on VP6 reactivity with monoclonal antibodies, there are at least seven different rotavirus groups (A through G). Second-generation rotavirus vaccines are now recommended for global use by the World Health Organization; however, there is a small recognized risk of intussusception, at around 1 in every 60,000 vaccinated infants (24).

Other significant human enteric viruses include the astroviruses, sapoviruses, and HEV. Astroviruses are spherical nonenveloped viruses that are star shaped and have single-stranded, positive-sense RNA that is 6.8 to 7.2 kb in length (19). These viruses have been occasionally associated with outbreaks, causing a diarrheal disease with an

incubation period of 1 to 3 days and symptoms lasting for 1 to 4 days. HEV is a small (~30-nm) virus with single-stranded, positive-sense RNA and three ORFs. Recently classifi ed in the species *Orthohepevirus A* and genus *Orthohepevirus* in the family *Hepeviridae*, HEV appears to have at least four major genotypes shown to infect humans (25). HEV causes a disease similar to that caused by HAV but with severe manifestations in pregnant women. It is much more prevalent in developing countries, although there is recent evidence of autochthonous infections in the developed world (26). HEV is transmitted predominantly through sewage-contaminated water and consumption of raw or undercooked meats from infected animals (27, 28).

The last human enteric viruses of note are the sapoviruses. These were thoroughly covered by Lopman et al. (29) and continue to be the cause of both sporadic gastroenteritis and outbreaks related to consumption of contaminated food. Sapoviruses are part of the genus *Sapovirus* in the family *Caliciviridae*. This group of viruses shares many characteristics with the closely related noroviruses. These similarities include clinical presentation of disease, broad age range of impacted populations, outbreak settings (e.g., long-term-care facilities and hospitals), and implicated food products (e.g., oysters). With respect to microbiological aspects of sapoviruses, they are small (~30-nm) viruses with singlestranded, positive-sense RNA and two ORFs. Similar to noroviruses, sapoviruses are divided into seven genogroups, with four (GI, GII, GIV, and GV) infecting humans and the remaining three (GIII, GVI, and GVII) infecting pigs. The actual burden of disease due to sapovirus infection is difficult to quantify given the limited foodborne outbreaks reported and the lack of routine diagnostics for suspected clinical cases.

FOODBORNE TRANSMISSION OF HUMAN ENTERIC VIRUSES

From a foodborne disease standpoint, three types of commodities are commonly associated with viral disease outbreaks: (i) molluscan shellfish contaminated by feces-impacted growing waters; (ii) fresh

produce items contaminated by human feces during production or packing, usually through workers' hands or contact with contaminated water; and (iii) ready-to-eat (RTE) and prepared foods contaminated by infected food handlers (Fig. 23.3).

Contamination of marine waters with human sewage is the critical factor with respect to virus contamination of molluscan shellfi sh (e.g., mussels, clams, cockles, and oysters). Sources of contamination in shellfish harvest waters include illegal dumping of human waste, failing septic systems along shorelines, sewage treatment plants overloaded with storm water, and discharges of treated and untreated municipal wastewater and sludge. Molluscan shellfi sh are of particular concern because they are filter feeders, meaning that they filter and even concentrate microorganisms in their gut during the process of feeding. Interestingly, hNoVs can specifically bind carbohydrate ligands within the oyster digestive tract (30). This is further complicated by the fact that viruses tend to be environmentally persistent and the shellfish are usually consumed either raw or only lightly cooked. Furthermore, there is no significant relationship between the presence of virus contamination and the levels of coliform and fecal coliform indicator bacteria, which are used in most countries to monitor and regulate molluscan shellfi sh harvesting waters. This means that there is no reliable means of screening by which to preventvirally contaminated shellfish from reaching the marketplace (19).

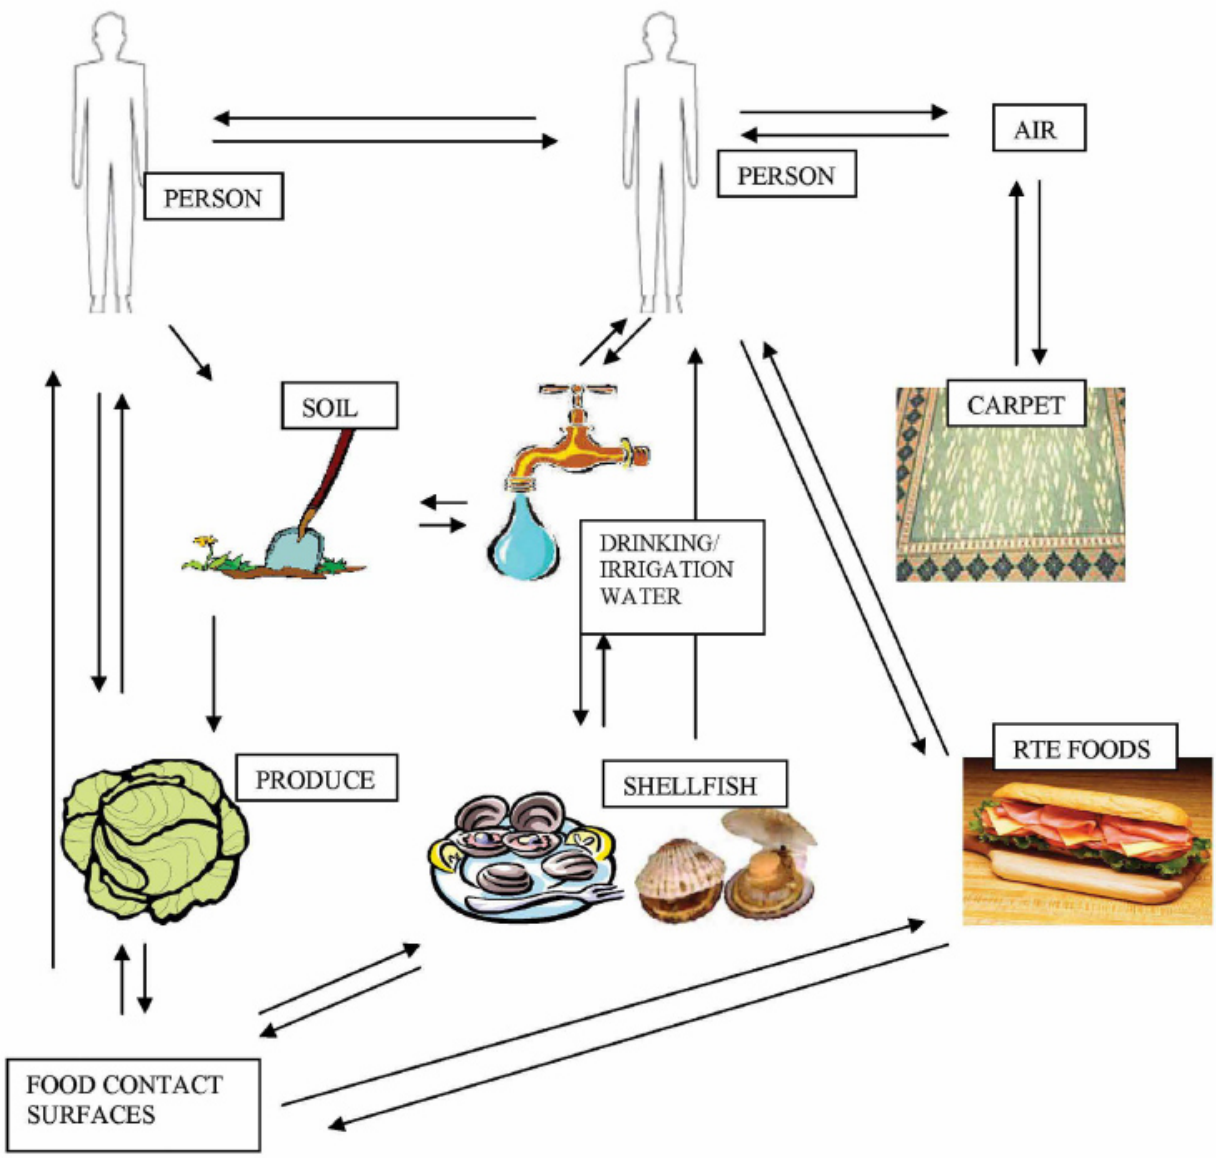

Figure 23.3 Transmission routes of foodborne viruses.

Although viral gastroenteritis outbreaks due to contaminated fresh produce occur regularly, there are many unanswered questions with respect to how fresh produce items actually become contaminated with enteric viruses. Certainly, produce may become contaminated when grown in fields irrigated with wastewater or fertilized and conditioned with improperly decontaminated sewage effluent. In fact, common sewage sludge treatments, such as drying, pasteurization, anaerobic digestion, and composting, reduce but do not necessarily eliminate enteric viruses (31). Viruses can survive in contaminated soil for long periods of time, depending upon factors such as growing season, soil

composition, temperature, sunlight, moisture, rainfall, resident microflora, and virus type (32, 33). Despite the potential for preharvest contamination, the role of infected farm workers who pick, wash, and pack produce cannot be overlooked, especially since simple produce items that are often associated with outbreaks (e.g., leafy greens, strawberries, raspberries, and green onions) are most often harvested by hand (34). While washing of produce may reduce contamination loads, it will not eliminate enteric viruses if they are present (35).

Poor personal hygienic practices of infected food handlers are one of the most important contributors to the spread of viral foodborne disease, more so for hNoVs than HAV (36). The CDC indicates that about 70% of foodborne hNoV outbreaks are linked to ill food service workers (3). There is strong evidence suggesting that contaminated hands frequently play a role in enteric virus spread, acting as either virus donors or recipients. Hands usually become contaminated by direct contact with any virus-containing fluid from oneself or others; they may also become contaminated by contact with virus-contaminated surfaces or objects. The extent of such contamination will vary depending on a variety of factors, including the virus load, the handwashing habits of the infected person, and the efficiency with which the virus is transferred and persists (37). Studies of hNoV persistence have revealed that viral RNA can be detected on the hands of volunteers for at least 2 hours after deliberate contamination (38). Food handlers may transmit viruses to foods from contaminated hands, a contaminated surface, or other food items. Technically, any food handled by a person infected with the virus—symptomatic or asymptomatic—and then consumed without a subsequent heating step can be a potential vehicle for transmission of enteric viruses. Common food items falling into this category include hand-sliced deli meats and cheeses; sandwiches; meat, vegetable, and fruit salads; baked goods; and various desserts.

EPIDEMIOLOGY OF FOODBORNE VIRAL DISEASE

Although many different types of enteric viruses can contaminate bivalve mollusks, only a few (HAV, hNoVs, sapoviruses, and astroviruses) have been epidemiologically linked to shellfi sh-associated viral disease, particularly in oysters (39). The first documented epidemiologic linkage between hNoVs and shellfi sh-associated gastroenteritis occurred in the mid-1970s, and many more outbreaks have been reported since then. For example, three large outbreaks associated with improper discharge of untreated human waste material occurred in Louisiana in the 1990s alone (40, 41). Between 2003 and 2004, three distinct hNoV outbreaks in Australia were associated with the consumption of imported oyster meat whose harvest was traced back to a single Japanese estuary system (42). In 2010, 334 hNoV cases associated with shellfish consumption were reported in five European countries (43). Interestingly, a 1988 outbreak of HAV disease in Shanghai, China, which was linked to the consumption of shellfi sh harvested from a feces-impacted site, ranks among the largest foodborne disease outbreaks ever reported, with a total of about 300,000 cases (44).

Enteric virus illness outbreaks have been associated with fresh and frozen produce as well. Among “simple” food products (i.e., those consisting of a single commodity type), berries and green onions have been the most common culprits. For example, between 2005 and 2009, berry-associated hNoV illness outbreaks were reported in France, Denmark, Sweden, and Finland (45). More recently in 2012, a large multistate outbreak of hNoV due to contaminated frozen strawberries was reported in Germany, with nearly 11,000 cases of gastroenteritis (46). A similar outbreak of hNoV illness linked to individually quickfrozen raspberries resulted in 615 confi rmed cases in Quebec and 15 cases in the United States from August 2016 to July 2017 (47). In most cases, these products were imported and thought to be contaminated during production or processing in their country of origin rather than through subsequent handling. Recent HAV illness outbreaks linked to imported frozen pomegranate arils (Turkey) and frozen strawberries (Egypt) were reported in 2013 and 2016, respectively, and were linked to 165 and 143 cases of viral hepatitis (48, 49).

An interesting group of HAV illness outbreaks occurred in 2003 in the United States. The largest of these occurred among patrons of a single Pennsylvania restaurant over a 3-day period, with a total of 601 confi rmed illnesses, 3 deaths, and at least 124 hospitalizations. A case-control study implicated foods containing green onions, particularly mild salsa. Although some of the restaurant workers became symptomatic, all became ill at the same time as the patrons, ruling them out as the source of the outbreak (50). A series of smaller outbreaks occurred among restaurant patrons in three other states in the months preceding this one, also implicating green onions (51). In both cases, the origin of the green onions could be traced back to northern Mexico. Comparative analysis of the HAV genome sequences associated with these 2003 outbreaks revealed substantial sequence similarity to endemic Mexican HAV strains, suggesting that the green onions were likely contaminated before arrival at the restaurants (50).

Although the ultimate source of viral contamination (e.g., water or harvester) in the case of the green onion and berry outbreaks was never identifi ed, it should be noted that these two products are almost always harvested by hand and hence subject to substantial human handling. The potential importance of human hands is also supported in a recent study by León-Félix et al. (34), who determined that between one-quarter and one-third of northern Mexican field workers' hands had evidence of hNoV contamination, with 30 to 45% of the green peppers they harvested having contamination as well. There is a clear need to better characterize the source of viral contamination in fresh produce items.

The contamination of RTE and prepared foods most frequently results from poor handwashing practices of infected food handlers after toilet use, as fecal material can be left on hands or even under nails and then can come in contact with food products. Consequently, handling cooked products with bare hands has been identified as a major factor for pathogen transfer to RTE foods (52). HAV outbreaks can also occur as the result of a single infected food handler at a single food establishment and have been reported in association with lettuce, salads, sandwiches, hamburgers, spaghetti, and bakery products (53). However, the numbers of these types of outbreaks have declined since

the implementation of vaccination recommendations for high-risk groups and infants (54).

Human NoVs have been associated with many outbreaks caused by poor hygiene of food handlers, including outbreaks involving the consumption of contaminated salads and sandwiches, delicatessen meats, and bakery products (3). In recent outbreak investigations, scientists have increasingly used molecular sequencing to support epidemiologic evidence indicating a common food source for hNoV transmission (55). These methods have enabled investigators to link multiple clusters of illnesses as well as implicate the contaminated food items. For example, Friedman et al. (56) described an hNoV disease outbreak among 2,700 guests attending 46 different weddings on a single weekend. All of the wedding cakes were baked at the same bakery, where there were at least two ill employees. The same hNoV strain was detected in stool specimens from two wedding guests, one wedding hall employee, and one ill bakery employee. Similarly, using molecular epidemiologic evidence, Malek et al. (57) were able to link 137 cases of hNoV illness occurring on 13 Colorado River rafting trips to one batch of delicatessen meat purchased from a single processing plant. It was determined that the implicated meat was sliced by an employee who did not wear gloves and had just returned to work one day after an episode of gastroenteritis. This outbreak was an eye-opener to facilities inspected by the U.S. Department of Agriculture Food Safety and Inspection Service, which frequently do not consider enteric viruses as hazards in their hazard analysis and critical control point (HACCP) plans.

Secondary transmission after a primary foodborne outbreak of hNoV illness can also occur. For instance, a GI hNoV that initially infected athletes on a single college football team who consumed sandwiches made by an infected food handler was later passed on to the rival team after contact during a football game in which the first team's members were actively ill (58). Alfano-Sobsey et al. (59) reported on a foodborne outbreak of hNoV associated with undercooked oysters and determined a secondary attack rate of 14% among susceptible household contacts. Isakbaeva et al. (60) investigated a hNoV gastroenteritis outbreak on a cruise ship that affected six consecutive cruises despite extensive

sanitation measures. Using genetic sequence analysis, the investigators documented strain persistence with likely foodborne, environmental, and person-to-person transmission. In general, foodborne hNoV illness outbreaks have higher primary attack rates than outbreaks spread through other routes, but as illustrated above, a single contamination event can affect many more people that those simply consuming the contaminated food.

DISEASE, PATHOGENESIS, AND TREATMENT

Human Noroviruses

Symptoms of Disease

The disease caused by hNoVs is usually self-limiting and characterized by nausea, vomiting, diarrhea, and abdominal pain, with occasional headache and low-grade fever. Data from outbreak investigations and human challenge studies indicate that the incubation period ranges from 12 to 51 hours, with a mean of 24 hours, and illness usually lasts 48 to 72 hours (61). In a community-based cohort study of hNoV infection in The Netherlands, Rockx et al. (62) reported a median duration of symptoms of 5 days and found that diarrhea was more prevalent in hNoV-infected children of <1 year of age, whereas infected children of ≥5 years of age were more likely to vomit. Some outbreak investigations have revealed less frequent vomiting in older individuals (63). Severe illness or hospitalization is uncommon except in children, the elderly, and the immunocompromised, for whom rehydration therapy may be necessary. Some deaths, particularly in elderly patients, occur in association with norovirus infection (64). Outbreaks associated with hNoV were historically characterized by the Kaplan criteria defined as vomiting in >50% of cases, a mean incubation period of 24 to 48 hours, an average duration of symptoms of 12 to 60 hours, and stool specimens that are negative for bacterial pathogens. However, Lively et al. (65) reported greater sensitivity and specificity as well as broader application in reported acute gastroenteritis outbreaks with the following CART (classification and regression tree)-derived profile: ratio of proportion of cases with fever to the proportion of

cases with vomiting, <1; proportion of cases with bloody stool, <0.1; proportion of cases with vomiting, ≥0.26. Finally, median attack rates are usually 20 to 53% (16).

Asymptomatic hNoV infections have been documented in outbreaks (66), human challenge studies (61, 67), and community- and hospital-based studies of sporadic hNoV infection (68, 69). Virus can be shed in the stool both before symptoms occur and for at least 60 days after the onset of infection, although peak shedding occurs during the acute phase of illness and for the first few days thereafter (5, 61). Atmar et al. (61) reported that median peak virus concentration in stool specimens from volunteers infected with Norwalk virus was approximately 10^{11} genomic copies per gram of feces. Meanwhile, Teunis et al. (5) estimated average peak values ranging from 10^5 to 10^9 genomic copies per gram of feces. As stated previously, virus can also be shed in high numbers (10^8 genomic copies per vomiting episode) in vomitus (6).

Pathogenesis

Host susceptibility to infection appears to be due to both genetic determinants and acquired immunity. Human challenge studies with Norwalk virus, a GI hNoV, and various GII strains have revealed that some volunteers remained uninfected even after exposure to high doses (6, 67). Further investigation revealed that these subjects lacked the H type 1 antigen, a histo-blood group antigen (HBGA) present in saliva and also on the surfaces of epithelial cells that likely serves as a receptor or coreceptor for Norwalk virus binding. *In vitro* assays provide additional evidence that recombinant Norwalk virus capsid protein binds to H type 1 antigen; specifically, the P domain of the capsid protein is now recognized as the exact binding domain (70). Synthesis of the H type 1 antigen depends on the α-1,2-fucosyltransferase enzyme, which is encoded by the *FUT2* gene and determines the secretor status of an individual. Individuals who are homozygous recessive for the *FUT2* gene are secretor negative and appear to have innate genetic resistance to infection with Norwalk virus while maintaining susceptibility to other norovirus strains (71). Overall, *FUT2* varies with ancestry, as confi rmed by Currier et al. (72). About 20% of Caucasians are secretor negative, and this proportion is

variable in Asian and African ethnic groups (73). Along with secretor status, the role of individual blood type in Norwalk virus infection has also been investigated. For instance, blood group O individuals in Norwalk virus human challenge studies were more susceptible to Norwalk virus infection than group A or B individuals (67, 74). In contrast to Norwalk virus, a human challenge study with Snow Mountain virus, a GII.2 hNoV, revealed no relationship between infection with the virus and blood group secretor status (75).

There have been mixed reports about whether there is a relationship between infections with other hNoV strains and HBGAs in outbreaks. Hennessy et al. (76), in their investigation of an outbreak in a military field hospital in Afghanistan, reported that individuals with blood group B were less susceptible to symptomatic hNoV infection than people of other blood types. Tan et al. (77) reported that secretor status and HBGA were associated with risk of infection in two GII outbreaks in China. Positive secretor status was strongly associated with risk of symptomatic infection in both outbreaks ($P = 0.0007$), and in the GII.4 outbreak, individuals with blood type A had a significantly increased risk of infection, whereas type O individuals had a decreased infection risk. In contrast, Halperin et al. (78) did not find a relationship between infection with GII hNoV and ABO histo-blood group in their investigation of two outbreaks in military units in Israel. The GII.4 hNoVs appear to bind to all HBGAs (not just type 1) (79) and, hence, are likely to have a greater pool of susceptible individuals in the population. This characteristic may explain the greater frequency of outbreaks due to GII.4 than that of other hNoV strains. The relationship between hNoV infection and HBGAs was recently reviewed (80). Through a meta-analysis, the authors concluded that recognition of and binding to carbohydrate receptors constitute an important feature of hNoV infection and may also play a role in virus evolution.

Immunity

Immunity to hNoV was recently reviewed by Newman and Leon (81). There is some evidence of acquired immunity, although the mechanisms for this have not been elucidated. Some human challenge

studies have revealed that volunteers who became ill after a primary hNoV challenge did not become ill when rechallenged with the same virus 6 to 14 weeks later; however, the volunteers did become ill when rechallenged with same virus 24 to 42 months after the primary challenge (82, 83). This suggests the development of short-term protective immunity but perhaps not long-term immunity. The high attack rates observed in hNoV outbreaks also suggest that most of the population do not have protective immunity against hNoV infection, either because the protective immunity is so short-lived or because hNoV strains are very diverse, and protective immunity is not cross-reactive.

The role of serum antibodies in hNoV infection is also not well understood. Sera collected in human challenge studies and hNoV outbreak investigations indicate that titers of hNoV-specific humoral antibody (immunoglobulin G [IgG], IgM, and IgA) increase in response to infection. Serum IgG produced in response to infection with one hNoV strain often cross-reacts with antigens from other hNoV strains, and common epitopes within and between genogroups have been identifi ed (84). IgA and IgM responses appear to be more type specific than that of IgG. However, it is not clear that serum antibodies provide any protection against subsequent hNoV infection, and these antibodies may only be markers of susceptibility to hNoV infection. *In vitro* experiments suggest that serum IgG produced in response to Norwalk virus infection is capable of blocking Norwalk virus attachment to synthetic H type 1 antigen (85). However, volunteers with anti-Norwalk virus IgG in their prechallenge sera were more likely to become infected after Norwalk virus challenge than those who did not have anti-Norwalk virus IgG (67). There are a small number of studies on the cellular immune response to hNoV infection (75, 86, 87). Overall, these studies have revealed that peripheral blood mononuclear cells from subjects in hNoV challenge studies respond to hNoV antigen *in vitro* and secrete anti-inflammatory and inflammatory cytokines, but gamma interferon secretion responses differ by individual and are probably confounded by the effect of individual prechallenge exposure history.

One Norwalk virus human challenge study from 2003 revealed that 62% of secretor-positive volunteers became infected, suggesting that some mechanism exists to protect genetically susceptible individuals from Norwalk virus infection (67). Examination of Norwalk virus-specific salivary IgA levels revealed that the secretor-positive volunteers who did not become infected mounted an early (before 5 days postchallenge) Norwalk virus-specific salivary IgA response to the virus. In contrast, infected secretor-positive volunteers did not mount a Norwalk virus-specific salivary IgA response until after 5 days postchallenge. Until recently, the role of the mucosal response in protective immunity to Norwalk virus infection was not understood. Ramani et al. (87) reported that a lower risk of gastroenteritis and decreased severity of gastroenteritis were associated with preexisting hNoV-specific salivary IgA. hNoV-specific fecal IgA was also evaluated and showed no correlation with protection from infection or disease; however, the authors did observe that prechallenge levels of fecal IgA did correlate with reduction of viral load and that fecal IgA induction seemed important in decreasing the longevity of virus shedding.

Histopathology

Patients who suffer from hNoV illness have broadened and blunted villi of the proximal small intestine (duodenum), resulting in a 47% reduction in villus surface area (88). Intraepithelial infiltration of cytotoxic lymphocytes along with cytoplasmic vacuolization has also been visualized. In addition, duodenal biopsies in subjects with hNoV infections had reduced expression of tight junctional proteins and an increase in epithelial apoptosis (88). Biopsy specimens collected in 1973 during one of the first human challenge studies reveal that histopathologic changes appear within 24 hours of virus challenge and usually persist for up to 2 weeks (89). Histopathologic testing revealed that the intestinal mucosa appear intact, and viruses were not detected in the epithelial cells of the mucosa by electron microscopy. Also, transient malabsorption of fat, d-xylose, and lactose was observed, along with decreased levels of small intestine brush border enzymes (trehalase and alkaline phosphatase). However, adenylate cyclase activities of the jejunum were not elevated. Reduced gastric motility is likely responsible for the nausea and vomiting caused by hNoV (90).

Vaccine Development

Vaccine development efforts are under way and have been reviewed by Herbst-Kralovetz (91) and most recently by Melhem (92) and Lucero et al. (93). Researchers are exploring various vaccination strategies, which have most recently focused on the use of recombinant hNoV capsid protein virus-like particles (VLPs) made in insect cells and plants to stimulate immunity in oral and parenteral vaccination strategies (91, 94). Additional approaches to hNoV vaccines include Venezuelan equine encephalitis virus replicon-based vaccines (95), hNoV P particles (96), and an adenovirus-vectored vaccine that uses an oral pill formulation for which the phase I human trial was completed in 2018 (NCT02868073). Nearly 2 decades ago, phase 1 clinical trials in humans found that Norwalk virus VLPs are safe and immunogenic, stimulating the production of systemic and mucosal anti-Norwalk virus antibodies and antibody-secreting cells (97, 98). Additional hNoV vaccine trials in humans have evaluated the efficacy of intranasal administration of GI.1 VLPs with and without an adjuvant to elicit greater immune response (99, 100). Phase 1 clinical trials have also been performed using GI.1 and GII.4 VLPs administered intramuscularly, and strong immune responses were observed (101–104).

Because hNoV outbreaks continue to occur in countries with high standards of sanitation and hygiene, vaccination may be an effective way to control epidemic hNoV infection and reduce the burden of hNoV disease. Moreover, there are a variety of potential vaccination strategies (e.g., age based, occupational, and risk based) which could all potentially help in preventing epidemic disease. However, at this stage there are many questions that need to be addressed about whether the current vaccine approaches stimulate a cross-protective immune response, whether it is possible to develop long-term immunity, and how to measure immune correlates of protection (92). Furthermore, these viruses are diverse and evolve rapidly. The number of antigens that would be needed for an effective vaccine and the degree of cross-protection provided against other strains is not known. The development of a chimpanzee model for hNoV infection was recently reported and used to test GI (Norwalk virus) and GII (MD145) VLP

vaccines (105). This landmark study revealed that the Norwalk virus VLP vaccine induced protective homologous immunity in chimpanzees that were challenged with Norwalk virus 18 months later, but the chimpanzees that received the MD145 VLP vaccine or placebo were not protected from Norwalk virus infection.

Treatment

hNoV infection is self-limiting, and if necessary, oral fluid and electrolyte replacement therapy is usually adequate for replenishing fluid loss. The symptoms of the disease can also be reduced by the oral administration of bismuth subsalicylate (106). In cases of severe vomiting and diarrhea, intravenous administration of fluids may be necessary. Hospitalization, particularly for severe dehydration, is necessary and occurs most often in young children and older adults. Norovirus-associated deaths can also occur across the age spectrum, but over 90% are estimated to occur among elderly patients (107, 108). Repeated diarrheal episodes may promote intestinal mucosal damage, resulting in eventual malnutrition (106). The development of antiviral drugs that block hNoV binding to host cells may be valuable as a prophylactic approach in settings where hNoV outbreaks are common. For instance, Chang and George (109) have reported that interferon and ribavirin inhibit Norwalk virus replication in replicon-bearing cells and may have therapeutic value. More recently, antiviral strategies targeting viral entry and inhibition of viral protein production have been reviewed, as well as additional approaches to inhibiting viral replication (110). One such approach includes the use of small inhibitory molecules that target host cell factors (e.g., La protein and DDX3) thought to be involved in viral RNA replication and genome circularization. Another option could be the use of nonnucleoside analogs that target and inhibit the hNoV RNA-dependent RNA polymerase, such as suramin (111).

Hepatitis A Virus

Symptoms of Disease

The incubation period for HAV infection is 14 to 50 days, with an average of 28 days. The virus is more readily transmitted during the

latter half of the incubation period and can be attributed to inadequate hand hygiene, but not as frequently as hNoV. Symptomatic HAV infection generally presents in four phases. The first phase is characterized by viral replication but a lack of symptoms. In the second, the so-called preicteric, or prodromal, phase, which usually lasts 5 to 7 days, patients may experience anorexia, nausea, vomiting, alterations in taste, arthralgias, malaise, fatigue, urticaria, and pruritus. When seen by a health care provider during this phase, patients can be misdiagnosed. The third, or icteric, phase presents as darkening of the urine, pale stools, jaundice, and right-upper-quadrant pain with hepatomegaly (112). Fecal shedding and viremia are maximal at the onset of the icteric phase and subside during its 7- to 28-day duration. During the last, or convalescent, phase, symptoms resolve, and liver enzymes return to normal. Although icteric disease occurs in fewer than 5% of children younger than 3 years of age and in 10% of 4- to 6-year-olds, it occurs in 40 to 50% of older children and in 70 to 80% of adults. In most cases, infection is mild and self-limiting; however, in older patients, more severe disease is possible. Complications such as acute liver failure, cholestatic hepatitis, and relapsing hepatitis occur but are rare (e.g., <1% of cases result in acute liver failure). A variety of extrahepatic manifestations occasionally occur in patients with acute hepatitis A, including hemolysis, skin involvement, vasculitis, acute renal failure (i.e., glomerulonephritis), lung inflammation, aplastic anemia, and pancreatitis; on occasion, neurological syndromes have also been reported (112). The overall mortality rate for HAV infection is approximately 0.01%. Immunity after infection is complete and considered to be lifelong (112).

Pathogenesis

HAV infection begins with ingestion of the virus, which penetrates the mucosal barrier of the gastrointestinal tract and reaches the liver via the portal circulation to begin replication in hepatocytes.

Approximately 10^2 to 10^5 HAV copies/ml of blood serum can be detected during the clinical illness phase of the disease (113). Studies are still under way to elucidate the nature of the host cell receptor that determines the tissue tropism of HAV for the hepatocyte. Hypotheses for viral cell entry have indicated a mucin-like glycoprotein receptor or

possibly an asialoglycoprotein receptor through recognition of a virus-IgA complex (112). However, a more recent review by Lemon et al. (114) indicates that the previously assumed HAV receptor, TIM1 (T cell immunoglobulin and mucincontaining domain protein 1, also known as HAVCR1), is not an essential factor for HAV cell entry based on cell culture and mouse models. Interestingly, the study authors determined that TIM1 may play a role during the early stages of infection by binding quasi-enveloped HAV virions—another infectious form of HAV resulting from nonlytic release from infected cells (115). Possible "enterohepatic" cycling of HAV may occur via ingestion of infected material, absorption from the small intestine, replication in the liver, secretion into bile following delivery to the intestines, and excretion in stool or reabsorption (112). Enlargement of Kupffer cells (liver macrophages) is the first evidence of infection by HAV. In experimental studies with owl monkeys, viral antigens were first detected in Kupffer cells of the liver at 14 days and in hepatocytes at 21 days after oral administration of the HM-175 strain of HAV (116).

Histopathology

Cardinal pathologic features of acute hepatitis include the presence of hepatocellular degeneration, characterized as either ballooning or acidophilic (apoptotic) change, together with varying degrees of portal and lobular inflammation and hepatocyte regeneration (117). Interestingly, although HAV targets liver cells, it usually does not kill those cells. Rather, immune-mediated lysis, particularly involving natural killer and lymphokine-activated killer cells, is recognized as the most probable cause of hepatic inflammation even before the initiation of cytotoxic-T-cell injury (118). In addition, human gamma interferon produced by HAV-specific T cells may participate in pathogenesis and probably promotes clearance of HAVinfected hepatocytes, as increased levels of interferon have been detected in the serum of infected patients (119, 120). Biochemical changes associated with active HAV infection include bilirubin excretion in the urine and elevated alkaline phosphatase, alanine aminotransferase, and aspartate aminotransferase/serum glutamicoxaloacetic transaminase levels, all of which persist until recovery from illness (121).

Immunity

The immune response against HAV infection occurs on two levels, humoral and cellular. In the humoral response, IgM, IgG, and IgA antibodies are directed against conformational epitopes, mostly the surface proteins VP1 and VP3 and precursor protein (VP2+VP4) of the HAV particle. The IgA and IgM responses precede the IgG response with IgM and IgG detectable within 5 to 10 days before symptoms and at the onset of symptoms, respectively, but the latter is long-lived and provides immunity (117). Because immune-mediated injury causes hepatic inflammation, cytotoxic T cells also play a significant role in the cellular immune response. Since detection of virus particles, viral antigen, or RNA is complicated, the method of choice for diagnosis of infection is immunoassay, which detects the presence of IgM anti-HAV antibody in the blood (113).

Treatment

Historically, administration of Igs at doses as low as 0.01 to 0.04 ml/kg of body weight was used for HAV postexposure prophylaxis. However, in the United States, due to the decreased levels of HAV in the overall population, the dose has been increased over 10-fold to 0.1 ml/kg of body weight (122). This can be effective in controlling both the incidence and severity of disease as long as the Igs are administered within 2 weeks of exposure (123). The prophylactic administration of Ig is recommended for patrons and food handlers provided that all of the following criteria are met: (i) the infected worker was responsible for handling RTE foods and was not wearing gloves; (ii) the infected worker demonstrated poor hygienic practices or already had diarrheal symptoms; and (iii) the patrons can be identifi ed and treated within 2 weeks of exposure (124). As Ig provides only short-term protection against HAV infection, its administration is not recommended for pre-exposure prophylaxis, though some exceptions exist for travelers. For that sort of protection, various FDA-licensed formalinkilled whole-virus vaccines are available, generally administered as a single primary immunization followed by a booster dose after 6 to 12 months (114). The efficacy of the vaccine is 87 to 100%, and protection should last for about 20 years (125). Routine vaccination of all food handlers and

restaurant employees is usually cost prohibitive, even during a hepatitis A epidemic (126). In 2006, hepatitis A vaccination was recommended for children up to 2 years of age (124, 127).

BARRIERS TO THE STUDY OF HUMAN ENTERIC VIRUSES

Most naturally occurring human enteric viruses cannot be easily cultivated *in vitro*, nor are there relevant animal models to facilitate their study. This has been the single most important barrier to understanding these important agents of foodborne disease. Human NoVs are the best example of this phenomenon. For instance, the only way to work with these viruses in their natural form is to obtain fecal material from infected individuals. Hence, there are only limited supplies of this material, usually obtained from federal, state, or local health departments, or from the few investigators engaged in human challenge studies. In the early days following their identification, hNoVs could be detected only by electron-microscopic methods, which lack sensitivity. Antibodies were later raised against some of these viruses, but it quickly became apparent that hNoVs are antigenically diverse, with antibodies raised to one strain having minimal crossreactivity with other strains. Likewise, these viruses are genetically diverse.

With the advent of the molecular biology revolution, the first hNoV genome was cloned and sequenced (128), and investigators began making VLPs, i.e., intact virus capsids lacking only the viral RNA (129). These have become important reagents for binding studies and antibody production. Molecular techniques also provided an opportunity to detect hNoVs and other enteric viruses using nucleic acid amplification methods, most notably reverse transcription-PCR (RT-PCR). While it is a vast improvement over electron microscopy, RT-PCR is not perfect: it relies on the availability of broadly reactive primers and probes, it is prone to matrix-associated inhibition, and interpretation of positive results must be approached cautiously, as detection of viral RNA does not necessarily correlate with the presence of infectious virus.

In the absence of an easily and reproducibly cultivable hNoV strain, surrogate viruses are often used as proxies. In the early years, bacteriophages such as MS2 were commonly used surrogates, but these viruses have significant structural and functional differences from mammalian viruses. Over the last 20 years, two cultivable mammalian viruses have emerged as the most widely used surrogates for hNoVs, i.e., feline calicivirus (FCV), which can be readily propagated in feline kidney cells (130); and murine norovirus (MNV), which is slightly more difficult to propagate but shares more biochemical and genetic features with hNoVs (131). An additional, more recently discovered surrogate, Tulane virus (TuV) (132), is a member of the genus *Recovirus* of the family *Caliciviridae*. TuV was isolated from the stools of rhesus macaques and shows genetic similarities and relatedness to GII NoVs. Moreover, TuV binds to HBGAs, unlike the more closely related MNVs, which recognize only sialic acids and glycoproteins (133). Overall, the availability of these surrogates has enabled investigators to extrapolate the behavior of hNoV strains with respect to persistence, resistance, and inactivation kinetics. However, there is growing evidence that the behavior of the cultivable surrogates does not always mimic that of human strains. For example, FCV is more sensitive to extremes of pH than is MNV or hNoVs, and MNV is more sensitive to ethanol and to desiccation (134, 135). Comparison of TuV and MNV also reveals different characteristics between surrogates and lack of alignment with hNoV strains (134, 136). Hence, surrogate data must be interpreted with caution. Ideally, comparative studies using both hNoVs and cultivable surrogates would provide a more comprehensive picture of the behavior of these viruses, but only a few such studies have been reported to date (137).

Fortunately, the ability to actually evaluate the physicochemical characteristics of hNoVs *in vitro* is now a possibility with the recently described replication of hNoVs in stem cell-derived human enteroids (138). A team of researchers reported on the cultivation of multiple GII.4 variants as well as GII.3, GII.17, and GI.1 hNoVs, with the latter group requiring the presence of bile. These strain-specific requirements for replication of hNoV are noteworthy, and further investigation revealed that it was the exposure of the human intestinal enteroids to bile and not the virus itself which increased hNoV

replication. The identification of this combination of human intestinal enteroids and bile as the replication niche for certain hNoV genotypes was groundbreaking and led to further identification of enterocytes as the primary targets for infection and replication in the small intestine.

PERSISTENCE AND RESISTANCE OF ENTERIC VIRUSES

As a general trend, the persistence, resistance, and stability of enteric viruses depend on the initial load, temperature of the environment, relative humidity, degree of inoculum drying, suspension medium (organic load or fecal material), type of virus, and type of material (surface or food matrix) being contaminated, as previously reviewed (139). Most laboratory studies on the persistence and stability of hNoVs have been based on cultivable surrogates or molecular detection of hNoV RNA. The following sections briefly summarize and highlight studies on viral persistence in foods and water, on fomite surfaces, and under various treatment conditions.

Persistence in Foods and Water

Studies of virus persistence on food commodities have revealed that hNoV GII.4 and GI.4 remained detectable after a 7-day storage at 10°C when inoculated on the surfaces of lettuce, turkey, strawberries, and raspberries, with decreased survival when stored at 21°C for 3 days (140). Enteric viruses (hNoVs, HAV, and rotavirus) and their surrogates (FCV) can survive on berries and herbs when kept frozen at −20°C or colder for 3 months (141). Also, MNV persisted, with minimal reduction (approximately 1.6 log), in bottled water over 42 days at room temperature (142). Fermented food products have also been investigated with respect to hNoV survival. Lee et al. (143) reported on the persistence of hNoV GII.4 (ca. 3 log genomic copies) in cabbage kimchi stored at 4°C and 10°C for 28 days. Intact-hNoV titers of 1.67 (4°C) and 1.31(10°C) log genomic copies/20-μl reaction mixture were detected even in the presence of increasing concentrations of lactic acid and acetic acid—two compounds known to inactivate microorganisms.

While many studies on the persistence of enteric viruses, specifically hNoVs, in bivalve mollusks have been published (144, 145), Souza et al. (146) reported recently on the bioaccumulation and persistence of enteric viruses by *Anomalocardia brasiliana* clams during a 24-h period. hNoV GI was the most adsorbed virus after 24 h, with hNoV GII having the least bioaccumulation at <1% among the viruses tested (HAV, rotavirus, and adenovirus). Previous studies have revealed detection of infectious HAV for up to 3 weeks in oysters that were allowed to accumulate HAV for 16 h in experimentally contaminated water (147).

With regard to enteric viral survival and persistence in surface and groundwater, MS2 bacteriophage, FCV, and poliovirus survive better at lower temperatures of 4°C than at 25°C (148). TuV remained stable in surface water even after 28 days, with <1 log reduction, although in groundwater, TuV was reduced by ≥3.5 to 4 log by day 21 (149). To date, the only human volunteer challenge study on the long-term persistence of hNoV in groundwater revealed that the volunteer subjects became ill after drinking groundwater 61 days after inoculation with hNoV; however, hNoV GI.1 RNA could still be detected after 3 years of storage of the contaminated groundwater (150).

Along with postharvest persistence, a growing body of work has focused on the persistence of viruses on fresh produce under preharvest conditions. Hirneisen and Kniel (151) reported that hNoV could persist on the leaves of mature spinach plants during a 7-day study period. Additional studies have reported on the persistence of viral surrogates (MNV, porcine sapovirus, and TuV) on lettuce and spinach plants subjected to abiotic stressors, including physical damage, heating, and flooding (152). Overall, reductions (≥1.5 log) in infectious virus 7 days after inoculation on both lettuce and spinach plants—a trend also observed for hNoV GII.4 RNA over a 14-day period—were observed. Furthermore, these viral surrogates persisted on lettuce leaves stored at room temperature for 3 days and at 4°C for up to 14 days (153).

Persistence on Fomite Surfaces

Considerable research has been conducted on the persistence of human enteric viruses on fomite surfaces (139, 154, 155). For brevity, only selected studies are highlighted here. In 2009, Liu et al. (38) determined the persistence of two hNoV strains on food contact surfaces and reported a <1-log reduction after 42 days on stainless steel, ceramic, and Formica coupons. According to Lamhoujeb et al. (156), enteric virus persistence on surfaces is increased (49 to 56 days) at low temperatures (7°C) and elevated humidity (86%) compared to room temperature (20°C) and decreased humidity (30%), at which hNoV persisted for only 7 days on plastic. A similar study revealed 2-log and 2.3-log reductions of hNoV GI.1 and GII.2, respectively, after 42 days at room temperature (157). More recently, Colas de la Noue et al. (158) reported that virus infectivity after storage at 25°C in high and low relative humidity was increased at low (10%) as opposed to high (85 to 100%) humidity, counter to most of the previously reported data. Interestingly, the authors investigated the integrity of binding capacity of hNoV VLPs as opposed to relying on detection of viral RNA. While most available data address hard, nonporous surfaces, the importance of porous, soft surfaces in the persistence of enteric viruses was recently reviewed by Yeargin et al. (159). To summarize, the authors noted that temperature, relative humidity, organic content, and deposition method all influence viral survival on soft, porous surfaces.

Transfer of microorganisms between surfaces has also been frequently investigated. This transfer is dependent upon the application of varying levels of pressure, friction, time, temperature, and moisture, though variable rates of transfer have been observed even under the most controlled conditions (160). Sequential transfer of hNoV by contaminated fingers occurred after contact with soiled toilet paper, leading to contamination of seven clean surfaces (161). A study involving the transfer of GI hNoV from stainless steel surfaces to lettuce revealed positive hNoV transfer from the stainless steel surface to eight of nine lettuce samples (162). Additional studies by Escudero et al. (157) revealed that transfer of enteric viruses from fomite surfaces depended on the type of food: the rate of transfer of GII.2 hNoV and MNV to deli meats was 55 to 95%, whereas that to lettuce was 0 to 26%. Stals et al. (163) also determined that rates of hNoV and MNV transfer from contaminated gloves and stainless steel to

sandwich components (meat, lettuce, and bread buns) varied according to food type. Varying rates of hNoV transfer to raspberries, blueberries, and grapes after handling with contaminated hands have also been reported after direct contact and by sequential contamination, which can be encountered in kitchens and food preparation settings (164, 165).

Physical and Chemical Resistance

Along with the persistence of human enteric viruses, their resistance to common control strategies on fomite surfaces as well as on foods has also been extensively investigated, and many of these studies have been summarized by Hirneisen et al. (8), Alidjinou et al. (155), and Shukla et al. (166). One of the most recent studies was a comprehensive evaluation of virus inactivation by Cromeans et al. (134). The responses of Aichi virus, hNoV, TuV, MNV, FCV, and porcine enteric calicivirus were determined after exposures to extreme pH, heating at 56°C, alcohols, chlorine on surfaces, and high hydrostatic pressure. The results revealed variability across all viruses and treatments. For instance, FCV was completely inactivated at pH 2, whereas MNV, TuV, and Aichi viruses were resistant. In addition, all viruses were resistant when exposed for 5 minutes to 1,000 ppm chlorine on stainless steel surfaces, with the exception of FCV, which was reduced by 5 logs. Of note, viruses are more resistant to chemical inactivation on surfaces than in suspension, as determined by Tung et al. (167) and Hirneisen and Kniel (136). Additional studies have determined the inactivation rates of enteric viruses when exposed to organic acids and phenolic acids. Lacombe et al. (168) reported a 4.5-log reduction of TuV after a 5-minute exposure to 0.5:0.7% (vol/vol) for lactic acidsodium dodecyl sulfate at pH 3.5, whereas only a 2.6-log reduction was observed with 0.5:0.7% (vol/vol) acetic acid-sodium dodecyl sulfate at pH 4.0.

With respect to thermal resistance *in vitro*, Cromeans et al. (134) reported complete inactivation of all viruses (Aichi virus, hNoV, TuV, MNV, FCV, and porcine enteric calicivirus) after exposure to 56°C for 20 minutes as well as variable log reductions after treatment with alcohols, with TuV and Aichi viruses not being affected. These data on

thermal inactivation align with the conclusions from a 2012 meta-analysis on thermal treatment of enteric viruses in which the authors state that thermal inactivation was generally most successful at temperatures above 50°C (169). Another evaluation of thermal inactivation studies of enteric viruses revealed similar findings in addition to highlighting methodological discrepancies which hinder the ability to compare results across studies (170).

Thermal resistance of various hNoV genotypes in food items such as tomato sauce, minced meat, baked frozen pizza, and fresh culinary herbs (i.e., when added to dishes during the cooking process) has also been investigated, and the data typically reveal greater inactivation at higher temperatures and longer exposure times (171, 172). This resistance to heat treatment within the food matrix is of particular interest when effective control strategies in bivalve mollusks are being considered. Araud et al. (173) determined that oyster tissues inoculated with TuV required heating for nearly 2 min at 80°C to obtain a 1-log reduction in TuV, whereas <1 min at 80°C was needed for a 1-log reduction of MNV. The thermal resistance of hNoV GI and GII in naturally contaminated oysters was determined after heating at 72 and 95°C (174). Using a PMAxx pretreatment before quantitative RT-PCR (RT-qPCR), the authors observed reductions of 2.99 and 1.93 log RT-PCR units/100 µl for GI and GII hNoV, respectively. On the basis of data such as these, higher temperatures and longer treatment times are being recommended to inactivate hNoV in shellfish to prevent hNoV illness and outbreaks (175).

CONTROL OF VIRUSES IN FOODS AND THE FOOD PRODUCTION, PROCESSING, AND PREPARATION ENVIRONMENTS

Molluscan Shellfish

The role of molluscan shellfi sh in the transmission of human enteric viral disease has been recognized for decades, with accompanying efforts to develop effective pre- and postharvest controls for this food commodity. Preharvest controls continue to include prevention of

human sewage pollution of shellfish harvesting waters and the establishment of alternative microbiological indicators to monitor shellfi sh-growing areas. Prevention of sewage pollution can be difficult because of the presence of both diverse and diffuse sources and the unpredictable nature of a contamination event; however, preventing illegal dumping of human waste in marine waters is likely to be a particularly important control practice (176). Oyster beds close to sewage plants may need special consideration because of concerns about the potential for sewage overflow, particularly during times of excessive rainfall (177).

Preventing human sewage contamination of molluscan shellfi sh overlay waters is complicated by the lack of a reliable microbiological indicator whose presence and/or levels are correlated with the presence of enteric virus contamination (178). Bacteriophages, especially F-specific coliphages (FRNA phages or male-specific coliphages), somatic coliphages, and phages of *Bacteroides fragilis*, have long been proposed as alternative indicators of viral contamination of the environment. Among these, the distribution and survival of FRNA phages are considered more similar to those of human enteric viruses (179), although shellfish may contain pathogenic viruses even though they lack FRNA phages (180). Similar difficulties in establishing relationships between the presence and levels of somatic coliphages and those infecting *B. fragilis* have been reported (181). The feasibility of using human adenoviruses and polyomaviruses as indicators of human enteric viruses in environmental and shellfi sh samples has likewise been proposed; however, the evidentiary data reveal poor correlations between these viruses (178). More recently, pepper mild mottle virus (PMMoV) has been identifi ed as a suitable indicator for human enteric viruses. While PMMoV is a pathogen of peppers, it has been reported to be the most abundant virus in human stool (182), and it is detected more frequently and in greater abundance in wastewater, surface water, and marine water than previously proposed human enteric virus indicators, including human adenoviruses and polyomaviruses (183, 184). In addition, PMMoV is cited as being more persistent in surface and marine waters than human enteric viruses (183). However, a reliable

microbiological indicator for enteric virus contamination in shellfi sh and their harvesting waters has yet to be officially established (185).

Controlled purification, widely used in Europe, is an early postharvest control strategy. Depuration and relaying are based on the principle that shellfi sh can purge at least some of their microbial contaminants by extended feeding in clean water, provided that the feeding conditions (e.g., temperature, salinity, and dissolved oxygen) are favorable (186). In depuration, freshly harvested shellfish are placed for several days in a controlled environment, usually in tanks provided with a supply of clean, disinfected seawater under specific operating conditions. In relaying, shellfish are transferred from contaminated growing areas to approved or naturally unpolluted (pristine) areas (186). Unfortunately, the scientific consensus is that enteric viruses are not eliminated during controlled purification. For example, Schwab et al. (187) found only a 7% reduction in hNoV concentration after 48 hours of depuration treatment. More recently, Polo et al. (188) reported that HAV and hNoV (GI and GII) at concentrations ranging from 10^3 to 10^5 RNA copies/g digestive tissue could be detected in shellfish undergoing commercial depuration over a 7-day period.

Other postharvest controls for virus contamination of shellfish include heating and alternative food-processing technologies, including nonthermal approaches such as high-pressure processing (HPP), ionizing irradiation, and high-intensity ultrasound. Early reports documented outbreaks of both HAV and viral gastroenteritis linked to the consumption of cooked shellfi sh (189, 190). Thermal inactivation studies—as discussed above—have substantiated the resistance of enteric viruses in bivalve mollusks to heat treatment. These studies have resulted in European heat processing recommendations (internal temperature of 90°C for 1.5 min) to control HAV in shellfi sh (175). Unfortunately, such high temperatures often result in unacceptable sensory changes to the product.

In general, enteric viruses are quite resistant to ionizing radiation, and studies have determined this to be an inconsistently effective control for molluscan shellfish contaminated with viruses, at least at the relatively low doses necessary to maintain the organoleptic quality of the product (191). There has, however, been much interest in the

efficacy of HPP as a postharvest treatment to inactivate human enteric viruses in shellfish, particularly because it also works well for inactivating pathogenic *Vibrio* species under conditions that result in a product that maintains its "fresh-like" properties (192). In early work, Kingsley et al. (193) determined that HAV and FCV suspended in cell culture medium were inactivated after exposure to 450 MPa for 5 minutes and 275 MPa for 5 minutes, respectively. Grove et al. (194) reviewed the studies on HPP inactivation of enteric viruses prior to 2006, and they concluded that there is a wide range of viral susceptibility to HPP and that continued research was needed. Despite some promising preliminary results, Leon et al. (195) determined that when human subjects consumed Norwalk (hNoV GI.1) virus-contaminated oysters with and without prior HPP treatment, infection occurred among one or more volunteers consuming HPPtreated products, except those products receiving the most severe treatment (600 MPa). However, this treatment resulted in a product having a mildly cooked, whitish appearance. A subsequent study by Lou et al. (196) provided additional evidence that the hNoV capsid is highly resistant to HPP based on experiments with hNoV VLPs and HBGA receptor binding assays. An additional study was conducted to characterize the HPP susceptibility of TuV-inoculated oysters and determined that only moderate treatment levels (≤300 MPa at 4°C) were needed to inactivate TuV (197). Overall, more research is needed to determine whether HPP is a viable postprocessing technology for inactivation of enteric viruses in molluscan shellfish (192).

Fresh Produce

Preharvest measures directed at prevention of viral contamination of fresh produce are addressed by the good agricultural practices recommendations provided by federal agencies and industry trade groups (198). One important consideration in these documents is ensuring the absence of human fecal contamination in irrigation water and waters used to mix pesticides and fungicides (199) or in manure, fertilizer, and/or compost. Unfortunately, sewage spills, storm-related contamination of surface waters, illicit discharge of waste, and residential septic system failures are widely recognized as the leading sources of surface water and groundwater contamination, and these are

relatively common and frequently unavoidable occurrences (200). Since many produce items are subject to extensive human handling during harvesting, preharvest food safety strategies must also focus on individuals harvesting the food, particularly if the product is hand-picked. This might include issues such as ready access to clean, on-site toilet and handwashing facilities, restriction of children and ill workers in production fields, and adequate employee education (198).

From a postharvest perspective, it is generally recognized that current preservation and storage processes such cooling, freezing, acidification (pH ≤4.5), and moderate heat treatments (pasteurization) are usually inadequate to completely inactivate foodborne viruses such as hNoV or HAV if they are present on or in a food matrix (171). Most of the decontamination efforts applied to fresh produce have focused on washing. The water used for washing and ice used for transport and cooling must be free of human fecal contamination. For produce washing, waters are frequently supplemented with sanitizers, the most common of which is chlorine, although others, such as chlorine dioxide and organic acids, have been used. Generally, washing fresh produce can reduce but not eliminate foodborne pathogens. In some instances, simple home-use remedies such as water immersion, hand rubbing, or use of detergents or vinegar (10%) can be moderately effective, providing approximately 1-$\log_{10}$ reductions in virus concentration on the surface of strawberries (201). Alternatives to chlorine include hydrogen peroxide, peroxyacetic acid-hydrogen peroxide formulations, and trisodium phosphate (8). Use of ozonated wash water also has promise (202). Particularly promising, Predmore and Li (203) determined that supplementation of chlorinated (200 ppm) wash water with surfactants (sodium dodecyl sulfate and polysorbates) enhanced the removal of MNV from fresh produce approximately 100-fold. Since some of these compounds are approved as food additives and/or GRAS (generally recognized as safe), this may be a promising control strategy for the future.

Although novel surface sanitizers continue to be evaluated, the data on chemical disinfection for the inactivation of viruses from food surfaces remain less than desired with respect to the level of virus inactivation. Not only is efficacy relatively poor, but some of the novel agents (such

as hydrogen peroxide) cause unacceptable organoleptic changes to the product. Product-specific surface morphology and physiological characteristics make disinfection complicated; leafy vegetables can be more difficult to decontaminate because of their rough or wrinkled surfaces, and small fruits such as raspberries and blackberries have more porous and complex surfaces, including "hydrophobic pockets" that can entrap virus particles (140). Furthermore, disinfectants incorporated into wash water may not be effective in removing or inactivating viruses that have penetrated the skin of the product or those that might have entered tissues through cuts and abrasions.

There is substantial interest in several emerging foodprocessing technologies for inactivating viruses on the surface of fresh produce. For example, FCV and poliovirus are highly susceptible to inactivation by UV radiation, with 3-$\log_{10}$ reductions obtained by treating contaminated water with doses of 23 and 40 mJ/cm^2, respectively (204, 205). Fino and Kniel (206) determined that when green onions, lettuce, and strawberries were artificially contaminated with HAV, Aichi virus, or FCV and subsequently exposed to UV light at doses of ≤240 mW • s/cm^2, about a 4.6-$\log_{10}$ reduction for lettuce, a reduction of 2.5 to 5.6 $\log_{10}$ for green onions, and a reduction of 1.9 to 2.6 $\log_{10}$ for strawberries were obtained. Su et al. (207) studied the effect of high-intensity ultrasound on the inactivation of MNV and FCV in buffer and orange juice. Using a treatment of 20 kHz for 2, 5, 10, 15, 20, and 30 minutes with pulses of 30 s on/30 s off, a 15-minute treatment was required for complete inactivation (reduction of 4 $\log_{10}$) of FCV, but only a 1.6-$\log_{10}$ reduction in MNV was achieved, even after a 30-minute treatment. More recently, atmospheric cold plasma technology was investigated for inactivating viruses on fresh produce. Lacombe et al. (208) investigated the inactivation of TuV and MNV on the surfaces of blueberries by cold plasma with and without air and reported a 3.5-log reduction in the number of TuV PFU per gram after a 120-s treatment with air and a 5-log reduction of MNV after a 90-s treatment with air. Based on preliminary data, novel processing technologies have promise, but much more research is needed to validate their efficacy, and a major investment is needed to commercialize those that are most promising. As is the case for molluscan shellfish, ionizing radiation is

not a promising technology for inactivating viruses in produce, as high doses are relatively ineffective and likely to adversely affect product quality (209).

A combination of two or more controls, so-called hurdle approaches, may be necessary to completely eliminate viral contamination of fresh produce. A few studies have investigated such combinations. For example, Li et al. (210) determined that a minimal reduction in the titer of MNV (<1 $\log_{10}$) inoculated on shredded iceberg lettuce occurred with a treatment of liquid (2.1%) or vaporized (2.5%) hydrogen peroxide; however, the combination of UV light and vaporized hydrogen peroxide substantially increased the efficacy of inactivation. Butot et al. (172) determined the effect of freeze-drying, freeze-drying combined with heating, and steam blanching on inactivating HAV and FCV on the surfaces of berries and herbs. While freeze-drying itself was only minimally effective, the addition of a terminal dry heat treatment at 120°C improved the degree of inactivation.

RTE and Prepared Foods

Adherence to strict hygienic practices when handling and preparing foods is critical to controlling viral contamination in RTE food products. These issues have been reviewed extensively by others (211, 212). The first line of defense in this regard is employee education and regular supervision of employees. For instance, a 2006 study associated having a certified kitchen manager with a lower incidence of hNoV outbreaks in restaurants (213). The importance of controlling viral contamination is further illustrated by the FDA's 2017 Food Code, which includes recommendations for (i) exclusion and restriction of ill employees, (ii) emphasis on handwashing procedures, and (iii) prohibition of bare-hand contact with RTE foods (214). Because ill employees shed viruses in large numbers, managers of food manufacturing, catering, and food service industries should restrict these individuals from working directly with food or food equipment and should provide a sick leave policy that allows workers to stay home while ill. Even with such controls, virus shedding by individuals is still a concern because it can occur pre- or postsymptomatically as well as asymptomatically (5, 61). Glove use (and changing of gloves if damaged

or soiled), frequent handwashing, and prevention of cross-contamination during handling and preparation of foods are essential. One of the most important considerations in hand hygiene is the role of fingernails, as virus-containing fecal material can be harbored here and long, artificial fingernails have been linked to consistently greater hand contamination (215).

Hand disinfection remains an important issue. Reliable hand decontamination relies on three primary factors: (i) an effective disinfecting agent, (ii) adequate use instructions, and (iii) regular compliance (216). Compliance with recommended handwashing regimens is notoriously poor (217). Additionally, although handwashing helps prevent and control the transfer of viruses, handwashing agents differ in their ability to inactivate viruses (137). Consistent with the results of suspension assays described previously, finger pad assays confi rm that commonly used handwashing agents have minimal efficacy against human enteric viruses, rarely exceeding 1- to 2-$\log_{10}$ inactivation when used at manufacturer-recommended concentrations (218). Some have suggested that many of the commercial hand sanitizers are not even as effective as soap and water alone (219). Tuladhar et al. (220) confirmed this suggestion by reporting greater log reduction of hNoV and MNV after 30 s of handwashing with soap and water than with an alcohol-based hand disinfectant using finger pad assays.

Overall, there is increasing consensus on the need to establish new standards for the selection of effective formulations for handwashing agents with regard to antiviral activities, particularly with respect to labeling. Over the past decade, research has aimed to develop more effective virucidal formulations for handwashing and sanitizing agents. For example, Macinga et al. (221) described a new ethanol-based hand sanitizer containing a synergistic blend of polyquaternium polymer and citric acid that reduced the infectivity of FCV and MNV by >3 $\log_{10}$ after a 30-s exposure, as evaluated by both suspension and finger pad assays. More recently, Ionidis et al. (222) described another novel, alcohol-based hand disinfectant with added urea and citric acid that resulted in a 4-log reduction of virus after a 60-s exposure using the standardized suspension assay.

Frequently handled objects, such as faucet taps, doorknobs, and even food preparation surfaces, can serve as sources of virus contamination in the food preparation environment, and standard surface disinfection is used as a control measure (155). Not unexpectedly, the efficacy against enteric viruses of most chemical disinfectants commonly used in both institutional and domestic environments is questionable (167). Early research revealed that sodium hypochlorite was most effective for HAV and rotavirus inactivation, with improved efficacy when used at high concentrations and extended contact times (223). Nearly the same results were obtained in most of the surface decontamination studies involving hNoV and its surrogates, with variation depending on the surrogate-disinfectant combination (159). In particular, bleach used at concentrations ranging from 1,000 to as much as 5,000 ppm appears to be the most effective surface-sanitizing regimen relative to other disinfectants tested. However, the specific $\log_{10}$ inactivation achieved using sodium hypochlorite varies with virus type, surface type, and study design. In addition, the presence of fecal material not only increases virus survival but is likely to protect viruses from the antimicrobial activity of bleach (224). Based on such data, the CDC recommends a minimum of 1,000 ppm for disinfecting surfaces contaminated with hNoVs (225).

DETECTION METHODS

Despite extensive efforts to develop robust methods to not only recover viruses but also detect them in foods, this remains a challenging area of research (166, 226). Because the numbers of virus particles present in contaminated foods are usually low and there is no universal or rapid culture-based method for growing hNoVs or HAV, cultural enrichment is not an option. Therefore, the viruses must be concentrated and purifi ed from the food matrix before a detection method is applied, with molecular amplification being the detection method of choice. Sequence-based determination of amplicon identity is used for further confi rmation. The major steps for the detection of viruses in foods are as follows: (i) virus concentration and purification, (ii) nucleic acid extraction, (iii) detection of amplicons, and (iv) confi rmation of amplicon identity.

Virus Concentration and Purification

Virus concentration and purification schemes are designed to reduce sample volume and remove at least some of the matrix while simultaneously recovering most of the contaminating viruses. In order to achieve these goals, sample manipulations are undertaken that capitalize on the behavior of enteric viruses to act as proteins in solutions, to cosediment by simple centrifugation when adsorbed to larger particles, and to remain infectious at extremes of pH or in the presence of organic solvents. Many virus concentration and purification methods use manipulation of pH and/or ionic conditions to favor virus adsorption to, or elution from, the food matrix. This is then followed by relatively lowspeed centrifugation, after which the virus-containing phase (either precipitate or eluate) is recovered for further purification. Other steps in the virus concentration and purification process may include various forms of filtration (crude filtration and ultrafiltration), ultracentrifugation, precipitation (achieved through the addition of polyethylene glycol or organic flocculants or by manipulation of pH), organic solvent extraction (to remove matrix-associated lipids), ligand-bound magnetic separation (using immunobeads or cationic particles), and/or enzyme pretreatment (to break down matrixassociated organic matter, particularly complex carbohydrates). In almost all instances, virus extraction is accomplished by combining two or more of these steps in series (227).

It is generally recognized that elution of viruses from the surface of foods is relatively inefficient, mostly because of underlying hydrophobic, ionic, and van der Waals interactions that tend to favor adherence of viruses to organic matter. In addition, other forces may influence virus binding to solids, including virus association with sugar or carbohydrate moieties on food tissues, as has been observed for shellfi sh and fresh produce (30, 228). During the past decade, efforts to capitalize on these interactive forces have brought about some new methods to facilitate virus concentration and purification. For example, Papafragkou et al. (229) used cationically charged beads to facilitate HAV capture from a variety of food matrices, achieving recoveries of about 50% of input virus and detection limits of ca. 10 PFU per 25-g

sample. Cannon and Vinjé (230) took advantage of the specifi city of HBGAs by using them as potential binding ligands for hNoVs, revealing that a magnetic bead-based HBGA assay could be developed for the recovery of low numbers (30 to 200 genomic units) of hNoVs from seeded environmental waters. This approach has since been applied and expanded upon by others, who have used recirculating magnetic capture equipment to increase the sample size and volume (231, 232).

A good virus concentration and purification method (Fig. 23.4) should be relatively simple and result in sample volume reductions of 10- to 1,000-fold and recovery of >90% of the target virus. However, recovery efficiency is both virus and matrix specific (226). For example, HAV recovery tends to be low in comparison to the relatively high recovery of human enteroviruses (e.g., poliovirus); simple sample matrices such as lettuce tend to be easier to work with than more complex matrices, such as sandwiches and RTE salads. All methods have their own advantages and disadvantages. For instance, immunocapture methods tend to be simple, requiring fewer sample manipulations, which entails a lower likelihood of virus loss and favors the recovery of infectious virus; however, they may be hindered by high specifi city, since broadly reactive antisera are not readily available for hNoVs (233). To address these limitations, development of novel cross-reactive bivalent synbody (i.e., a synthetic protein constructed from two peptides) affi nity ligands are being investigated for their ability to capture a diverse group of hNoVs. Gupta et al. (234) recently reported on the development of 20 synbodies for the capture of both GI and GII hNoVs. The authors determined that four of the synbodies were able to crossreact with four diverse genotypes of hNoV (GI.1, GI.6, GII.4 Sydney, and GII.6) as well as producing results similar to those for porcine gastric mucin-coated magnetic beads—a standard method for capturing hNoV (230). The potential advantages of synthetic ligands include the ability to standardize the production of the ligands as well as the ligand-coated beads (234). Regardless, there is no universal extraction method currently available that can be applied to all foods, particularly when contamination levels are low (235, 236).

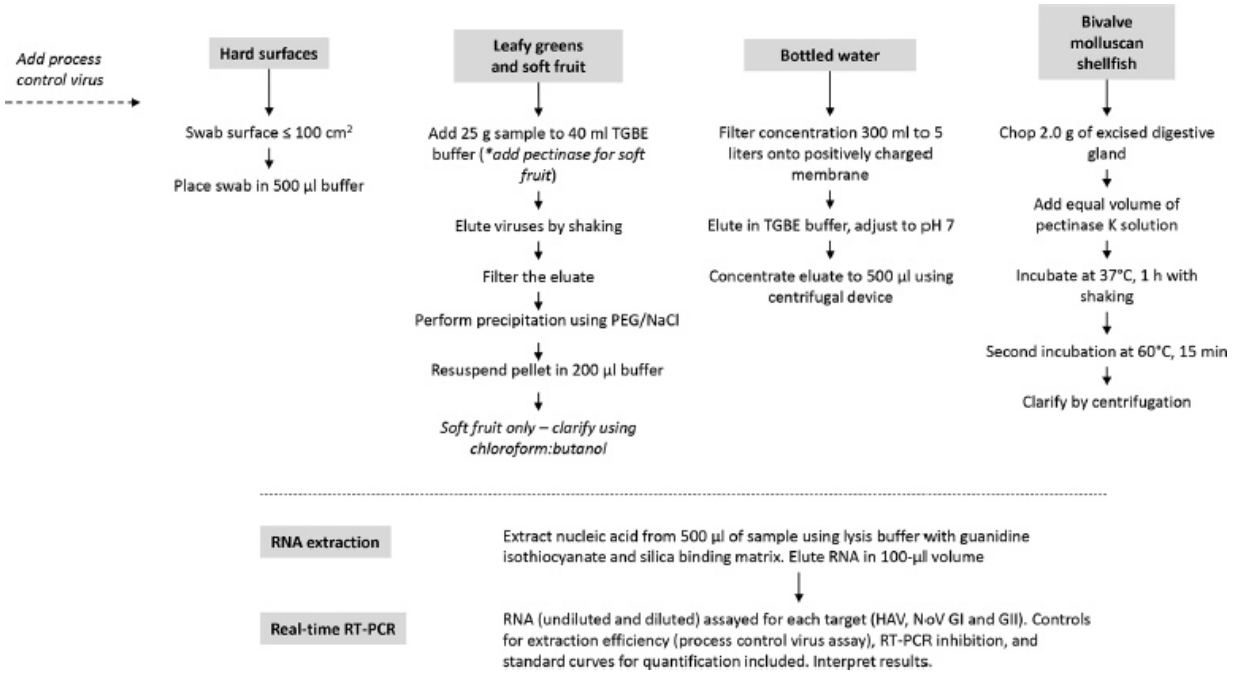

Figure 23.4 Flow diagram of the ISO method for the detection of HAV and NoV in food and bottled-water samples. Image adapted from ISO/TS 15216-1:2017, annex A (251). TGBE, Tris-glycine-beef extract; PEG, polyethylene glycol.

Nucleic Acid Extraction

Although viral RNA can be released from capsids and made available for amplification using a simple heat treatment (99°C for 5 minutes), this is rarely done because, even with the best virus concentration method, residual matrix-associated components persist and frequently interfere with, or inhibit, nucleic acid amplification. Therefore, an efficient nucleic acid extraction step is critical. The science of RNA extraction has developed rapidly over the last 2 decades, and what was once a complex procedure is now much simpler and more reliable. Over the years, there have been many comparative studies to identify the best RNA extraction method(s) for use with food systems. Many investigators are now using combination guanidinium-silica-based methods, which have actually been automated by a number of diagnostics manufacturers (203). In addition, to enhance RNA purity, investigators have also added gel filtration columns (i.e., Sephadex-based columns or similar products) to the sample preparation to

further purify extracted RNA, resulting in an increased likelihood of virus detection through the removal of RT-PCR inhibitors (237, 238).

Detection of Amplicons

RT-PCR is the most commonly used method for the detection of viral RNA. The sensitivity and specificity of RT-PCR depend upon the efficiency of the virus concentration and purification steps, as well as the nucleic acid extraction. They also depend on primer choice and amplification conditions. The use of primers with low degeneracy and high melting temperature is recommended, because this reduces the likelihood of nonspecific amplification, which is common when nucleic acids are extracted directly from a complex sample matrix. For HAV detection, broadly reactive primers with high annealing temperatures are available, usually corresponding to the VP1-2A junction or 5′UTR of the viral genome (110). The high degree of genetic diversity of hNoVs has made the development of broadly reactive primers difficult. Four regions of the hNoV genome have been used for primer design (designated regions A, B, C, and D) (13, 239), but the ORF1-ORF2 junction (just downstream of region B) is the most conserved and is frequently used for genogroup-specific detection. For strain comparison (as might be appropriate in outbreak investigations), a dual-typing scheme with primer sets corresponding to the hNoV capsid and polymerase genes was recently recommended for molecular surveillance of hNoV (55) and is now utilized by CaliciNet. It is also recommended that multiple primer pairs be used when food samples are screened for NoV contamination (240), as one pair may perform better than another, depending on virus load and the matrix from which the sample was derived. Historically, nested reactions have been used to increase the sensitivity of detection, particularly for naturally contaminated food products (240).

Beginning in the mid-2000s, real-time PCR or RT-qPCR methods replaced the traditional method. The term “real time” refers to the simultaneous detection and confirmation of amplicon identity as the amplification progresses through the use of hydrolysis probes (e.g., TaqMan), hybridizing probes (Molecular Beacons), or double-stranded-DNA intercalating dyes (e.g., SYBR green). It is said that real-time

assays can be made quantitative, but residual matrix-associated inhibitors frequently affect the reliable quantification of viral load in naturally contaminated samples. Therefore, simple presence-absence testing, rather than quantification, is generally used for virus detection in foods and environmental samples. Further, there is some debate as to whether an RNA or DNA standard is best when the standard curve for real-time quantification is designed. While using a DNA standard provides a defined assessment of the efficiency of DNA amplification, it does not take into account an inefficient reverse transcription step, which may result in an underestimate of the number of viral genome copies in the sample.

Confirmation of Amplicon Identity

When RT-PCR products are obtained from naturally contaminated foods, the amplicons must be sequenced for further confi rmation and strain typing. RT-qPCR is not very amenable to the sequencing that needs to be done for confi rmation due to the small amplicon size and target region, so presumptively positive samples are almost always rescreened with traditional RT-PCR prior to cloning and sequencing of amplicons. Sequences derived from foods can be compared to those obtained from clinical specimens in an effort to make causal associations. Although this approach has been used success successfully to link contaminated foods to outbreaks of viral gastroenteritis, it is often challenging to achieve amplification of viral RNA from implicated foods (241, 242).

Several ways to facilitate confirmation of a positive signal for target viruses in foods have been under development. For example, Schultz et al. (243) developed an RT-qPCR assay that allows the user to detect and genotype hNoV strains in a single step using a long-template approach. DNA microarrays are now used for the simultaneous detection and genotyping of hNoVs (244) and even for the identification of a broad range of foodborne viruses, including HAV, hNoVs, rotavirus, and certain human enteroviruses (245). Over the past several years, these methods have been improved upon, especially with respect to analysis of clinical samples. For instance, Chen et al. (246) developed a tiling microarray assay that can simultaneously

detect and genotype multiple foodborne viruses, including coxsackievirus, HAV, and hNoVs; however, the detection limit was cited at 10^4 viral genome copies, although this has since been improved upon (200 to 500 genome copies) by other researchers (247). A thorough description of nucleic acid-based detection methods for foodborne viruses was recently reviewed (248).

Recent Advances in Detection and Diagnostics

Initial efforts in the development of methods to detect viral contamination in foods were limited almost exclusively to molluscan shellfi sh. By the mid-2000s, relatively standard methods were developed for detecting HAV and hNoVs in shellfi sh, with the most recent method comparison study having been completed in 2015 (249). Here, the authors reported that an adsorption-twice elution-extraction method yielded high sensitivity (1.4 genome copies/g) for the detection of rotavirus in bivalve digestive shellfish tissues. Ensuing studies characterized the prevalence of contamination, particularly in European shellfish (188, 250). Since then, there has been an explosion of interest in developing methods for other foods. For example, there are now well-accepted methods for the detection of viruses in berries, and the European Committee for Standardization has established standard methods (251) for the detection of hNoVs and HAV in selected foods (soft fruits and leaf, stem, and bulb vegetables), bottled water, and food contact surfaces (EN ISO 15216-1:2017).

There has also been increased scrutiny relative to the need for inclusion of appropriate controls in attempts to detect viruses in naturally contaminated products. Not only are the standard negative and positive amplification controls needed, but there is now a strong recommendation from the international community for the inclusion of sample process (extraction) controls and internal amplification controls (IACs) as are published in the ISO (International Organization for Standardization) methods for extraction and detection of viruses in foods (251). Extraction controls are intended to evaluate the efficiency of the virus concentration and purification steps; as such, the analyst adds a relatively high concentration (10^6 to 10^8 infectious units) of a harmless virus with physical characteristics similar to those of enteric

viruses. Viruses used as process controls have included mengovirus, MNV, FCV, TuV, armored RNA, and various bacteriophages. The concept is that if the process control is recovered and detected by RT-qPCR, the sample preparation method was successful; if not, it calls into question the efficiency of that method (226).

Recent efforts have been aimed at determining the most appropriate process controls depending on the matrix and target virus. Gentry-Shields and Jaykus (252) investigated five different process control viruses for use in the recovery of hNoV from lettuce and sliced deli ham. The process control viruses included mengovirus, MNV-1, MS2 coliphage, TuV, and turnip crinkle virus. Results revealed that mengovirus most closely mimicked the behavior of hNoV throughout the sample processing steps, whereas MNV-1 had the least similar behavior. Hennechart-Collette et al. (253) also evaluated process control viruses in the recovery and detection of HAV and hNoV in bottled water, lettuce, and semidried tomatoes and determined that MNV-1 was the most appropriate virus for validating the detection of HAV and hNoV GII across all three matrices and of hNoV GI in lettuce. Interestingly, mengovirus was the most appropriate virus for validating hNoV GI detection in bottled water and semidried tomatoes. These conflicting observations will be important to consider during selection of the appropriate process control virus, and it is important to note that currently mengovirus is the selected process control for EN ISO 15216-1:2017.

Differing from the process control, IACs are sequences of nontarget RNA or DNA, usually flanked by the target-specific primer binding sites. These are added to the amplification reaction mixtures to account for reaction failure due to residual matrix-associated amplification inhibition (238). Diez-Valcarce et al. (254) constructed and applied IACs for viruses relevant to the food industry. The authors designed IAC primers to include a 16- to 18-bp fragment of the *Listeria monocytogenes prfA* gene combined with the specific primer sequence for each target virus and a minor groove-binding probe targeting the *L. monocytogenes prfA* gene. Conversely, the ISO method for detection of hNoV and HAV in food employs an external amplification control RNA

for detection of sample inhibition, requiring a reaction separate from that for detection of the target virus.

Another important area of research has focused on differentiating infectious and noninfectious viruses. Several candidate methods have been identifi ed, to be used in conjunction with RT-qPCR, to aid in this discrimination. These methods fall into two general categories, those estimating capsid integrity and those targeting genome integrity. Candidates in the former category are more popular and include the use of nucleic acid intercalating agents (e.g., propidium monoazide [PMA]), RNase pretreatment, ligand and antibody capture, and direct detection of damaged protein. The most widely used method to date is RNase pretreatment. While these methods have been reviewed on various levels (255, 256), researchers have also attempted to undertake comprehensive, sideby-side comparisons of these techniques. For example, Escudero-Abarca et al. (257) compared PMA and RNase pretreatment to determine the thermal resistance of a GII.2 hNoV called Snow Mountain virus (SMV). The authors reported slightly different decimal reduction values of SMV depending on the exposure temperature and pretreatment method applied. Overall, it was concluded the RNase pretreatment achieved more consistent results with respect to nucleic acid amplification and that the PMA treatment proved difficult to optimize unless larger amplification products were used, as reported previously by others when applying this method for the pretreatment of bacteria (258). Moreno et al. (259) also evaluated two intercalating agents—PMA and ethidium monoazide—for discrimination of viable HAV in food samples (lettuce, parsley, spinach, cockles, and clams), and reported successful viability discrimination when samples were treated with PMA plus 0.5% Triton X-100 (a nonionic surfactant). Recently, novel iterations of these intercalating dyes (e.g., PMAxx and PEMAX) have been released on the commercial market and have been evaluated by researchers focused on food virology (174). Additional viability-discriminating reagents, including platinum and palladium compounds, were recently evaluated for virus infectivity and were determined to perform more efficiently than PMA and other related intercalating dyes (260).

Advances in detection of viral nucleic acids targets have also been reported. Recently, novel detection technologies were investigated and compared to the RT-qPCR standard, including isothermal amplification (nucleic acid sequence-based amplification and loop-mediated isothermal amplification), microfluidic digital RT-PCR (RT-dPCR), and nucleic acid aptamers (or aptamer-based biosensors). While the isothermal amplification technologies have been thoroughly investigated and reviewed (13, 166), RT-dPCR is one of the newer technologies on the horizon.

Briefly, RT-dPCR is an absolute quantification approach that allows the determination of target copy numbers without the reliance on a standard curve. In this approach, the sample is partitioned into microdroplets, thus creating individual reaction mixtures with one or no copies of the nucleic acid target. Absolute quantification is achieved using binomial Poisson statistics by calculating directly from the ratio of positive to total reactions (261). Moreover, by micropartitioning the sample, inhibitors are effectively diluted out and/or eliminated, resulting in increased confidence of virus quantification (262). Investigators in the European Union have compared RT-dPCR to RT-qPCR for the quantification of both HAV and hNoV in lettuce, water, and soft berries (263, 264). Coudray-Meunier et al. (263) reported that while sensitivity of the RT-dPCR assay was comparable to or lower than that of RT-qPCR, viral recoveries determined by RT-dPCR analysis were significantly greater than those obtained with RT-qPCR for lettuce and water samples, possibly due to the removal of inhibitory substances. Similarly, Fraisse et al. (264) compared these methods for the detection of hNoV and HAV recovered from soft berries (raspberries and strawberries) and reported that RT-dPCR reduced PCR inhibition, thus increasing viral efficiencies.

With respect to the development of biosensors for the detection of foodborne viruses, researchers have been working to improve the analytical sensitivity of biosensors for the detection of pathogens in complex samples (265). Recently, Moore et al. (266) described the development of broadly reactive single-stranded DNA aptamers targeting the P domain protein of a GII.4 hNoV capsid; however, these

aptamers were merely proof of concept to show the potential for optimization into biosensors, or “aptasensors,” for detection.

Applications of Virus Detection Methods to Naturally Contaminated Samples

Regardless of their drawbacks, there has been an increase in the use of virus detection methods applied to naturally contaminated samples. For example, in their 2007 U.S. market survey, DePaola et al. (267) determined (as evaluated by RT-qPCR) a prevalence of virus contamination (hNoVs or HAV) in U.S. oysters ranging from 5.2 to 11.3%, depending upon the region from which they were harvested. Kokkinos et al. (268) determined the prevalence of viral pathogens and indicators on leafy green vegetables across three countries, including Greece, Serbia, and Poland. Positive detection of viruses on produce samples ranged from 0.82% to 9%, with hNoVs detected in about 2.5% of general samplingpoint samples. Baert et al. (269) reviewed data on the prevalence of hNoV in fresh produce from Belgium, France, and Canada and reported relatively high rates of detection of hNoV in leafy greens, soft red fruits, and other popular fresh produce items. For instance, hNoV was detected in 28.2% to 50% of leafy green samples depending on the country of origin, although none could be confi rmed by sequencing. Unfortunately, no such survey studies on the prevalence of hNoV in U.S.-grown fresh produce have been conducted to date. Detection of hNoVs in environmental swabs and hand swabs has been used for hNoV outbreak investigations of restaurants and cruise ships (270). Boxman et al. (271) successfully detected hNoV RNA in foods associated with two outbreaks, although only with the aid of nested RTPCR. Environmental contamination by hNoVs has also been detected in the absence of outbreaks, and this approach was recently reviewed by Leone et al. (272).

Despite the tremendous strides that have been made in virus detection, these protocols are still underutilized and are usually applied only in response to known or suspected foodborne disease outbreaks. The primary reasons for their limited use include (i) the inability of molecular amplification methods to consistently discriminate between infectious and inactivated virus, even with the use of sample

pretreatment; (ii) the lack of widely accepted, collaboratively tested methods, as the available ISO methods are used only to a limited extent within the United States; (iii) the requirement that most methods be product specific, meaning that universal approaches for detecting a variety of viruses in a variety of foods do not exist; and (iv) the cost and the need for highly trained personnel.

In addition, care should be taken when both negative and positive test results are interpreted. For example, while a sequence-confirmed positive test definitively indicates the presence of the viral genome in the product, it does not necessarily confi rm that the contaminant was infectious. Negative test results are fraught with interpretive challenges related to sampling, the potential for virus inactivation (particularly if an extended time occurs between sampling and testing), low levels of virus contamination, and the impact of the matrix on assay detection limits as well as sample inhibition. Hence, a negative test result cannot be relied upon to ensure the absence of virus contamination, especially given the low infectious dose (50% human infectious dose, ~1,320 to 2,800 virions) of hNoVs (9).

An additional emerging issue is how to interpret marginally positive RT-qPCR results (e.g., a quantification cycle [C_q] value of >37), especially when amplicon concentrations are too low to be used in sequencing reactions. These difficulties were recently highlighted by Li et al. (273), who reported that 7 positive samples out of over 2,000 samples of frozen berries were collected and processed for recovery and detection of foodborne viruses over a period of 7 years. More specifically, positive samples corresponded to high C_q values (36.9 to 41.1), and these high C_q values are deemed suspect, requiring further investigation and inquiry.

RISK ASSESSMENT

Interest in applying the principles of risk analysis to foodborne viruses has increased over the past decade. The Food and Agriculture Organization and the World Health Organization conducted an expert consultation in 2007 to address this topic (274). Overall, the panel believed that there were so many unanswered questions that

embarking on a formal risk assessment would be premature. However, the document produced from their meeting served as the basis for a new work charge for the Codex Alimentarius Committee on Food Hygiene. In the meantime, the academic sector has sought to apply mathematical modeling to the development of criteria for enteric pathogens in irrigation waters (275) and the transmission of hNoVs in the food-handling environment (276). Recently, Duret et al. (211) published a quantitative risk assessment of hNoV transmission in food establishments designed to evaluate the impact of intervention strategies (e.g., handwashing, glove use, and elimination of contact between hands) and the behavior (e.g., exclusion from work and limited contact with food) of food service employees on the risk of hNoV contamination of foods. The study revealed that efficient handwashing and handwashing frequency combined with glove use as well as elimination of contact between hands and high-touch-rate fomite surfaces in bathrooms would significantly reduce the average number of infected customers. A similar study quantified the effects of environmental and direct transmission of hNoV on cruise ships and again confirmed that while isolation of ill persons is beneficial, good handwashing practices are more effective for preventing outbreaks (277).

A particularly interesting study seeks to use hNoV genotype profiles for selection and differentiation of foodborne outbreaks. The first phase of this work focused on developing a predictive model that could serve prospectively in the selection of outbreaks most likely to be associated with foodborne transmission. Using prospective epidemiologic surveillance data from the European Union, the investigators developed a logistic regression model that was adapted to a Web-based tool. The odds of an outbreak being foodborne were highly influenced by venue (home versus institution versus restaurant) and genotype (most foodborne outbreaks are associated with GI strains) (278). A follow-up project was initiated to determine whether hNoV genotype frequency distributions could be used to enhance detection of the sources of foodborne outbreaks (279). Both studies revealed how epidemiologic data might eventually be used to support better source attribution of foodborne virus illnesses and perhaps a move toward eventual risk-based decision-making for management of foodborne

viral diseases. Matthews et al. (16) conducted a similar study examining global trends of hNoV outbreaks based on a systematic literature review; however, this study considered only published outbreaks, and foodborne outbreaks are disproportionately published relative to nonfoodborne outbreaks. In contrast to the report by Verhoef et al. (278), the investigators reported that multiple strains (GI and GII) were associated with foodborne and waterborne outbreaks, whereas GI strains were significantly associated with waterborne outbreaks and GII strains were primarily associated with health care-related and seasonal outbreaks.

CONCLUSIONS

Epidemiologic evidence reveals that foods play an important role in the transmission of human enteric viruses. This can in large part be attributed to improvements in the ability to detect viral pathogens in clinical specimens, mostly related to recent advances in molecular detection techniques, as well as improvements in surveillance. Because both HAV and hNoVs can be transmitted by a variety of nonfoodborne routes, it is necessary to conduct comprehensive surveillance for outbreaks transmitted through all potential routes to determine the relative importance of foods as a vehicle of transmission (280). The advent of the NORS provides such comprehensive outbreak surveillance in the United States and an opportunity to better characterize foodborne attribution for enteric viruses. Nonetheless, widespread surveillance for individual cases of viral gastroenteritis does not occur, and most people with such illness do not seek health care or undergo diagnostic testing. In addition, tests for the detection of hNoVs and HAV in stool specimens are not routinely applied, although the recent development of commercial multipathogen panels may change these practices (281). When outbreaks are investigated, the implicated food is rarely tested for viral contamination, and when it is, detection limits minimize the usefulness of the results. Improved and more widespread reporting and investigation of foodborne viral disease outbreaks, as well as targeted epidemiologic studies to identify the risk factors for acquiring viral gastroenteritis, would improve our understanding of source attribution. The implementation and

continued enhancement of outbreak surveillance systems, such as NORS and CaliciNet, may help to provide this information.

Even if better detection of viral disease is implemented, the availability of effective controls remains a stumbling block. For molluscan shellfi sh, the absence of a reliable indicator of viral contamination of harvesting waters, along with the weaknesses in efficacy of conventional control strategies (depuration, relaying, and mild heat), suggests that occasional viral contamination of shellfi sh will continue to occur. However, there may be promise on the horizon with the application of PMMoV as an adequate and conservative enteric virus indicator to monitor shellfi sh growing areas. Fresh produce can become contaminated with viruses through a variety of routes, but our understanding of how, why, and how often such contamination events occur is quite limited. Water contamination and subsequent produce contamination are likely to occur sporadically, and implementing effective measures to improve personal hygiene at the farm level is challenging. The lack of truly effective antiviral disinfectant agents for both hands and surfaces is a further complication. Multiple control strategies will likely be needed, requiring significant resources, including a comprehensive education campaign. As more people understand why and how enteric viruses are spread, day-today changes, such as routine handwashing and hand and surface sanitation, will become more of a way of life and lead to better control of foodborne virus transmission. Finally, further development of candidate norovirus vaccines may one day provide another tool for reducing the incidence of disease and preventing outbreaks.

Our understanding of the importance of enteric viruses for the overall burden of foodborne disease has improved dramatically over the past 30 years. However, many unanswered questions remain, and much research is still needed. The field has been limited in the past by the small number of scientists working with foodborne viruses as well as the absence of easily reproducible *in vitro* culture methods, which limits studies of infectious virus strains. However, this is changing as more food microbiologists begin to tackle this fascinating and challenging subject. It is likely that the next decade will bring exciting

new developments as more is done to understand and control these important causes of human foodborne disease.

We gratefully acknowledge Monique Foster and Mike Purdy from the CDC Division of Viral Hepatitis for critical review of the sections pertaining to hepatitis A and E virus. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the U.S. Centers for Disease Control and Prevention.

Helminths in Meat

Foodborne parasites pose a risk to human health in virtually allregions of the world. In addition to the direct effect that these parasites have on human health, zoonotic parasites found in food animals often serve as trade barriers for countries where these parasites occur. A considerable body of legislation has been developed for the purpose of preventing and controlling zoonotic parasites in food animals, including very costly meat inspection programs. There are four meat-borne helminths of medical significance: *Trichinella* spp., *Taenia solium*, and *Taenia asiatica*, which occur primarily in pork, and *Taenia saginata*, which is found in beef.

Despite the availability of sensitive, specific diagnostic tests, veterinary public health programs (meat inspection), and effective chemotherapeutic agents for human tapeworm carriers, these parasites continue to be a threat to public health in many parts of the world. There are a variety of reasons for this, including animal management systems that perpetuate infection, inadequate or poorly enforced inspection requirements for slaughtered animals, new sources of infection, and demographic changes in human populations that introduce new culinary practices of preparing meats. Current control and preventive procedures are often inadequate, and more effective control measures are needed to ensure safe meat for human consumption.

TRICHINELLOSIS

The history of trichinellosis is fascinating, going back many centuries. Whether the commandment in the Bible (Leviticus 11 and Deuteronomy 14) to not eat the flesh of cloven-footed animals (swine) was due in part to the potential danger of contracting trichinellosis is only speculative. In the 7th century CE, Mohammed prohibited the eating of pork. Hence, to this day, trichinellosis is rare among Jews and Muslims. The earliest known case of human trichinellosis may be evidenced by the mummy of a person who lived near the Nile River ca. 1200 BCE, an observation made only in 1980 when *Trichinella* larvae were presumptively identifi ed in the mummy's intercostal muscle (1).

Trichinella spiralis was first observed by Paget in 1835 in the muscles of a man during postmortem dissection (2). A landmark in the history of clinical trichinellosis was Zenker's demonstration in 1860 that encapsulated larvae in the arm muscle caused the illness and death of a young woman. Even after 1860, many cases of trichinellosis were undoubtedly not diagnosed because of the diffi culty in recognizing the infection clinically. Since its discovery, *Trichinella* has been the subject of a very large body of research as well as global efforts to prevent human exposure through meat inspection and other mitigations.

Species of *Trichinella*

Nematodes of the genus *Trichinella* are ubiquitous in animals, both domestic and wild. *Trichinella* was long thought to be monospecific, with just a single species, *T. spiralis*, being recognized. As biochemical and, more recently, molecular tools have been used to characterize *Trichinella* isolates, it has become clear that the phylogenetics of this genus is much more complex. Species and genotypes of *Trichinella* are differentiated by geographic distribution, host distribution, and host infectivity, as well as subtle morphological, physiological, and biochemical differences. These differences in traits and characters which loosely group the species and genotypes are supported by extensive molecular studies (3, 4). The genus *Trichinella* is divided into two groups, or clades, based on

whether the larva is encapsulated in host musculature or nonencapsulated. The encapsulated group currently includes six species and three genotypes: *T. spiralis, T. nativa, T. britovi, T. murrelli, T. nelson, T. patagoniensis, Trichinella* T6, *Trichinella* T8, and *Trichinella* T9. The nonencapsulated group includes *T. pseudospiralis, T. zimbabwensis, and T. papuae.*

Among these nine species and three genotypes, only *T. spiralis* is commonly associated with the domestic pig and circulates widely in the synanthropic cycle in temperate regions of the world. Other species and genotypes found in temperate regions include *T. murrelli* and *T. britovi*, which circulate primarily in the sylvatic cycle in North America and Eurasia, respectively (5). Both *T. nativa* and *Trichinella* T6 show resistance to freezing temperatures and are distributed in the Holarctic (*T. nativa*) and the northern parts of the United States and Canada (*Trichinella* T6). *Trichinella* T6 has been shown to be closely related to *T. nativa* based on interbreeding studies (6). *T. nelsoni* has been reported from wild animals in countries of the southeastern region of Africa, and its range overlaps that of *Trichinella* T8 (which through interbreeding studies has been determined to be closely related to *T. britovi*) (3). *Trichinella* T9 has a range limited, so far, to sylvatic carnivores in Japan. This genotype interbreeds with *T. britovi* but has been shown by molecular studies to be more closely related to *T. murrelli*. The most recently named species, *T. patagoniensis*, was isolated from a mountain lion in the Patagonian region of Argentina. Extensive genetic analyses identified this isolate as a new species, phylogenetically very close to the ancestral root species *T. spiralis* (7, 8).

Among the three nonencapsulated species, *T. pseudospiralis* has been found in North America, Europe, Asia, and Australia in mammals and carnivorous birds (9, 10). Originally identifi ed in crocodiles, and found only in Africa, *T. zimbabwensis* has a broad host range, including lizards and lions, but has also been shown in experimental studies to be capable of infecting many other homeothermic and poikilothermic hosts (11, 12). The

nonencapsulated species *T. papuae* has been reported to occur in Southeast Asia and Australasia in wild pigs as well as saltwater crocodiles and has been reported as a source of human infection in those areas (13).

Life Cycles of *Trichinella* Species

All species of *Trichinella* complete the life cycle within one host; no intermediate host or extrinsic development is required. When larvae contained in raw or inadequately cooked meat are ingested, the muscle fibers and capsules that enclose the parasites are digested in the stomach. In the intestine, the liberated larvae burrow into the lamina propria of the villi in the jejunum and ileum. Four molts occur within 48 h, and by the third day, the worms are sexually mature. The small tapered head of the adult worm has a round, unarmed mouth that opens into a tubular esophagus. Approximately one-third of the anterior portion of the body is composed of the stichosome, consisting of stacks of discoid stichocytes. The secreted contents of these cells are important for serological detection of infection and also contain antigens that confer protective resistance to the host. Immediately below the esophagus and the stichosome lies a thin-walled intestine, the hind portion of which terminates in the rectum, a muscular tube lined with chitin. The adult female worm measures about 3.5 mm in length and possesses a vulval opening about onefifth the body length from the anterior end (Fig. 24.1). The male measures 1.3 to 1.6 mm in length and possesses a single testis that originates in the posterior portion of the body and extends anteriorly to near the posterior end of the esophagus, where it turns posteriorly to form the vas deferens, which becomes the enlarged vesicula seminalis. The vesicula seminalis becomes the ejaculatory duct to join the copulatory tube in the cloaca. The copulatory tube forms the copulatory bell that is extruded during copulation (Fig. 24.2). There are two ventrally located copulatory appendages on each side of the cloacal opening, which possibly serve to clasp the female during copulation. Between these appendages lie four tubercles, or papillae.

In the host, sexually mature adult worms reenter the lumen of the small intestine, where copulation takes place. The adult males die shortly after copulation. The female worms burrow back into the mucosa and begin to larviposit, usually into the central lacteals of the villi, about 7 days after infection and may continue to do so for a period up to a few weeks. Each female worm can shed approximately 1,500 newborn larvae, but this number varies based on species and host.

Figure 24.1 Scanning electron micrograph of a female adult worm of *T. spiralis* with its prominent vulval opening (magnification, ×2,450).

The tiny newborn larvae (100 by 6 mm) are carried from the intestinal lymphatic vessels to the regional lymph nodes and into the thoracic duct and the venous blood, passing through the right side of the heart, through the pulmonary capillaries back to the left side of the heart, and into peripheral circulation. During migration, the larvae may enter many tissues, including those of the myocardium, brain, and other sites, but here they either are destroyed or reenter the bloodstream. Generally, only larvae that reach striated muscles are able to continue development. There they penetrate the sarcolemma of the fibers, where they mature, reaching approximately 700 to 1,100 mm in length. They become coiled within the fibers and, in the case of most species, are encapsulated as a result of the host's cellular response. This host-

parasite complex, called the nurse cell, is capable of supporting the infective larvae for months or even years. An increased vascular supply to the nurse cell provides nutrients and oxygen vital to the parasite's survival. The encapsulated cyst eventually becomes calcifi ed, and as a result, the larva dies.

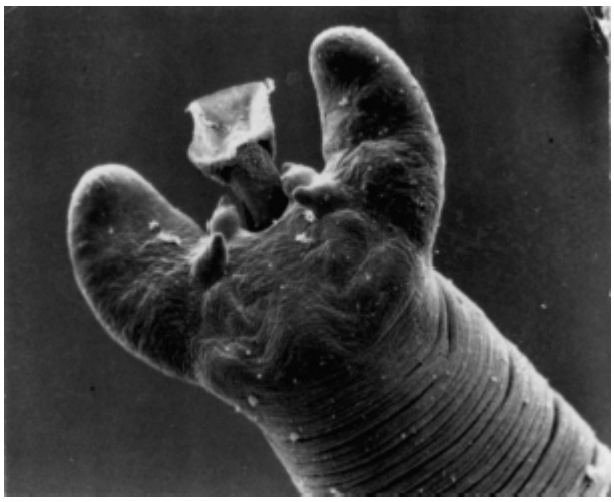

Figure 24.2 Scanning electron micrograph of a male adult of *T. spiralis* with its copulatory bell (magnification, ×1,400).

Infection in humans represents a dead end in the parasite's life cycle. However, in animal hosts, the carcass serves as a source of infection for carnivores and scavengers. Typically, infected animals are refractory to subsequent infection. However, molecular evidence has documented dual infection in animals (14), and it is possible that these dual infections result from multiple exposures.

Epidemiology

Trichinellosis, the human disease resulting from infection with species of the genus *Trichinella*, is considered a zoonosis because infection occurs as a result of ingestion of raw or poorly cooked meat from infected animals. *Trichinella* infection has been documented in domestic animals from 43 countries and in wildlife from 66 countries (15).

In the period of 1986 to 2009, the WHO reported 65,818 cases of human trichinellosis from 41 countries (16). Of these, 86.47% were

from the European region and another 10.90% were from the Americas. These numbers do not include reports from China. The mortality rate for these cases was 0.064%. Countries of Eastern Europe accounted for the majority of cases in the European region, while Argentina had the most cases in the Americas. Outbreaks in the period were linked to domestic pork and game meats in most countries, with the notable exception of horsemeat-related outbreaks in France, Italy, and Mexico and isolated outbreaks associated with dog meat.

The transmission patterns of *Trichinella* spp. can be divided into domestic-animal (synanthropic) and wildlife (sylvatic) cycles (14). Humans can become involved in both of these cycles. The domestic cycle, by definition, must involve domesticated (farm) animals. There are various patterns of transmission within the domestic cycle. Pigs may become infected through the deliberate feeding of uncooked or undercooked animal flesh containing infective larvae or by scavenging on infected animal carcasses. Infected pigs may then serve as a source of infection for other pigs through cannibalism. Within the domestic cycle, rats may serve as a reservoir or bystander host, acquiring infection from wildlife, carrion, or pigs. Rats may also transmit infection directly to pigs that ingest them.

The species of *Trichinella* most frequently associated with the domestic cycle in pigs is *T. spiralis*; however, there are an increasing number of reports of *T. britovi* as a cause of human infection caused by meat from domestic pigs (17). Low infectivity of other *Trichinella* species for the domestic pig diminishes their ability to circulate in the domestic cycle. Because cooking, freezing, and other processing methods kill *Trichinella* larvae in meat, most human infections have resulted from instances where meat preparation was not adequate. Pork products such as fresh sausage, summer sausage, and dried or smoked sausage have allbeen implicated as sources of human trichinellosis.

In several countries of the European Union, where slaughter inspection of pigs for *Trichinella* infection has been required for more than 100 years, the parasite has been essentially eradicated from domestic swine, and consequently, human trichinellosis resulting from domestic pork has not been reported for several decades. These countries do report sporadic outbreaks due to game meats or imported meats. Pork and pork products continue to serve as a major source of infection in many parts of the world (18–20). For example, in Romania, between 1980 and 1989, a total of 4,345 cases of human trichinellosis were reported. Between 1990 and 2004, a total of 23,948 cases were reported. In the year with the greatest number of human cases, 1993, more than 250 human cases were reported per 1 million inhabitants (21). This spike in human infection is attributed to changes in the pork production systems due to turmoil in the social and political systems. Reemergence of trichinellosis as a serious health risk has likewise been reported in Serbia (22), where infection rates in pigs between the years 1995 and 2006 were nearly 1.0%, and in Bulgaria, where 145 outbreaks were reported between 1990 and 2006 (23).

Trichinella continues to be a significant public health risk in parts of Asia and in Central and South America. Wang and Cui (24, 25) reported 23,004 cases of trichinellosis in China between 1964 and 1999. Almost allcases (95.8%) were linked to pork. From 2000 to 2003, there were 17 outbreaks involving 828 individuals and 11 deaths (1.33%) (26), and from 2004 to 2009, there were 11 outbreaks involving 1,387 individuals and 4 deaths (0.29%). All outbreaks occurred in southwestern China and involved ethnic groups which eat raw meat. In a serological survey in 10 provinces, autonomous regions, and municipalities, an average positive rate was 3.19% (range of 0.26 to 8.43%) (27).

In most cases, poor hygienic conditions for raising pigs and inadequate veterinary control at slaughter are the reasons for risk of human infection. Pigs raised outdoors, fed raw garbage, or raised in contact with large rodent populations are at risk of acquiring infection. Inadequate veterinary inspection may result from

insensitive or improperly performed testing methods or from pigs that are butchered outside of normal inspection channels (backyard pigs). In addition to poor animal management and gaps in inspection programs, culinary habits (improper cooking) impact the risk of human exposure, and this is exemplifi ed in some Asian countries where epidemics have been reported, including Thailand, Laos, Japan, China, and Hong Kong.

Another domesticated animal that emerged as a major source of human trichinellosis is the horse. Outbreaks in 1975 and 1985 in the southern suburbs of Paris were attributed to the consumption of raw horsemeat in the form of steak tartare (28). Fifteen outbreaks of human trichinellosis were associated with consumption of horsemeat in France and Italy between 1975 and 2005. These outbreaks involved a total of 3,334 individuals with five deaths (0.15%). As a result of these outbreaks, mandatory testing of horse meat was required in France beginning in 1985 and throughout the European Union as of 1991 (29).

Three species have contributed to human trichinellosis from horsemeat: *T. spiralis*, *T. britovi*, and *T. murrelli* (30). Following the first outbreaks, there was speculation that the horsemeat was contaminated with meat from other species (31). However, the recovery of larvae from suspected meat (32) and identification of naturally infected horses (33) have confi rmed this source of human exposure. The route by which horses become infected has been the subject of considerable speculation. The majority of horses linked to human outbreaks in Italy and France originated from countries or regions where a high incidence of *Trichinella* infection is known to occur in pigs, rats, and other animal species. One epidemiological study reported that the intentional feeding of animal products and kitchen waste is a common occurrence among horse owners in parts of Eastern Europe and that horses are more willing to consume meat than was previously realized (34). With better awareness of the risk of acquiring trichinellosis from horsemeat, inspection programs have been implemented, and horsemeat has not been implicated in any recent outbreaks.

The sylvatic cycle of *Trichinella* involves more than 100 species of animals, and many species pose a risk to humans who eat raw or undercooked game meats. In the sylvatic cycle, wild carnivorous or omnivorous animals scavenge the carrion of dead animals or eat meat from prey. Higher infection rates typically occur in animals near the top of the food chain. For example, in the arctic environment, *Trichinella* is quite prevalent in polar bears, grizzly bears, foxes, and wolves. Transmission in the arctic environment is further facilitated by the survival of larvae in frozen meat. In Alaska, allhuman cases of trichinellosis have been traced to the consumption of bear or walrus meat (35), and the etiological agent of these infections is the freezing-resistant species *T. nativa* (36–38). The repeated outbreaks of trichinellosis caused by the consumption of infected walrus meat have led to an inspection program for harvested walruses prior to distribution of the meat to Inuit communities (39).

The meat of wild boars is becoming an increasingly important source of *Trichinella* as these animals expand their range in many countries and has now become the second most common source of human infection (16, 40). Serological surveillance reported that up to 4% of wild boar tested had evidence of exposure to *Trichinella* spp. A review of human outbreaks between 2005 and 2015 reported 16 common source outbreaks due to wild boar meat from 13 countries involving 426 people and causing 12 fatalities (41).

Pathogenesis and Pathology

Disease caused by *Trichinella* infection varies with the intensity of the infection and the tissues invaded. The in-and-out movements of the adult worms, especially the females in intestinal tissue, cause an acute inflammatory response and petechial hemorrhages. The cellular response consists primarily of neutrophils with eosinophils. This is followed by an infi ltration of lymphocytes, plasma cells, and macrophages that peaks at about 12 days after infection, gradually declining thereafter. Thus, lesions in the intestine are due to the host's response to the adult worms or their protein products.

The newborn larvae cause an acute inflammatory response as they pass through or become lodged in various tissues and organs. The infiltration consists of lymphocytes, neutrophils, and especially eosinophils. Although there is myocarditis, viable larvae are more numerous in the pericardial fluid than in the myocardium. Pulmonary hemorrhage and bronchopneumonia may be observed during this stage of larval migration through the capillaries. Rarely, encephalitis may result if the larvae migrate through cerebral capillaries.

When larvae encyst in striated muscle fibers, there is an immediate tissue response consisting of inflammation of the sarcolemma of the involved muscle fibers. The disturbance of ultrastructure and metabolic processes in muscle fibers results in basophilic transformation. This is followed by destruction of the muscle fibers and the eventual formation of a capsule. The larvae gradually die, provoking an intense granulomatous reaction or foreign-body cellular response that culminates in calcification. The most heavily parasitized striated muscles include the diaphragm, intercostal muscles, and ocular and masseter muscles. Larvae that enter tissues other than striated muscles disintegrate and are eventually absorbed.

Clinical Manifestations

The vast majority of individuals infected with *Trichinella* spp. are asymptomatic, probably because low numbers of larvae are ingested. Classical trichinellosis is usually described as a febrile disease with gastrointestinal symptoms, periorbital edema, myalgia, petechial hemorrhage, and eosinophilia (42). During the intestinal stage of infection, gastrointestinal symptoms such as nausea, vomiting, and “toxic” diarrhea or dysentery, as well as fever (over 38°C) and sweating, may be observed. Malaise can be severe and lasts longer than fever. The onset of intestinal symptoms occurs usually within 72 h after infection and may last for 2 weeks or longer.

Generally, from the second week, when the newborn larvae are migrating and can reach almost any tissue within the body, a characteristic edema is noted around the eyes and in some cases around the sides of the nose, at the temples, and even on the hands. Periorbital edema is present in about 85% of patients and is often complicated by subconjunctival and subungual splinter hemorrhages that disappear within 2 weeks. Eosinophilia greater than 50% is the most consistent manifestation. In severe cases, however, the number of eosinophils may be low. As the larvae enter striated muscle fibers, a striking myositis and muscular pain are evident. In addition to inflammation and pain, eosinophilia is observed during this phase. Serum creatine phosphokinase and transaminase levels can be elevated as a result of leakage of these enzymes from muscle fibers into the serum. Higher levels of enzymes in serum may not correlate well with the severity of the clinical condition. Hypoalbuminemia, which is believed to be due to a demand for protein by the parasite, is usually accompanied by hypopotassemia. Muscle atrophy and contractures may also occur.

Respiratory symptoms, including dyspnea, cough, and hoarseness, may either be due to myositis of respiratory muscles or be secondary to pulmonary congestion. Neurologic manifestations are rare but may result from invasion of the brain by migrating larvae. In severe cases, death may result following cardiac decompensation or respiratory failure, cyanosis, and coma.

Intimate contact between the parasite and host tissues stimulates the production of antibodies that can be demonstrated in the serum. The exact role of antibodies in acquired immunity is not entirely clear, but antibodies appear to be involved in destruction of newborn larvae. On the basis of experimental animal data, it would be safe to assume that in most cases in humans, the severity of infection is reduced considerably by the development of immunity from previous subclinical infections. Local gut immunity in mice has been shown to be T-cell dependent (43).

It has been reported that different species of *Trichinella* present somewhat different clinical pictures in humans. For example, Serhir et al. (44) described a diarrheic syndrome in outbreaks caused by *T. nativa* in arctic regions of North America. This syndrome, characterized by persistent diarrhea and little edema or fatigue, differs from the traditional myopathic syndrome characterized by edema, fatigue, fever, and rash. These distinct syndromes occur concurrently in outbreaks; following the accumulation of serological and epidemiological evidence, it was concluded that the diarrheic syndrome is seen in patients who have preexisting immunity to *T. nativa* from prior exposure (44). Similarly, infection with *T. murrelli* results in a greater number of patients developing a rash (44%) and fewer patients developing facial edema (58%) (45). Only a few outbreaks of human trichinellosis have been attributed to nonencapsulated species of *Trichinella* (46, 47). The only clinical difference observed in these cases was a prolonged period of symptoms (fever and myalgias), which lasted twice as long as those reported for encapsulated species.

Diagnosis

It is difficult to clinically diagnose trichinellosis because it mimics so many other infections as a result of its dissemination throughout the body. Thus, individual or small groups of cases may go undiagnosed, whereas common-source outbreaks make diagnosis easier (46).

Diagnosis is based on a history of eating infected meat, symptoms, laboratory findings (including serology), and recovery of larvae from muscles (48). Classical symptoms of trichinellosis include fever, myalgia, and periorbital edema, although, as discussed previously, these symptoms may vary depending on the species of *Trichinella*. The most characteristic feature of laboratory tests is marked eosinophilia. Although eosinophilia is not restricted to trichinellosis, its presence in 30 to 85% of infected individuals is a constant and important diagnostic aid. Eosinophilia is initiated in the second week of infection, reaching its peak by about day 20. It

may be absent not only in patients with very severe and fatal cases but also in individuals with secondary infection. Levels of muscle enzymes, including creatine phosphokinase and lactate dehydrogenase, are frequently elevated in trichinellosis patients, as are overall leukocyte counts (46, 49).

The most definitive diagnostic method is muscle biopsy to detect encapsulated or nonencapsulated larvae. The diagnostic success of biopsy depends on chance distribution of larvae in the particular striated muscle that is sampled. Gastrocnemius, pectoralis major, deltoid, and biceps muscles are commonly used because of easy accessibility. The muscle strip is compressed tightly between two microscope slides and examined for the presence of larvae (Fig. 24.3). Part of the biopsy sample can be digested or fixed and then sectioned, stained, and examined. The presence of active larvae following digestion with artificial gastric juice indicates a recent infection.

There are numerous immunological tests available for the diagnosis of trichinellosis (50–52). Recommendations for the use of these tests have been summarized by the International Commission on Trichinellosis (53). The enzyme-linked immunosorbent assay (ELISA), using an excretory-secretory (ES) antigen collected from muscle larvae or a synthetic tyvelose antigen containing a dominant epitope, is the test of choice for human trichinellosis based on a high degree of sensitivity and specifi city. Both ES and tyvelose antigens are preferable to crude extracts of *T. spiralis* muscle larvae due to a risk of crossreactions with other helminth infections. A sensitivity of nearly 100% has been obtained for humans infected with *T. spiralis* when immunoglobulin G (IgG) is measured by ELISA (54). Serological tests measuring other classes of antibodies result in lower sensitivity (52); however, detection of specific IgM or IgA is indicative of a recent infection. The use of antigens from other stages (adults and newborn larvae) has not resulted in comparable serodiagnosis. Western blotting to determine the presence of antibodies to ES antigens in the range of 40 to 70 kDa

has been used as a confi rmatory test. The sandwich ELISA has also been used to detect circulating antigens in sera (55).

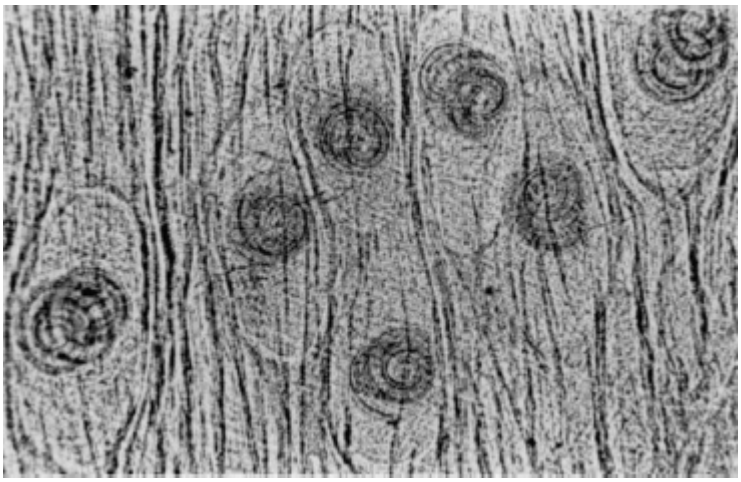

Figure 24.3 Example of *T. spiralis* muscle larvae in compressed muscle tissue viewed through a trichinoscope.

Trichinellosis patients typically become seropositive between the second and fifth weeks of infection, although this time varies with the species of *Trichinella*. The time required for seroconversion is inversely correlated with the infective dose. Thus, it is advisable to take multiple serum samples at intervals of several weeks in order to demonstrate seroconversion in patients whose sera were initially negative or to detect rising titers. Once patients become seropositive, antibody levels do not correlate with the severity of the disease (52). Patients typically remain seropositive for several years, but seropositivity has been reported to last for up to 35 years following infection (45, 56).

Treatment

The efficacy of treatment of trichinellosis depends on the intensity of infection, the species of *Trichinella*, the stage of infection, and the character and intensity of the host response. The purpose of treatment during the intestinal phase is to destroy adult worms and to interfere with the production of newborn larvae. The drug of choice is mebendazole (Vermox) at dosages of 200 to 400 mg three times a day for 3 days and then 400 to 500 mg three times a day for

10 days (42, 48). Mebendazole is also believed to be active against developing and encysted larvae but at dosages higher than those used against adult worms. Mebendazole is administered during the first week of infection before newborn larvae migrate, in moderate or severe infections in combination with corticosteroids, and in infections with *T. nativa*, which responds poorly to treatment with nonbenzimidazole compounds. Mebendazole is not recommended for women in the first trimester of pregnancy. Thiabendazole (Mintezol) is no longer used because of adverse reactions. Albendazole (Valbazen and Zentel) is better absorbed and is probably as active as or even more active than mebendazole (42). Pyrantel (Antiminth) at 10 mg/kg of body weight/day for 4 days and levamisole at 2.5 mg/kg/day (maximum of 1 to 50 mg) are active only against adult worms in the intestine.

To minimize hypersensitivity, it is recommended that corticosteroids be given in combination with anthelmintic drugs. Corticosteroids are recommended for acute severe trichinellosis not only for antiallergic action but also for anti-inflammatory and antishock actions. Supportive therapy, such as bed rest, is very important.

Prevention and Control

Prevention of human exposure to *Trichinella* from domestic pigs can be accomplished in a variety of ways: (i) by prevention of infection on the farm (preharvest), (ii) by testing animals at slaughter, (iii) by postslaughter processing using methods that have been proven effective for killing *Trichinella* larvae in meat, and (iv) by proper cooking by the consumer. The recommended application of these methods for the control of trichinellosis in pork has been summarized by the International Commission on Trichinellosis (57) and in guidelines published by the World Organisation for Animal Health (OIE) (58).

Prevention of Infection on the Farm

Knowledge of the routes of transmission of *Trichinella* to domestic pigs has allowed the design of swine management systems that essentially eliminate the risk of exposure of pigs to this parasite. By following a series of good management practices, including biosecure housing, effective rodent control, and good manufacturing and storage practices for feed, it is possible to certify the safety of pork without subsequent slaughter inspection or further processing. The requirements for producing pigs under conditions that greatly reduce or preclude exposure to *Trichinella* infection are outlined by several published sources. The International Commission on Trichinellosis provides guidance for *Trichinella*-free pig farming (57). The essential elements of these recommendations relative to pig farming are reiterated in EU Commission Regulation no. 1375/2015 of the European Union (59) and the OIE Terrestrial Animal Health Code (60). New guidelines from the Codex Alimentarius (61) provide that pork from pigs raised under the conditions outlined by OIE, and from territories where *Trichinella* is not endemic in domestic pigs, can be considered to have a negligible risk to humans, and therefore, testing and postslaughter mitigations are not necessary to protect consumer health.

Slaughter Testing

In virtually alldeveloped countries, animals slaughtered for human consumption are examined by a federal or state inspector to determine if the animal is healthy and suitable for use as human food. In many countries, the inspection process for slaughtered pigs includes testing each pig carcass for *Trichinella* infection by using one of several approved direct methods of inspection. Inspection methods for *Trichinella* infection have historically been performed by a trichinoscope examination, in which a piece of muscle is compressed between two glass slides and scanned under a microscope. This method is both tedious and ineffective, since it has a sensitivity of only about 5 larvae per g of tissue and nonencapsulated species of *Trichinella* are very difficult to visualize

(62); consequently, it is no longer recommended for routine use in testing pigs.

The development of a high-volume slaughter test, the pooled sample digestion method, takes advantage of the ability of *Trichinella* larvae to survive treatment with acidifi ed pepsin (as they do in the stomach of a host). Samples of tissue collected from sites of parasite predilection (diaphragm, cheek muscle, and tongue) are subjected to digestion in acidifi ed pepsin. Larvae, freed from their muscle cell capsules, are recovered by a series of sedimentation steps and then visualized and enumerated under a microscope. Requirements for performing the digestion test are found in the directives of the European Union (59), in the U.S. Code of Federal Regulations (63), and in the OIE *Manual of Diagnostic Tests and Vaccines for Terrestrial Animals* (64).

Using methods of inspection testing as practiced on pig carcasses, the sensitivity of the digestion method is approximately 3 larvae per g of tissue (65, 66). This level of detection is considered effective for identifying pork that poses a significant public health risk. Although there is insufficient information to determine the exact number of larvae that are necessary to cause clinical human disease (and these figures will be affected by the type of *Trichinella*, the amount of meat eaten, and the health of the individual), it is generally considered that infections of >1 larva per g of tissue are a public health risk. Thus, most infections that could cause clinical human disease would be detected by currently employed direct testing methods. Through the application of rigorous slaughter testing using artificial digestion methods, *Trichinella* infection has been virtually eliminated from domestic pigs in some countries.

Postslaughter Meat Processing

Many countries have requirements for ready-to-eat pork products that have not otherwise been demonstrated to be free from *Trichinella* infection; they must be processed by heating, freezing, or curing to kill any potential *Trichinella* larvae. Commercial

processing methods that have been proven experimentally to render pork free from infective *Trichinella* larvae are described in the U.S. Code of Federal Regulations (63). Pork meat must be heated to 58°C or frozen at one of several time-temperature combinations. With flash freezing, *Trichinella* larvae are killed instantaneously at −35°C. The effectiveness of curing depends on a combination of salt concentration, temperature, and time. Each method should be tested experimentally to determine effectiveness, as no model for curing conditions has been devised.

Consumer Education

The most effective measure to prevent trichinellosis in regions where the disease is endemic is education of the public. The responsibility lies with consumers to ensure that larvae are killed before the pork is eaten. The U.S. Department of Agriculture recommends that fresh pork be cooked to an internal temperature of 145°F (63°C) before consumption in the home (15). Rapid cooking methods, such as the use of microwave ovens, may not heat the pork uniformly or for sufficient time to destroy the larvae (67). Commercial cooking of pork products requires lower temperatures to ensure inactivation of *Trichinella*, presuming that temperature is more closely controlled by commercial meat processors. The U.S. Code of Federal Regulations (63) requires that pork be frozen for 20 days at 5°F (−15°C), 10 days at −10°F (−23°C), or 6 days at −20°F (−29°C) to kill the larvae, provided that the meat is less than about 6 in. (15 cm) thick. These freezing temperature and time requirements are not effective for killing the arctic isolate *T. nativa* or other freezing-resistant types of *Trichinella*.

TAENIASIS

Until the mid-1980s, it was believed that taeniasis was the result of ingesting tissue cysts of either *T. saginata* from cows or *T. solium* from pigs; however, Fan (68) identifi ed and characterized a third human taeniid with adult morphological characteristics like those of

T. saginata and larval characteristics more in line with those of *T. solium*. Pigs were putatively identifi ed as the intermediate host for this unique taeniid, which had a predilection for liver tissue in a multitude of experimental hosts. At that time, controversy arose over the classification and therefore the naming of this third human taeniid. However, sufficient morphological, biological, and genetic differences have been identifi ed to warrant use of the name *T. asiatica* (69–71). In addition, a DNA sequence-based study using formalin-fi xed samples dating back to 1929 clearly showed a partitioning of the taeniids into *T. saginata*, *T. solium*, and a distinct third species, *T. asiatica*, from the East (72, 73).

T. saginata Taeniasis

The history of taeniids has been described in the ancient literature dating back to 1500 BCE, with intriguing theories as to the parasites' origin and nature. However, it was not until 1782 that Goeze (74) identified a difference between the bovine and swine parasites, which was later confi rmed in 1857 by Küchenmeister based on the morphologies of the scolices (75). In 1861, Leuckart was the first to identify a relationship between the adult worm in humans and the larval bladder worm in cattle.

Life Cycle of *T. saginata*

The most prevalent intermediate host of *T. saginata* is cattle; however, buffaloes, camels, horses, and giraffes can harbor the intermediate stages. The life cycle of *T. saginata* begins with cattle ingesting *T. saginata* eggs during grazing. The eggs hatch in the duodenum, liberating a six-hooked embryo that penetrates mesenteric venules or the lymphatics and reaches skeletal muscles or the heart, where it develops into the cysticercus larva. The cysticercus is essentially a miniature scolex and neck invaginated into a fluid-fi lled bladder that measures about 10 by 6 mm. The bladder larva becomes infective within 8 to 10 weeks following ingestion and can remain infective for more than a year.

A person eating raw or poorly prepared beef harboring viable larval cysts (often referred to as cysticercus bovis) is subject to infection whereby the larvae are released from their surrounding muscle tissues by digestion in the small intestine. The scolex of the cysticercus evaginates from the vesicle or bladder and attaches to the mucosa of the jejunum, where the larva develops into a mature adult worm in 8 to 10 weeks. A mature adult worm is characterized by a scolex with four hemispherical suckers 0.7 to 0.8 mm in diameter situated at the four angles of the head. The entire strobila can grow to 17 m in length and possess 1,000 to 2,000 proglottids or segments immediately following the neck in a symmetric series of immature, mature, and gravid proglottids as they proceed posteriorly. The mature and gravid proglottids contain both male and female reproductive organs, resulting in self-fertilization when distal proglottids come together by folding of the worm's body. The presence of only a single worm per defi nitive host suggests that the mechanism of genetic variation results from other than crossbreeding among adult worms.

The scolex attaches to the mucosal surface of the upper jejunum by means of the four suckers, but because of its length, the entire worm might extend down to the terminal ileum. The developing proglottids extend down the small intestine, where the most distal gravid proglottids (20 mm long and 5 to 7 mm wide) detach singly from the rest of the strobila and independently migrate through the rectum to the outside. Each gravid proglottid contains about 80,000 eggs, which are expressed from the proglottids and deposited on the perianal skin. When gravid proglottids come to rest on the ground, eggs are extruded. The eggs may also be present because of indiscriminate, promiscuous defecation. Cattle ingest *T. saginata* eggs during grazing to complete the cycle.

Epidemiology

Taeniasis results when raw or inadequately cooked beef containing tissue cysts is consumed. Raw or rare beef is popular in many countries, particularly in the form of beef tartare (basterma) in the

Middle East; the equivalent of steak tartare (kitfo) in parts of Africa, especially Ethiopia; shish kebab in India; lahb in Thailand; and yuk hoe in Korea. Although wild cervids as well as other herbivorous animals have been reported to contain cysticerci of *T. saginata*, beef remains the primary source of *T. saginata* taeniasis in humans.

With respect to the incidence of taeniasis in humans, geographic areas can be classifi ed into three groups: countries or regions where infection is highly endemic (prevalence exceeding 10%); countries with moderate infection rates; and countries with a very low prevalence (0 to 0.1%) (76). The areas of high endemicity are Central and East African countries, such as Ethiopia, Kenya, and Zaire; Caucasian South Central Asian republics of the former Soviet Union; Middle Eastern countries, such as Syria and Lebanon; and parts of the six republics that constituted former Yugoslavia. However, recent reports suggest that the infection rates are on the decline in some regions (77). In Europe, the predominant taeniid is *T. saginata*. In a recent retrospective study encompassing the years 1990 to 2015 and five international databases, infections were found in 12 of 18 countries of Western Europe (78). In North America, the incidence is low. The last reported case in Canada was in 2013.

In 2008, a population-based survey was performed in the southwestern United States along the border with Mexico (79) among neighboring cities. Results indicated a combined prevalence of 3%; however, compared with the residents of Juárez, Mexico, residents of El Paso, TX, were 8.6-fold more likely to be tapeworm carriers. This difference between the United States and Mexico was attributed to widespread use of anthelmintics in Mexican border towns. In 2013, the U.S. Centers for Disease Control and Prevention (CDC) estimated that there were fewer than 1,000 new cases of taeniasis annually in the United States. It should be noted that the 2008 study and the estimates from the CDC do not distinguish between the pig and bovine tapeworms.

A recent issue, predicated upon genetic studies, is the within-species diversity in *T. saginata*. Findings by scientists in Southeast Asia

concluded that there are at least five different subgroups of *T. saginata*, most of which reside in that region of the world (80). Currently, no distinct information is available as to whether the genetic diversity can be linked to physiological parameters such as host range or virulence; however, studies of this nature provide groundwork for genetically identifying the source of new outbreaks, especially in countries where the prevalence is low.

Persistence and change in human *T. saginata* infections correlate with factors that govern infections in cattle. Infections in cattle are directly associated with environmental factors and animal access to pastures or cattle pens contaminated with human feces (81), sewage effluent used as fertilizer (82), or irrigation ditches and surface water (83). The U.S. Code of Federal Regulations (84) prohibits carcasses harboring as few as one dead larva from being approved for human consumption unless the carcass is first treated to remove the visible cyst(s). Eggs of *T. saginata* are capable of surviving for long periods in the environment and are resistant to moderate desiccation, disinfectants, and low temperatures (4 to 5°C). Longevities of 71 days in liquid manure, 33 days in river water, and 154 days on pasture have been reported (85). The eggs can also survive many sewage treatment processes and can remain viable in fluid effluent or dried sludge. Reviews (82, 86) summarize both biological and nonbiological treatments of sludge to reduce egg viability; however, a 2005 study in France (87) demonstrated that cows raised on pastures fertilized with liquid sludge did not acquire live cysticerci provided that a 6-week delay occurred between application and grazing.

The rate of reported cases of human taeniasis in many developed countries remains low. However, the true incidence is unknown because of underreporting. Among affluent Americans, infection has been attributed to international travel and to preferences for exotic diets while abroad. The penchant for raw beef and steak tartare is not limited to affluent Americans and Europeans but is also found, for example, among Ethiopians who eat beef. A combination of poor sanitation and culinary preferences for raw and

rare beef in many regions of high endemicity are key factors contributing to the risk of infection and transmission.

Pathogenesis and Pathology

The scolex of the adult worm generally is lodged in the upper part of the jejunum. Usually, only a single worm is present. Although multiple infections have been reported, these have come under scrutiny with the identification of *T. asiatica*. It has been suggested that these multiple infections with *T. saginata* were misdiagnosed infections of *T. asiatica*, which is capable of synchronically infecting human hosts (88). The adult tapeworm of *T. saginata* does not cause pathologic changes; however, mucosal biopsies have shown some inflammation, suggesting that the presence of the worm can trigger irritation that in turn results in bowel distention or spasm. Migration to unusual sites is rare, but complications such as appendicitis, invasion of pancreatic or bile ducts, intestinal obstruction, or perforation and vomiting of proglottids with aspiration have been reported. A recent retrospective examination of 34 case reports and 2 case series dating from 1957 through March 2016 showed that acute appendicitis and gastrointestinal perforations and migration to biliary tract can accompany infection. All these cases caused disease detected only by surgical intervention (89).

Clinical Manifestations

Although most cases of taeniasis are asymptomatic, up to one-third of patients complain of nausea or abdominal “hunger” pain that is often relieved by eating. Epigastric pain may be accompanied by weakness, weight loss, increased appetite, headache, constipation, dizziness, and diarrhea. The patient usually becomes aware of the infection when a proglottid is passed in the stool or is found on the perianal area or even on underclothing.

The adult worm is weakly immunogenic, as manifested by moderate eosinophilia and increased levels of IgE in serum. Allergic reactions,

such as urticaria and pruritus, may be due to the worm and its metabolites. The adult worms induce the production of antibodies. The persistence for years of a large, actively growing worm reflects lack of protective immunity to resident worms but is consistent with concomitant immunity observed in other helminth infections.

Diagnosis

Morphological diagnosis is based on the proglottid, since the eggs of *T. saginata* cannot be distinguished from those of other species of *Taenia* or those of *Multiceps* and *Echinococcus* species. The gravid proglottid of *T. saginata* has 15 to 20 lateral branches of the uterus on each side of the main uterine stem, a characteristic feature (Fig. 24.4); however, a similar range of uterine branches has been identifi ed in *T. asiatica* as well, suggesting that the geographic source of the infection may play a role in diagnosis if uterine branches are used in identification. If the scolex is present, the four characteristic hookless suckers can be used as a distinguishing character.

The egg is nearly spherical, measures 30 to 40 mm in diameter, has characteristic radial striations on its thick shell, and contains a hexacanth embryo with delicate lancet-shaped hooklets (Fig. 24.5). Rather than looking for the eggs in the stool, it is better to use the commercial Scotch tape method to obtain the eggs or proglottids from the perianal region. Since morphological identification of eggs is nonspecific, molecular techniques have been developed. Earlier methods were based upon DNA hybridization probes; however, PCR (90) and DNA sequencing (91) have advanced the ability to discriminate among various *Taenia* species. A recent review describes the advantages and disadvantages of conventional end-point PCR, real-time PCR, multiplex PCR, and loop-mediated isothermal amplification (92) in differentiating taeniid species.

Although an antibody response is induced by the adult worm, specific serological tests are not routinely used for diagnosing taeniasis; the disease is not lifethreatening, and detection of proglottids shed in human feces is the easiest and most defi nitive

test. In contrast, serology tests for bovine cysticercosis have been scrutinized through the years (93, 94), though problems have arisen from the disparate immune responses among the hosts (95) and the lack of correlation between the level of parasitism and the level of the immune response. Consequently, neither the efficacy nor the sensitivity of these methods has proven superior to that of physical inspection, including tests based upon recombinant proteins, peptides, or secreted antigens (ES), though recent results have been promising (96). One additional political hurdle impedes the commercialization of such a test: a viable antibody test for cysticercus bovis might result in the condemnation of a greater number of animal carcasses.

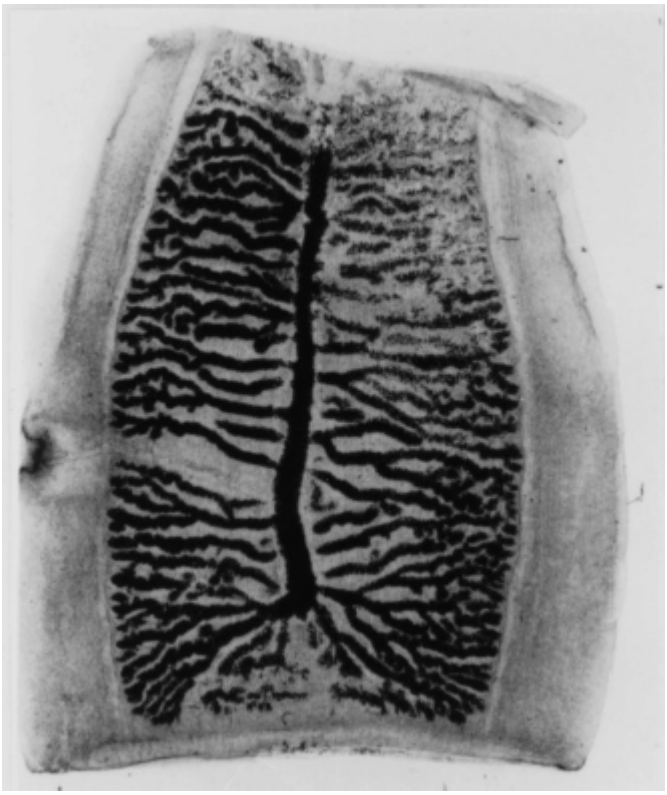

Figure 24.4 Taeniids are segmented flaworms consisting of proglottids. This micrograph depicts a gravid proglottid of *T. saginata* which possesses both male and female reproductive systems and at least 16 lateral uterine branches flled with eggs.

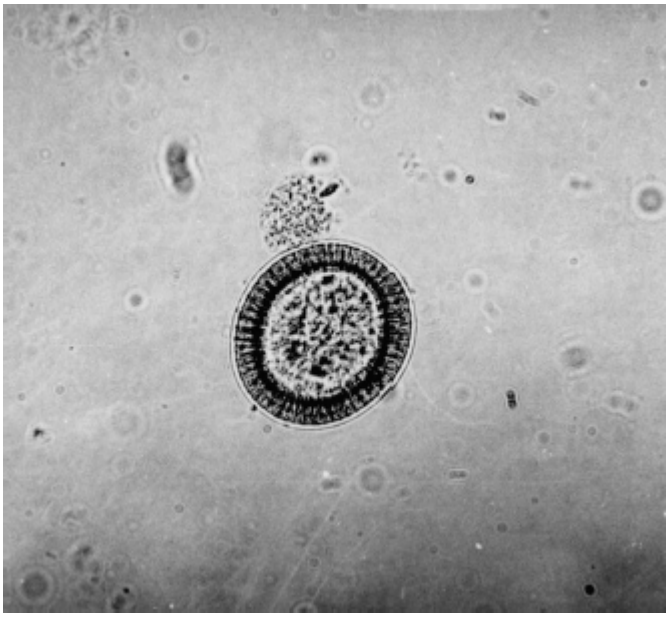

Figure 24.5 A gravid taeniid proglottid contains uterine branches filled with eggs (see Fig. 24.4). This micrograph shows a single *T. saginata* egg (magnifcation, ×590) extracted from the uterine branches.

Currently, meat inspection is used to detect cysticercosis in slaughtered cattle. Although practiced extensively, this method has limitations. Even routine examination of the heart and masseter muscles can miss a significant percentage of infected cattle. It is estimated that as few as 25% of infected cattle are detected by visual inspection (97). This is due to assumptions regarding predilection sites in host tissues, the inability to use the heart, diaphragm, cheek, and/or tongue as representative of wholebody infections, and the small number of tissue cysts generally found in areas of low prevalence.

In the United States, the percentage of carcasses inspected by state and municipal authorities varies. Cattle from small farms where sanitary conditions can be poor are frequently slaughtered in local abattoirs that tend not adhere to governmental inspection requirements. Clearly, allinfected carcasses should be condemned; however, approximately 70% of infected carcasses are trimmed of visible cysts and then passed unrestricted for human consumption.

This is prohibited by the U.S. Code of Federal Regulations (84), which also requires heavily infected carcasses to be condemned. Nonetheless, the combination of trimming the cysts with the less than 100% animal inspection requirement is consistent with the perceived low infection rates at the abattoir.

Treatment

The drug of choice for treating taeniasis is a single oral dose of 5 to 10 mg of praziquantel (Biltricide) per kg of body weight for adults or children. This treatment provides very high success rates (98). A good alternative is niclosamide (Niclocide and Yomesan) at 2 g orally once for adults and 50 mg/kg orally once for children. This taeniacide damages the worm such that a purge following therapy will often produce the scolex. Other drugs, such as albendazole and mebendazole, can also be used, but only under specialized circumstances. Reports of failure of treatment with allmajor drug classes (niclosamide, albendazole, and praziquantel) date back to 1970 and continue to surface today (99–101). It is unknown if these relate to unrecognized complications of the infection, rare naturally occurring isolates, misdiagnosis, or drug resistance. Given that the reports are sporadic and noncentralized and have not increased over the past 47 years, the failed treatments are unlikely the result of a resistant phenotype.

Prevention and Control

The best way to prevent taeniasis is to thoroughly cook meats before ingesting. In addition, one can limit cysticercosis in cattle by controlling sewage disposal so that tapeworm eggs are unavailable to the animals. Humans are the only defi nitive hosts of *T. saginata* and thus the only disseminators of eggs. Inasmuch as *T. saginata* adults can shed eggs at a rate of 480,000 to 720,000 daily, control depends on educating livestock producers and their employees about modes of transmission. Providing adequate toilet facilities in cattle feeding establishments can help to reduce the incidence of infection. Where toilet facilities are available, overloading of

systems should be avoided. In addition to education and monitoring, prevention should include sanitary protection of cattle feed as well.

The development of an effective cattle vaccine for use in areas of high endemicity would certainly reduce human infections. However, development of vaccines for bovine cysticercosis, natural or otherwise, has been slow. In addition to the difficulties in generating parasite vaccines, research in this area has not flourished because of the absence of human pathogenicity and the ease and economics of anthelmintic treatment. Going forward, it is anticipated that monetary and logistical issues will continue to deter development of vaccines as a prophylactic measure for bovine cysticercosis. If, however, developed countries see a benefit or if inspection criteria change to condemning allinfected carcasses, this mindset may change as well.

With regard to the consumer, public health education concerning the risks of eating raw or inadequately cooked beef is important. The cysticerci in meat are inactivated by freezing at –10°C for 10 days or –18°C for 5 days, heating to an internal temperature of 56°C, or salt curing under appropriate conditions. Major obstacles to this approach have been reluctance by consumers to modify preferred culinary habits and to break with long-established cultural traditions. Thus, attempts to eradicate *T. saginata* taeniasis have been unsuccessful.

T. solium Taeniasis

Taeniasis caused by *T. solium* was known at the time of Hippocrates. The Greeks described the larval stage in the tongue of swine as resembling a hailstone. In contrast to *T. saginata*, *T. solium* uses swine as an intermediate host, possesses an armed rostellum, has a smaller number of lateral uterine branches, and lacks a vaginal sphincter (102). Its phylogenetic classification as a unique species in 1758 is attributed to Linnaeus. It has been estimated that there are 50 million people worldwide with

neurocysticercosis, a plausible outcome of *T. solium*-derived taeniasis wherein an infected individual reacquires the infection from eggs rather than tissue cysts. In this case, human cysts form in the brain. One percent of these infected individuals die annually (103). For this reason, the World Health Organization lists neurocysticercosis as an important neglected tropical disease worldwide.

Life Cycle of *T. solium*

When pork containing a viable cyst of the larval stage of *T. solium* (often referred to as cysticercus cellulosae) is ingested, the head of the larva evaginates from the fluidfilled milky white bladder. The scolex bears four suckers and an apical crown of hooklets. The cysticerci are referred to as pork measles and are larger (5 to 20 mm in diameter) than cysticercus bovis. They attach to the wall of the small intestine and mature into adult worms in 5 to 12 weeks. The adult worm measures up to 8 m (usually 1.5 to 5 m) and has a scolex that is roughly quadrate, possessing a conspicuous rounded rostellum armed with a double row of large and small hooklets, numbering 22 to 32. A short cervical region is anterior to a series of proglottids or segments. Immature proglottids are broader than they are long, mature ones being nearly square, while gravid ones are longer than they are broad. The total number of distinct proglottids is less than 1,000. The terminal proglottids become separated from the rest of the strobila and migrate out of the anus or are passively expelled in the stool. A single gravid proglottid contains fewer than 50,000 eggs. Upon escape from the ruptured uterus of the gravid proglottid and after deposition on the soil, the eggs may remain viable for many weeks. The eggs of *T. solium* are more apt than those of *T. saginata* to appear in the stool.

In the normal cycle, the eggs are ingested by pigs, the usual intermediate host. The hexacanth embryo hatches in the duodenum, migrates through the intestinal wall to reach the blood and lymphatic channels, and is carried to the skeletal muscles and the myocardium. The embryo develops in 8 to 10 weeks into a

cysticercus. In the abnormal cycle, humans can serve as intermediate, but terminal, hosts and harbor cysticerci acquired by accidental ingestion of eggs or by the autochthonous cycle (an infection that results from the movement of eggs or gravid proglottids from the intestine back into the stomach by reverse peristalsis). The cysticercus develops most commonly in striated muscles and subcutaneous tissues but also in the brain, eye, heart, lung, and peritoneum.

Epidemiology

T. solium taeniasis has a worldwide distribution (104) and is important in allcountries where pork is consumed, especially those with suboptimal practices of sanitation and pig husbandry. Humans are the only known natural defi nitive host for this parasite. It is very difficult to evaluate the prevalence of human infection, because coproscopical methods cannot differentiate between infections caused by *T. saginata* and *T. solium*. Serological methods have been developed for this purpose but have not yet been tested in large field studies.

Infections resulting from *T. solium can* have much more serious consequences than those caused by *T. saginata*, because the eggs of *T. solium*, which normally infect pigs, can also infect humans. Thus, humans can acquire both taeniasis and cysticercosis from *T. solium* tissue cysts and eggs, respectively. Cysticercosis in humans is an important public health problem in developing countries where hygiene and sanitary conditions are deficient or nonexistent and in areas where swine-rearing practices are primitive (105). Infection of humans with larvae results from inadvertent ingestion of eggs in contaminated water or foods, e.g., vegetables fertilized with night soil (human excrement), from indirect contact with hands of individuals already infected with the adult worm (external autoinfection), or from direct contact with a tapeworm carrier. Also, internal autoinfection can occur in which the eggs from proglottids are carried by reverse peristalsis back to the duodenum or stomach,

are stimulated to hatch, and then invade extraintestinal tissues to become cysticerci. This is a key cause of neurocysticercosis.

The prevalence of human neurocysticercosis is increasing in some parts of the world, and a considerable body of literature is devoted to the diagnosis, treatment, and prevention of this disease (106–108). The relevance of neurocysticercosis as a public health problem in the United States has been highlighted by reports of autochthonous cases (109). Furthermore, with the increase in illegal immigration and the number of migrant workers from Central America, cysticercosis has garnered attention as a neglected infection in the United States that is linked to poverty (110). Infections are quite common in Mexico, Central and South America, central and southern Africa, Asia, non-Islamic Southeast Asia, Slavic countries, and Southern and Eastern Europe. A recent endemicity map with corresponding levels of intensity is available through the World Health Organization (111). Although the disease is present in Mexico, current evidence suggests that the incidence and severity of infection did not increase between 1994 and 2009 (112), offering encouragement for advancing efforts to control this disease. It should be noted that most of these studies, as well as other similar studies, used indirect serology-based assays, which are prone to false-positive and false-negative results. In general, specific habits of eating raw or undercooked pork are linked to foci of taeniasis; however, in some regions there is no link between porcine and human cysticercosis, where those who do not eat pork have as great a chance of contracting the disease as those who do (113). An interesting development is that reports worldwide are showing an association between the presence of neurocysticercosis and the incidence of epilepsy, suggesting that many infected patients are being misdiagnosed as epileptics (114, 115).

Pathogenesis and Pathology

As in *T. saginata* infection, there is usually only a single adult worm, and pathologic changes are similar. There is mild local inflammation of the intestinal mucosa resulting from attachment

by the suckers and especially the hooklets. However, because of its smaller size, *T. solium* is less likely to cause intestinal obstruction. Rare instances of intestinal perforation with secondary peritonitis and gallbladder infection have been reported.

Pathologic changes due to cysticerci can be serious, depending on the tissue invaded and the number of cysticerci that become established. Damage results from pressure caused by encapsulated larvae on surrounding tissue, since the cysticerci produce occupying lesions. There may be no prodromal symptoms or only slight muscular pain and a mild fever during invasion of the muscles and subcutaneous tissues. In ocular cysticercosis, which accounts for about 20% of neurocysticercosis cases, there may be loss of vision. Invasion of the meninges, cortex, cerebral substance, and ventricles evokes tissue reactions, leading to focal epileptic attacks or other motor or sensory involvement. The reasons for the predilection of cysticerci for the central nervous system remain unknown.

Clinical Manifestations

Since only a single adult worm is present in *T. solium* taeniasis, there are no symptoms of epigastric fullness. Patients are generally asymptomatic and become aware of the infection only when they find proglottids in their stools or on perianal skin. However, there may be vague abdominal discomfort, hunger pains, anorexia, and nervous disorders. Rare instances of intestinal perforation with secondary peritonitis and gallbladder infection have been reported. Retrospective studies conducted in 2017 linked surgical endoscopic abdominal intervention to taeniasis (71). Eosinophilia, as high as 28%, and leukopenia can occur. The persistence for years of actively growing tapeworms is not consistent with the development of protective immunity. Seizures that often accompany neurocysticercosis are to a high degree misdiagnosed as epilepsy, primarily because of the inability to adequately diagnose the infection.

Diagnosis

Diagnosis of taeniasis is based on examination of stool specimens and perianal scrapings; sensitivity is increased by increasing examinations to three times daily. Since *T. solium* eggs cannot be distinguished from those of *T. saginata*, specific diagnosis is based on the identification of the gravid proglottid, which has fewer lateral branches (7 to 12) on each side of the main uterine stem (Fig. 24.6). If the scolex is obtained, it can be identifi ed by its hooklets and four suckers. Other tests involving PCR, multiplex PCR (116), loop-mediated isothermal amplification (117), and serology testing have also been developed (118).

Diagnosis of neurocysticercosis is more problematic. Clinical presentation is unpredictable but often accompanied by neurologic symptoms, intracranial hypertension, mental changes, or sudden unexplained death among individuals at highest risk for disease (for a review, see reference 119). Histologic studies are always the most definitive; however, whole-body imaging (120), neuroimaging (121, 122), and other lab results can assist in final diagnosis and treatment (118). A set of diagnostic criteria have been developed (123) that remain applicable today. Clearly, image scanning is the most sensitive; however, a study using cerebrospinal fluid to compare antibody and PCR-based diagnostic tests showed that PCR was the most sensitive of the tests (95.9%), but with variable specifi city (80 or 100%), and that most antibody-based tests had similar sensitivities (124).

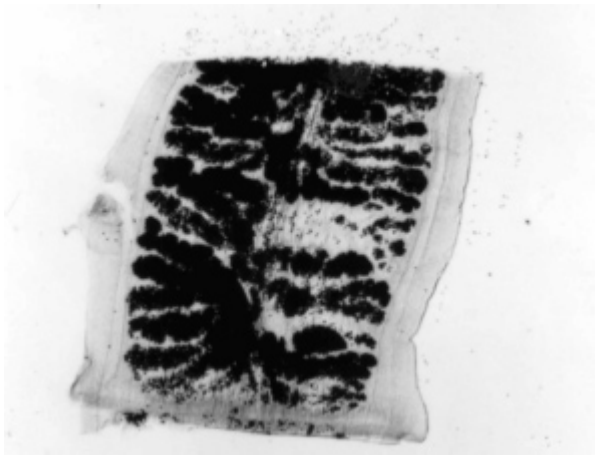

Figure 24.6 Gravid proglottid of *T. solium*. Note that there are fewer lateral uterine branches than in *T. saginata* (Fig. 24.4).

The sensitivity of serological tests for taeniasis and cysticercosis varies by the method and the clinical form of infection. Efforts have been made to improve the sensitivity of serology-based modern methods (118), although emphasis on the use of serology has shifted primarily to the diagnosis of cysticercosis rather than taeniasis. As with *T. saginata*, obtaining sufficient parasite antigen poses logistical problems in the absence of a validated recombinant product.

Treatment

Surprisingly, asymptomatic neurocysticercosis is left untreated. In contrast, treatment for symptomatic neurocysticercosis is contentious. Anthelmintic recommendations include praziquantel and albendazole. Unfortunately, the cysticidal efficacies of both drugs alone are not optimal. Further, studies showed that praziquantel can cause severe adverse conditions if given in large dosages or if given as the first course of treatment. This prompted a switch by clinicians to albendazole as the first-line treatment. In 2014, Garcia et al. (125) conducted a double-blind, placebo-controlled, phase 3 trial comparing combination therapy involving praziquantel and albendazole to albendazole alone. The study had three groups receiving treatment over a 10-day period: combination therapy (albendazole at 15 mg/kg per day plus praziquantel at 50

mg/kg per day), standard albendazole (15 mg/kg per day), or high-dose albendazole (22.5 mg/kg per day). The results clearly showed that combination therapy had increased parasiticidal effects, leading to better seizure control and long-term prognosis without increasing the side effects. However, drug treatment is not a panacea for allinfections. Distal lesions such as ocular, ventricular, and spinal cysts are best treated surgically, because anthelmintics can provoke tissue damage from irreversible, drug-induced inflammation. It is recommended, therefore, that alltreatments be accompanied by high-dose glucocorticosteroids and anticonvulsants to reduce the host inflammatory response as the cysts are destroyed, and thereby lower the risk of seizures.

With respect to taeniasis, even though the infections result in minimal side effects, it is imperative to treat patients harboring the adult worm, since cysticercosis can occur from internal autoinfection. The major concerns in treating patients with *T. solium* taeniasis are to prevent vomiting and to ensure rapid expulsion of disintegrated proglottids from the intestine. Niclosamide was once the drug of choice because of its effectiveness against the scolex, in which it causes necrosis of the head and adjoining segments by blocking sugar uptake. This in turn causes the tapeworm to lose its hold, after which it is eliminated in pieces during defecation. Praziquantel, however, is more effective, with fewer side effects, in purging the adult worm. After treatment with praziquantel, the tapeworm loses its ability to resist digestion in the gastrointestinal tract. Thus, only digested pieces are passed in the feces. Trials using a new drug, tribendimidine, that is effective against soil-transmitted parasites have shown promise in treating rodent cestode infections (126). One open-label study (127) also showed effective treatment against *Taenia* spp., but studies have not advanced beyond experimental treatments for this indication.

Prevention and Control

Prevention and eradication of *T. solium* adults in the intestine and of cysticerci in various tissues in humans and in pigs are a concern

in areas of endemicity where economic, social, and sanitary conditions are substandard. Without fundamental changes, the most scrupulous personal hygiene and eating habits will not prevent or eradicate infection in underdeveloped or developing countries. In developed countries, infection can be avoided simply by adherence to modern animal husbandry practices. The best preventive measure for interrupting transmission from humans to animals is to introduce and maintain proper sanitary facilities to dispose of contaminated human feces. Even with proper toilet facilities, measures must be taken to make sure that sewage treatment is adequate to kill the eggs.

Since one infected individual can infect thousands of pigs by contaminating feedlots, allpersonnel with access to the pastures must be educated regarding the parasite and the means of avoiding transmission. Prospective employees who will come into contact with animals should be examined for tapeworm infection before employment and periodically during employment; chemical toilets should be installed and properly maintained at convenient locations, and whenever possible, pigs should be kept in enclosures or indoors to prevent access to human fecal matter.

Meat inspection programs are only partially effective for identifying and condemning infected carcasses. Inspection for measly pork is performed in the United States for animals intended for interstate commerce, but as with *T. saginata*, organoleptic inspection can miss lightly infected carcasses. Thus, the consumer should make sure that meat is cooked to an internal temperature of 56°C or is frozen at −10°C for 14 days to kill cysticerci (128). Other means of inactivating cysticerci in pork, such as irradiation, have not been commercially applied. The best preventive measure is to avoid eating raw or uninspected pork.

Assuming that eliminating swine cysticercosis will greatly assist in eradicating human taeniasis and neurocysticercosis, efforts to immunize pigs with recombinant antigens have met with remarkable success in both laboratory studies and field trials (129,

130). Unfortunately, vaccination as a means of prevention and control is subject to problems other than a lack of efficacy. Economic and regulatory issues as well as dissemination and vaccine stability also come into play. Thus, a swine vaccine has yet to be made commercially available.

Other approaches are being entertained to control the disease. On a local scale, success has been achieved through a mass drug administration program within a community in Tanzania (131). Also, an 8-year, community-based public health intervention program in Honduras (132) reduced disease long term through deworming, education, the construction of health clinics and systems for water and sewage control, surveillance, animal husbandry training, and local advertising.

T. asiatica Taeniasis

T. asiatica was first detected in the aboriginal population in the mountainous regions of Taiwan (68). Initially, the etiologic agent was thought to be *T. saginata* because of morphological similarities among the adult worms; however, notable differences, including shorter length, fewer proglottids, wider diameter of the scolex, and fewer testes in the mature proglottid of the agent, were observed (68). Molecular studies also showed that that *T. asiatica* was genetically distinct from *T. saginata* (133) and provided the ability to differentiate *T. asiatica* from other human cestodes (72, 134). Even though swine are the intermediate host for *T. asiatica*, the close relationship between *T. asiatica* and *T. saginata* in the absence of neurocysticercosis among populations exhibiting the highest prevalence of infection is consistent with *T. asiatica* not being a cause of human cysticercosis (135). Research suggests that *T. asiatica* and *T. saginata* are capable of hybridization (136); however, given that these studies involved single-gene analyses, normal genetic variation among geographic isolates could have become obscured. The application of comparative genomics will hopefully better address this issue in the future.

Epidemiology

T. asiatica infection has been found in several Asian countries, notably the mountainous regions of Taiwan, Cheju Island of Korea, and Samosir Island of Indonesia. It is estimated that public health costs in these areas alone exceed $35 million annually (137). In Taiwan, a study of 1,661 cases of Asian taeniasis among nine aboriginal tribes in 10 mountainous counties found an overall clinical infection rate of 76% (138). Multiple studies since that time have suggested that the infection rate is quite variable among the aboriginal populations of Taiwan; nonetheless, the rate remains comparatively high. Pigs, cattle, goats, wild boars, and monkeys can serve as intermediate hosts, and this has been validated in experimentally infected animals (139). Of these, the wild boar appears to be the probable natural intermediate host in Taiwan. This may be true also in Indonesia, where people have become infected, presumably from consuming pork (140).

The cysticercus of *T. asiatica* is armed with tiny rostellar hooklets like that of *T. solium* and develops in a period shorter than that required for either *T. saginata* or *T. solium*. Interestingly, it is found mainly in the parenchyma of the liver (68), whereas the predilection sites for cysticerci of *T. saginata* and *T. solium* are the muscles of cattle and pigs, respectively. Thus, the custom of eating the viscera, especially the liver, of freshly killed animals appears to be a major contributing factor to transmission.

Most recently, reports (141–143) on taeniasis and cysticercosis in Middle East countries revealed some interesting and previously unreported information on *T. asiatica*. First and foremost, the reports tremendously expanded the western limits of areas of endemicity of this pathogen far beyond its previously known boundaries, i.e., Southeast Asia. Indeed, an epidemiological study conducted in northern India indicated that nearly allcases were caused by *T. asiatica* and not *T. saginata* (144). Similar findings were obtained in a communitybased survey in Nepal (142). Equally important, for the first time, *T. asiatica* was found outside its

normal predilection site (liver) and in swine muscle tissue (144). Prior to this study, it was believed that muscle cysts in swine cysticercosis were characteristic of *T. solium* only. Thus, in the absence of additional data and given the expanded range of dissemination of *T. asiatica*, the presence of tissue cysts in swine can no longer be considered a diagnostic character delineating these pathogens. This heightens the risk of humans becoming infected with *T. asiatica* from undercooked swine meats.

Clinical Manifestations

Infected individuals pass proglottids in their feces, even for 30 years or more, suggesting that the life span of this form of *Taenia* is very long (138). Common clinical manifestations include pruritus ani, nausea, abdominal pain, and dizziness. Abdominal pain is usually localized along the midline of the epigastrium or in the umbilical region and varies in intensity from a dull, aching, gnawing, or burning feeling to an intense, colic-like, sharp pain. Infection is often accompanied by a change in appetite (positive or negative), headache, diarrhea, and/or constipation. In contrast to *T. solium* and *T. saginata* taeniasis, humans can simultaneously harbor multitudes of adult *T. asiatica* worms (88).

Treatment

Clinical trials performed some time ago in Taiwan showed that a single dose (150 mg) of praziquantel was highly effective against *T. asiatica* infection (145, 146). This treatment regimen remains current today. As with *T. saginata*, niclosamide is also effective.

Prevention and Control

The best preventive measure is to avoid eating raw, uninspected pork or other meat that contains the cysticerci. Since most cases of *T. asiatica* taeniasis result from the consumption of infected pork, the meat should be cooked thoroughly or should be frozen for at least 4 days at −10°C to kill the cysticerci, the same procedures used

to prevent *T. solium* taeniasis. Although new findings have identifi ed meat tissue as a predilection site for *T. asiatica* (144), the primary source of human infection is uncooked viscera.

Protozoan Parasites

Protozoan parasites have long been associated with foodborne and waterborne outbreaks of disease in humans. Inactivation of these organisms is difficult because of their resistance to environmental stresses. Groups of protozoan parasites transmitted via foods include apicomplexans, flagellates, ciliates, and amoebae (Table 25.1).

A major characteristic of apicomplexan parasites is that a vertebrate host is required to complete the complex life cycle and produce infectious cysts. Of this group, *Cryptosporidium* species, *Cyclospora cayetanensis*, *Sarcocystis hominis*, and *Cystoisospora belli* frequently inhabit the intestinal mucosa and produce diarrheal illnesses in humans. These coccidian parasites affect immunocompetent as well as immunocompromised individuals, causing more severe and prolonged symptoms in the latter. Many species of *Cryptosporidium* can infect humans and a variety of animals, and some genotypes have been described as having host preferences or specificities. *Cryptosporidium hominis* and *Cryptosporidium parvum* are the two most prevalent species infecting humans. *C. cayetanensis* has been isolated exclusively from humans and has caused large foodborne outbreaks in the United States in the past 4 years. Another apicomplexan, *Toxoplasma gondii*, infects human tissues other than the intestinal mucosa and can cause birth defects, blindness, and chorioretinitis. *Sarcocystis* species in humans can also infect muscles and other organs. The life cycle stages of apicomplexan parasites are produced intracellularly in the host. For *Cyclospora*, *Toxoplasma*, and *Cystoisospora*, sporogony typically occurs outside the host, requiring the passage of time before oocysts are infective to a new

host, while *Cryptosporidium* oocysts are excreted already sporulated and are infectious when shed.

Microsporidia, once considered protozoan parasites, have been reclassified as fungi based on recent phylogenetic analyses. Microsporidia have been implicated in human foodborne and waterborne diseases and propagate and complete their life cycle intracellularly. Of the microsporidia, members of the following four genera have been most frequently implicated in human diseases: *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, and *Vittaforma*. None of these species is host, tissue, or organ specific, with the exception of *Enterocytozoon bieneusi*, which is known to infect only the human intestinal tract.

Flagellates, ciliates, and amoebae can propagate in more than one host. All three types of parasites can cause disease in humans and animals. The infectious stage of this group is the cyst. Once ingested by the susceptible host, the trophozoites, or motile forms, are released from the cyst and colonize the host's intestinal cells. In contrast with members of the *Apicomplexa*, microsporidia, and trypanosomes, flagellates, ciliates, and amoebae do not present intracellular stages but instead attach with specialized structures to the luminal surface of the intestinal cells and feed off the nutrients and cellular debris of the intestinal epithelium. *Giardia lamblia* (also called *Giardia intestinalis* or *Giardia duodenalis*), a flagellate previously considered a commensal organism, is now well recognized as an etiological agent of acute or chronic diarrhea in humans. *Balantidium coli*, a ciliate, also causes diarrhea in humans and, if the infection is not treated, can cause ulcerative colitis. Various species of amoebae can infect humans. Most of them are commensal, not producing disease; however, others can cause diarrhea, dysentery, or amebomas if the infection is not treated.

Table 25.1 Protozoa of medical importance acquired from food and water

Phylum or group	Protozoan	Infective stage
Apicomplexa	*Cryptosporidium parvum*	Oocyst
	Cyclospora cayetanensis	Oocyst
	Cystoisospora belli	Oocyst
	Toxoplasma gondii	Oocyst/tissue cyst
	Sarcocystis hominis	Oocyst
	Sarcocystis suihominis	Oocyst
	Sarcocystis spp.	Sarcocyst
Ciliophora	*Balantidium coli*	Cyst
Microspora[a]	*Enterocytozoon bieneusi*	Spore
	Encephalitozoon intestinalis	Spore
Sarcomastigophora	*Acanthamoeba* spp.[b]	Trophozoite
	Dientamoeba fragilis	Trophozoite
	Entamoeba dispar[c]	Cyst
	Entamoeba histolytica	Cyst
	Giardia intestinalis	Cyst

	Naegleria fowleri[b]	Trophozoite
	Euglenozoa Trypanosoma cruzi	Metacyclictrypomastigote/

[a] Microsporidia were originally considered parasites but have been reclassified as fungi.

[b] Species of normally free-living amoebae that invade through the mucosa and can in some instances infect the central nervous system of humans. Amoebic meningitis is usually fatal.

[c] Commensal, morphologically similar to *E. histolytica*, and not normally capable of inducing disease.

Trypanosoma cruzi is a vector-borne flagellate parasite that has been responsible for various outbreaks of foodborne illness. If the infection is not treated effectively during the acute phase, infection is usually lifelong, as there is no treatment for the chronic stage of the infection. The outcome is heart disease and may be complicated with “mega-” syndromes, particularly megaesophagus and megacolon (1). In Venezuela, an outbreak of American trypanosomiasis affected 103 individuals in a college community and was associated with consumption of guava juice. Of those, 75% were symptomatic, 44% had documented parasitemia, and one child died (2). In Brazil, 178 cases of acute Chagas’ disease were associated with consumption of açai paste and drinking açai juice. Among exposures tested, drinking açai juice at the local health facility was significantly associated with illness (3). The emergence of Chagas’ disease in the United States is possible, as opossums (sylvatic reservoir) and insect vectors infected with *T. cruzi* have been identified in the southern part of the country (4). Foodborne transmission of this parasite has been reported as the result of ingestion of foods contaminated with reduviid bugs or their feces that were inadvertently present in the fruits. Foodborne transmission is a significant route of infection in the Brazilian Amazon (estimated to be responsible for 50% of all cases between 1968 and 2000). In 2005, 25 cases of acute Chagas’ infection were reported in 2005 and were associated with consumption of sugar cane. There have also been reports of cases associated with

consumption of improperly cooked meats or blood of mammalian sylvatic hosts that served as reservoirs of the parasite. Studies designed to develop a vaccine to control Chagas' infection have also revealed that in mice, the parasite can cause illness via the oral, esophageal, gastric, or intestinal mucosa (5).

CRYPTOSPORIDIUM

Cryptosporidium was first isolated in 1910 from the intestines of mice. Various species of *Cryptosporidium* capable of infecting animals have since been described. It was not until 1976 that *C. parvum* infection in humans was first described. Since 1982, *C. parvum* has been one of the most frequently identified opportunistic pathogens associated with diarrhea and wasting syndrome in patients with AIDS. Cryptosporidiosis in immunocompromised patients produces a life-threatening, prolonged, cholera-like illness (6). In immunocompetent patients, *C. parvum* causes self-resolving, acute diarrheal disease with variability in the severity of symptoms. Isolate variations and associations with the severity of disease have been subjects of intensive investigation for some time. All *Cryptosporidium* infections were initially thought to be caused by *C. parvum*, even though there was some evidence that more than one *Cryptosporidium* species might be implicated. As molecular tools were developed, species-level identification of *Cryptosporidium* isolates allowed the description of *C. hominis*, previously recognized as *C. parvum* genotype I, which is isolated exclusively from humans. Genotype II, which belongs to the *C. parvum* group, was also described. This genotype is isolated from cattle and humans and is readily infective to laboratory animals. Subsequently, other *Cryptosporidium* species, originally called *C. parvum*, were described.

PCR targeting the small-subunit rRNA gene is usually employed to genotype *Cryptosporidium* isolated from humans, animals, and water samples. Genotype differentiation based on the sequencing of

the thrombospondin-related adhesive protein (TRAP-C2) has also been used (7, 8). Currently, the gp60 gene is being used to subtype *Cryptosporidium*. Six subtypes have been described for *C. hominis* and 11 subtypes for *C. parvum*. The denomination of each subtype includes the group type (I or II) and the type and number of the TCA, TCG, or TCT repeats. In some cases, other repeats (of 6 bp or 13 to 15 bp) located after the trinucleotide repeats are also included in the *C. parvum* or *C. hominis* subtype name, respectively. Human infections with *Cryptosporidium* are most frequently caused by five *Cryptosporidium* species (*C. hominis*, *C. parvum*, *C. felis*, *C. canis*, and *C. meleagridis*) and occur most frequently in HIV-positive individuals (9–15). Other species occasionally identified in humans include *C. muris*, *C. andersoni*, *C. suis*, and *Cryptosporidium* cervine, horse, rabbit, skunk, and chipmunk I genotypes (16).

Cryptosporidiosis is acquired after ingestion of food or water contaminated with infective *Cryptosporidium* oocysts. Once ingested, the oocysts excyst (Fig. 25.1). The released sporozoites proceed to invade the enterocytes. A parasitophorous vacuole is formed as the parasite enters the cell. This structure contains the intracellular parasites and communicates with the host cell via a feeder organelle. The parasite goes through two asexual multiplication stages called merogony: type I meronts contain eight merozoites, which are released and proceed to invade other enterocytes to form type II meronts, each containing four merozoites. Once merozoites from type II meronts are released, they infect enterocytes but differentiate into sexual stages identified as macrogametocytes (female) and microgametocytes (male). The union of a microgametocyte and a macrogametocyte produces a zygote (immature oocyst), which matures within its host into a fully sporulated oocyst (Fig. 25.2). Two types of oocysts are produced and excreted. Thin-walled oocysts excyst endogenously, resulting in autoinfection. Thick-walled oocysts, which are environmentally resistant, are shed in the feces and are immediately infectious to other hosts (17, 18). An additional life stage that may represent an extracellular trophozoite/gamont stage has been described for *C.*

andersoni, a parasite that infects the gut of cattle. This stage has also been reported for *C. parvum*. This finding is still under debate, as other groups have not been able to reproduce it. Phylogenetic analysis indicates that *Cryptosporidium* has a closer phylogenetic affinity with the gregarines than with the coccidian (19–21).

To date, 20 species of *Cryptosporidium* have been identified in humans, including *C. hominis*, *C. parvum* (cattle, sheep, and goats), *C. meleagridis* (of turkeys), *C. felis* (of cats), *C. canis* (of dogs), *C. ubiquitum*, *C. cuniculus*, *C. viatorum*, *C. muris*, *C. suis*, *C. andersoni*, *C. tyzzeri*, *C. fayeri*, *C. bovis*, *C. scrofarum*, *C. erinacei*, and others (22, 23). *Cryptosporidium* infects the brush border of the intestinal epithelium and causes villous atrophy, though the exact mechanism for this pathological alteration is not yet fully understood. Immunocompetent patients develop a profuse watery diarrhea accompanied by epigastric cramping, nausea, and anorexia, which is usually self-limiting and lasts for about 15 days.

Extraintestinal dissemination has been observed in immunocompromised patients. *Cryptosporidium* may be found in epithelial cells from other organs, such as those of the respiratory tract and the biliary tree (24). Immunocompromised patients (e.g., AIDS patients or those receiving immunosuppressive drugs) develop severe diarrhea (3 to 6 liters/day), which persists for several weeks to months or even years. These cases are the most severe and life threatening, with continuous shedding of oocysts. In patients with HIV infections, the $CD4^+$ cell count is the best marker for the ability of the immune system to self-resolve the infection. In the developed world, patients with $CD4^+$ counts of 180 cells/mm^3 or higher usually develop self-limiting cryptosporidiosis, whereas those with counts below 180 cells/mm^3 usually develop chronic and profuse diarrhea, which is exacerbated by the lack of effective therapy (25). The pathogenesis of the diarrhea is not clear, and the presence of a toxin has been suggested but not yet confirmed.

The mean prevalence of *C. parvum* infection in Europe and the United States is 1 to 3%, and the prevalence is considerably higher

in developing countries. Outbreaks of disease associated with *Cryptosporidium* have been reported in the United States as well as in other countries (18). *Cryptosporidium* infection is closely associated with travel abroad, exposure to farm animals, and person-to-person transmission in settings such as day care centers and medical institutions. A large number of waterborne outbreaks of cryptosporidiosis have been documented, and some of the most notable were those in Milwaukee, Wisconsin (26), and in Georgia (27), with a total of more than 400,000 cases reported. In Minnesota in 1995, *Cryptosporidium* was associated with cases of acute gastroenteritis experienced by attendees of a social event. This outbreak was epidemiologically associated with the consumption of contaminated chicken salad (28). In 1993 in central Maine and in 1996 in New York, apple cider was associated with outbreaks of cryptosporidiosis (29, 30). In 1998 in Spokane, Washington, another foodborne outbreak affected about 50 people, but it could not be traced to a specific type of food. In 2000, an infected food handler was responsible for a foodborne outbreak at a cafeteria of a university in Washington (31). *Cryptosporidium* has been identified in produce intended for human consumption. In 2008, a foodborne outbreak of cryptosporidiosis affecting 72 individuals in Helsinki, Finland, was associated with a salad mixture (32).

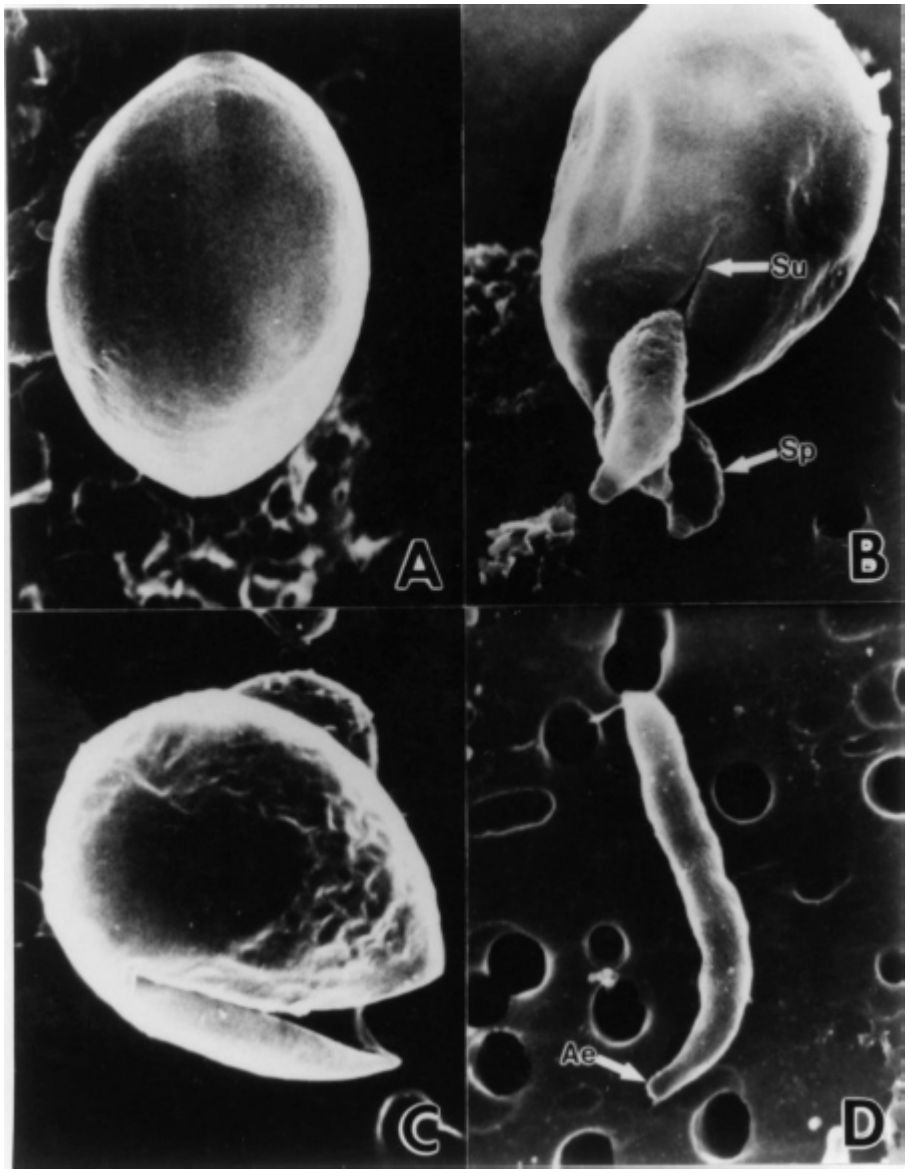

Figure 25.1 Scanning electron micrographs of oocysts and excysting sporozoites of *C. parvum*. (A) Intact oocyst prior to excystation (magnification, ×11,200). (B) Three sporozoites (Sp) excysting from oocyst simultaneously via the cleaved suture (Su) (magnification, ×11,200). (C) Empty oocyst (magnification, ×11,200). (D) Excysted sporozoite (magnification, ×9,800). Ae, apical end. Reprinted from reference 224.

In Denmark in 2005, an outbreak of diarrhea in 99 individuals occurred, of whom 13 were positive for *C. hominis* infection. The infection was associated with eating food from the canteen salad

bar. Peeled whole and grated carrots and red peppers were the likely source of the outbreak (33).

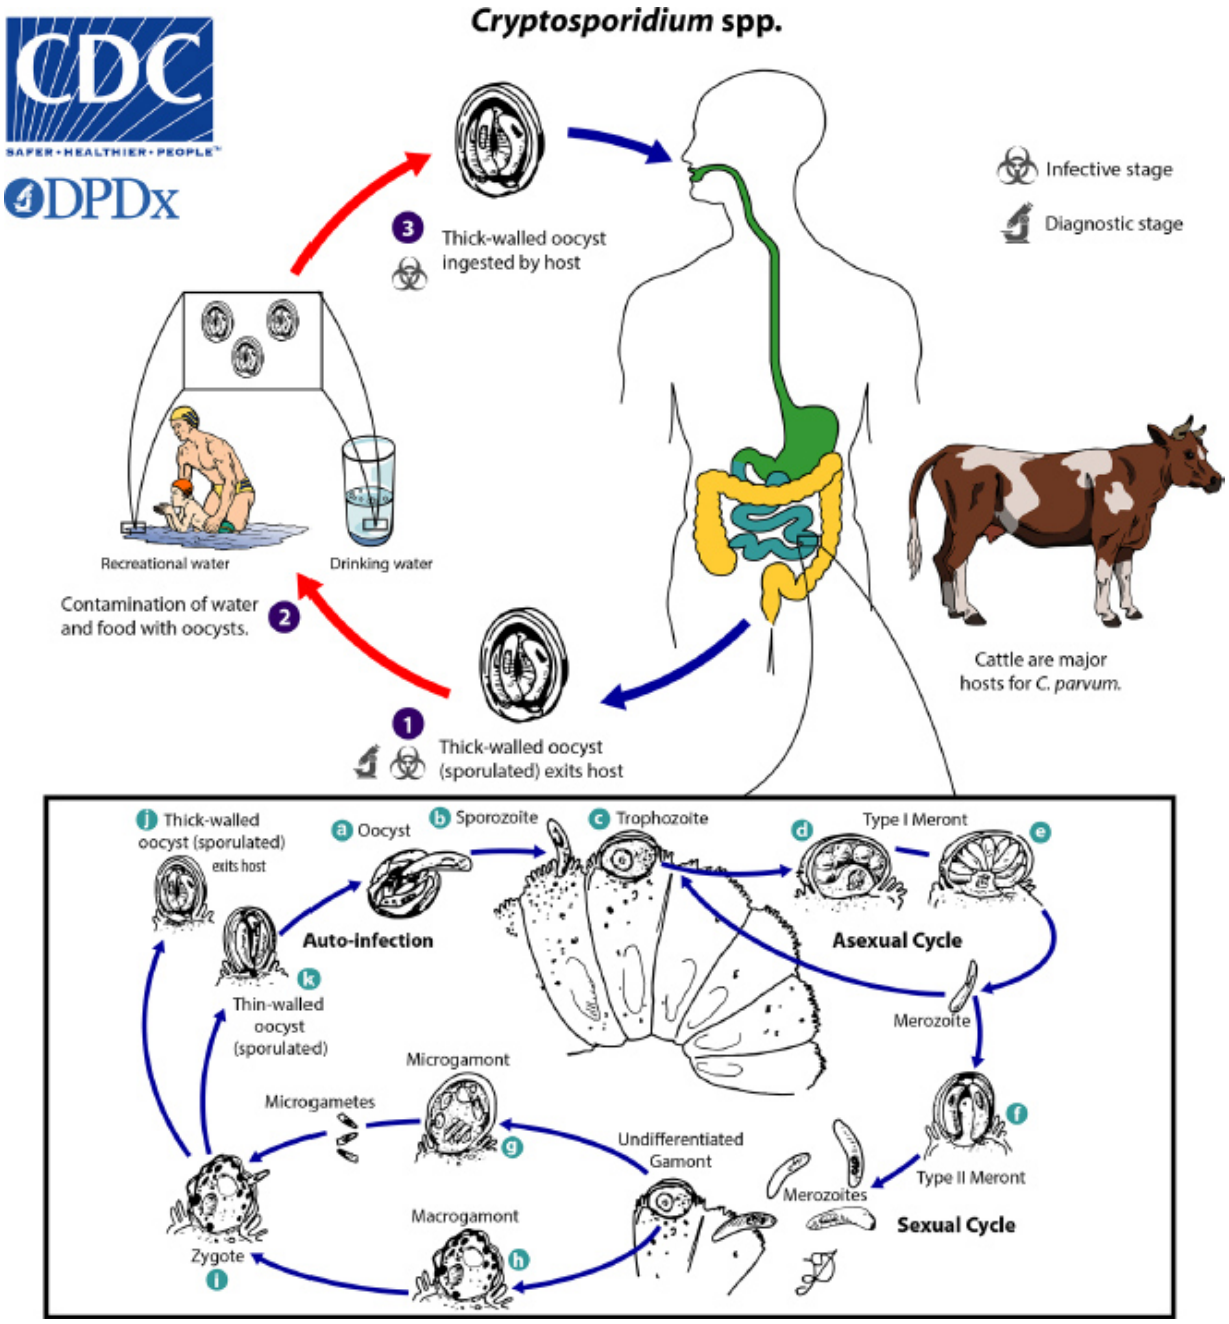

Figure 25.2 Life cycle of *Cryptosporidium*. From reference 225.

In Norway, 26% of lettuce samples and 74% of mung bean sprout samples assayed were *Cryptosporidium* positive. *Giardia* was identified in dill (20%), lettuce (20%), mung bean sprout (30%), radish (10%), and strawberry (20%) samples (15). The risk of

acquiring cryptosporidiosis and giardiasis based on frequency and level of mung bean sprout consumption was assessed to be 20 cases per 100,000 (34, 35). Analysis of produce obtained from a regional market in Peru revealed that 14.5% of samples contained *Cryptosporidium* oocysts (36). The immunofluorescence assay specific to *Cryptosporidium* was used for this study and is considered the gold standard assay. An alternative method for identifying *Cryptosporidium* from fresh produce uses polyclonal sera raised to a recombinant viral capsid protein of an RNA virus that is a symbiont of *Cryptosporidium* (37).

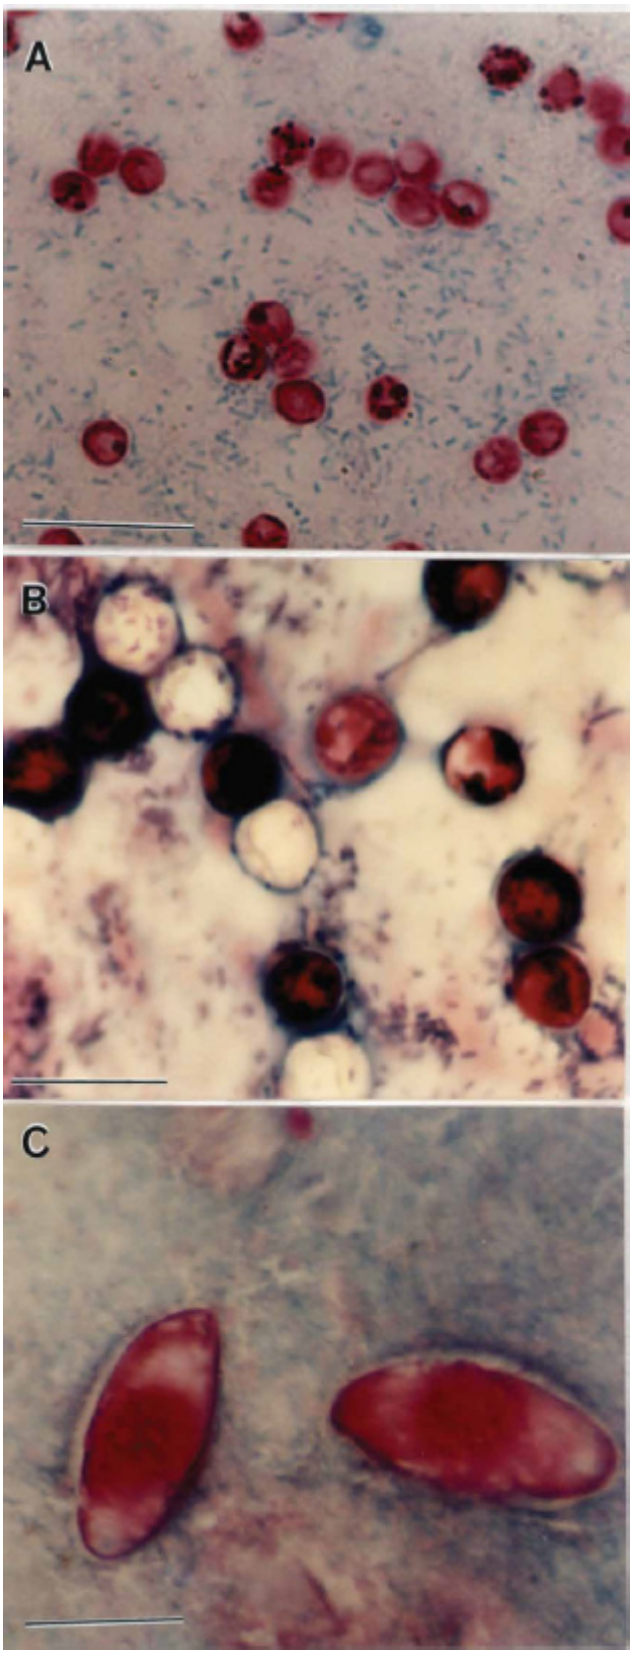
In a recent report, it was estimated that 8% of cases of cryptosporidiosis are foodborne, with 57,616 episodes of domestically acquired foodborne illness due to *Cryptosporidium* spp. occurring annually (38). This is much lower than the number estimated in 1999.

Although there is no effective and definite therapeutic agent for the treatment of cryptosporidiosis, spiramycin reportedly decreases diarrhea in the early stages of infection (39–41); however, it is not effective in treating advanced infections. Azithromycin, nitazoxanide, and paromomycin reportedly are effective in treating AIDS patients with cryptosporidiosis (42–45). Alternative experimental therapies that have been evaluated in humans include passive immunotherapies, such as hyperimmune bovine colostrum. Monoclonal antibodies and polyclonal hyperimmune hen yolk against *Cryptosporidium* have also been tested in animal models, with some success (46–48).

To date, nitazoxanide is the only drug approved by the Food and Drug Administration for the treatment of cryptosporidiosis. This treatment has been most effective in malnourished children. Nitazoxanide, paromomycin, and rifamycin derivatives are reportedly partially effective in severely immunocompromised patients with cryptosporidiosis (49).

Cryptosporidium oocysts are 4 to 6 μm in diameter. Because of their size, they can be overlooked in examinations of feces or

confused with yeast cells. *Cryptosporidium* can be identified by light microscopy using acid-fast staining. Immunoassays (fluorescent-antibody immunoassay or enzyme immunoassay) are available and are very sensitive and specific diagnostic tests (50–52). *Cryptosporidium* can be mistaken for *Cyclospora*, which is also positive in acid-fast staining but larger (Fig. 25.3). It is important that laboratories carefully measure the diameters of cells, particularly if the cells appear to be larger than those of *Cryptosporidium*. New molecular diagnostic tests such as PCR assays are being developed and could improve the sensitivity in detecting *Cryptosporidium* oocysts in produce (37, 53–58). It has been determined that shellfish can concentrate large volumes of *Cryptosporidium* oocysts along with other particulate matter (56, 59–63). *Cryptosporidium* has also been identified in shellfish organs by using conventional diagnostic assays, and molecular tools (multiplex nested PCR) have been evaluated to optimize parasite identification (56, 60, 64, 65). The use of natural grassland buffers may assist in controlling the parasite load that may potentially be deposited in water banks and oceans as a consequence of rangeland runoff, thus contaminating shellfish (66). To date, shellfish have not been associated with outbreaks of *Cryptosporidium* infections.



A
B
C

Figure 25.3 Acid-fast staining. (A) *C. parvum*. (B) *C. cayetanensis*. (C) *C. belli*. Bars = 20 μm.

Although *Cryptosporidium* oocysts are highly resistant to chlorine and chlorine dioxide, treatment with these chemicals at 1,000 μg/ml for 1 min resulted in 0.5- and 2-log reductions, respectively, according to the viability assay used (*in vitro* excystation or tissue culture infectivity) (67). More than 90% inactivation was achieved when *Cryptosporidium* oocysts were treated with ozone at 1 μg/ml for 5 min, chlorine dioxide at 1.3 μg/ml for 1 h, and chlorine and monochloramine at 80 μg/ml for 90 min (68). Various technologies effective at killing *Cryptosporidium* oocysts in drinking water and in treated wastewater have been developed, including pulsed UV light and pulsed-plasma gas (69) and chlorine dioxide at concentrations of 5 and 1.4 mg/liter in chlorinated recreational water venues (70).

Pasteurization of apple cider is effective for inactivating *Cryptosporidium* oocysts. Heating for 10 or 20 s at 70 or 71.7°C resulted in at least a 4.9-log oocyst viability reduction. When oocysts were exposed for 5 s, killing was 3.0 and 4.8 log, respectively. Hence, flash pasteurization used in the juice industry is sufficient for inactivating contaminating oocysts (71).

CYCLOSPORA

Cyclospora was probably first reported to be found in humans in 1979 by Ashford, who described it as an *Isospora*-like coccidian affecting humans in Papua New Guinea (72). Thereafter, other investigators found similar structures in fecal samples of patients with diarrhea, but because of the morphologies of the unsporulated oocysts and their autofluorescence, they were identified as coccidian-like bodies (or cyanobacterium-like bodies) (CLBs) (73–75). In 1993, conclusive identification was made, and the CLBs were fully characterized as coccidian parasites and placed in the genus

Cyclospora with the proposed species name *Cyclospora cayetanensis* (76, 77).

Cyclospora belongs to the family *Eimeriidae*, subphylum *Apicomplexa*. *Cyclospora* species infect moles, rodents, insectivores, snakes, and humans. In 1998, a *Cyclospora* species that morphologically resembles the *Cyclospora* isolated from humans was isolated from nonhuman primates (78–80). However, phylogenetic analysis has revealed that these isolates are a different species (78, 79).

Even before their true identity was established, epidemiologic information on the intriguing CLBs was being collected worldwide. In Nepal, the prevalence of *Cyclospora* infection is highest in adult expatriates (81), whereas in areas of Peru where infection is endemic, children under 10 years of age are the most susceptible to infection, although most are asymptomatic (82). Adults from areas of endemicity do not develop symptoms of infection, but adults of medium to high socioeconomic status living outside the areas of endemicity, as well as foreign travelers, typically present with clinical disease. These observations suggest that prior exposure to the parasite may result in protective immunity.

Newly shed oocysts (Fig. 25.4A) of *C. cayetanensis* require 2 weeks to sporulate and become infectious (Fig. 25.4B) under optimal laboratory conditions (77). The requirement of this amount of time for the oocyst to become infectious suggests that contamination of produce occurs with oocysts that are fully sporulated or almost fully sporulated. Otherwise, unsporulated oocysts would require the optimal time and environmental conditions to induce oocyst sporulation, while the produce would still be edible.

In studies performed in areas of endemicity, *Cyclospora* oocysts have been isolated from produce with removal by washing thoroughly with distilled water. The washes are concentrated by centrifugation, and pellets are fixed and preserved in 10% formalin. Samples are examined directly by using epifluorescence microscopy and phase-contrast microscopy (77). Nested PCR designed to

amplify the 18S rRNA gene is also used with these preparations; however, further testing using restriction fragment length polymorphism is required, because the described PCR assay cross-reacts with *Eimeria* species. *Eimeria* parasites are infectious to animals but not to humans and can be readily found in the environment (83, 84). An optimized TaqMan real-time PCR assay was developed and compared to a nested PCR assay using 0, 5, 10, and 100 oocysts in 25 g of cilantro or 50 g of raspberries (85). Detection by both methods was statistically similar. The authors indicated that the real-time PCR assay was simpler, less laborious, and less prone to amplicon contamination (85).

Cyclosporiasis is characterized by mild to severe nausea, anorexia, abdominal cramping, mild fever, and watery diarrhea. Diarrhea alternating with constipation has been commonly reported. Some patients present with flatulent dyspepsia and, less frequently, joint pain and night sweats. The onset of illness is usually sudden, and symptoms persist for an average of 7 weeks (86, 87).

C. cayetanensis infects epithelial cells of the duodenum and jejunum of humans. Merogony and gametogony occur intracytoplasmically within the parasitophorous vacuoles in intestinal cells (Fig. 25.4C) (87, 88). Duodenal and jejunal biopsy specimens from patients with cyclosporiasis show various degrees of jejunal villous blunting, atrophy, and crypt hyperplasia (86, 87). Extensive lymphocytic infiltration into the surface epithelium is present, especially at the tips of the shortened villi. The reactive inflammatory response of the host does not correlate with the number of intracellular parasites present in the tissues (87).

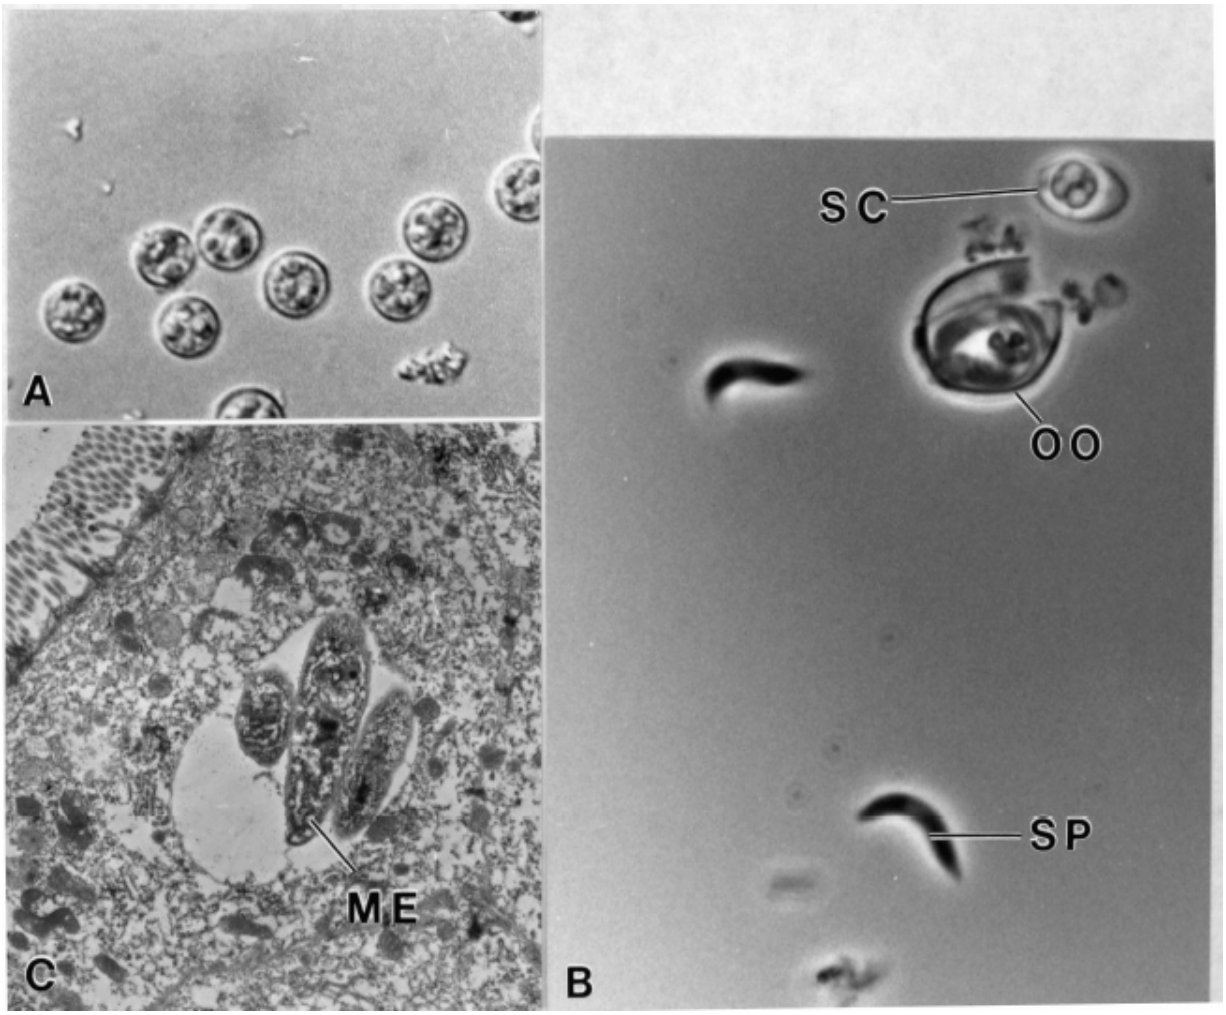


Figure 25.4 *C. cayetanensis* oocysts. (A) Phase-contrast microscopy of unsporulated oocysts. (B) Oocysts (OO) in the process of excystation. Note the two sporozoites (SP) free of the sporocyst (SC). (C) Transmission electron microscopy of human small intestine showing *Cyclospora* intracellular stages. ME, merozoite.

Routes of transmission for *Cyclospora* are undocumented, although the fecal-oral route, either directly or via water and food, is probably the major one. In the United States, epidemiologic evidence suggests that water has been responsible for sporadic cases of cyclosporiasis. In Utah, a man became infected after cleaning his basement that was flooded with runoff from a nearby farm following heavy rains. In 1990, an outbreak involving residents in a

physicians' dormitory in a Chicago hospital was epidemiologically associated with tap water from unprotected reservoir tanks that served the building and which had a broken water pump (89, 90). In Pokhara, Nepal, British Gurkha soldiers were confirmed to have cyclosporiasis; oocysts were isolated from their drinking water. The water, consisting of a mixture of river and municipal water, was routinely chlorinated and served the houses in the camp where the soldiers were stationed (91).

A few reports have described the isolation of *C. cayetanensis* oocysts from animals (chickens, ducks, and dogs) (92–95). At present, after several experimental studies attempting to infect these and additional animal species, it seems that *Cyclospora* species are host specific (96).

Since the early 1990s, *Cyclospora* has been linked to waterborne- and foodborne-disease outbreaks. Foodborne outbreaks have been epidemiologically associated with the consumption of contaminated fresh produce such as raspberries, lettuce, basil, and snow peas (97–100). In 1996, a large foodborne-illness outbreak occurred following a wedding reception at a restaurant in Boston, resulting in 57 guests having cyclosporiasis. Berries were implicated as the vehicle of transmission for *Cyclospora* oocysts (101). In 1999, another foodborne outbreak among attendees of two events was reported. Sixty-two cases of infection were documented, and the illness was associated with consumption of chicken pasta salad and tomato basil salad. The most likely vehicle of illness was fresh basil, grown either in Mexico or in the United States, which was included in both salads (102). However, *Cyclospora* oocysts were not recovered from or detected in the produce associated with these outbreaks. In the United States, most cases of cyclosporiasis have been reported in the months of April to August, suggesting a seasonal relationship.

In the United States in 1996 and 1997, *Cyclospora* infections were associated with imported Guatemalan raspberries (99, 100). It was speculated that the raspberries were contaminated when they were sprayed with insecticide that was possibly diluted with

contaminated surface water. Analysis of irrigation water revealed the presence of *Cyclospora* oocysts (103). In Peru, *C. cayetanensis* oocysts have been isolated from vegetables obtained from markets in areas of endemicity. In studies where vegetables were experimentally inoculated with *C. cayetanensis* oocysts, it was determined that washing with water does not remove all the oocysts (36). *Cyclospora* has also been isolated from produce from Nepal (104). In Germany in 2000, 34 individuals acquired *Cyclospora* infections that were associated with consumption of lettuce spiced with green leafy herbs which were all imported from southern Europe (105). In the same year, another outbreak occurred at a wedding reception in Philadelphia, Pennsylvania. The wedding cake tested *Cyclospora* positive, and cream filling containing raspberries was the food item strongly associated with illness (106). In 2001, in British Columbia, Canada, 17 cases of cyclosporiasis were reported. Eleven of these individuals had consumed Thai basil that was imported from the United States (107). In 2004, approximately 50 cases of cyclosporiasis were linked to consumption of raw Guatemalan snow peas (108). In 2009, a *Cyclospora* outbreak was reported in Sweden, involving 12 confirmed and 6 probable cases, and was associated with imported sugar snap peas from Guatemala (109).

In the most recent report from the Centers for Disease Control and Prevention, it is estimated that 99% of cases of *Cyclospora* infection in the United States are foodborne and that there are an estimated 11,407 cases annually (38). In the United States, in 2013, 643 cases of cyclosporiasis involving 25 states occurred during June to August. Three states had the largest number of cases: 279 cases were reported in Texas, 153 in Iowa, and 86 in Nebraska. The cases in Iowa and Nebraska in which the infected individuals ate at restaurants were linked to a salad mix produced by Taylor Farms de Mexico. The cases reported in Texas were associated with cilantro imported from Puebla, Mexico (110). In 2014, 304 cases of cyclosporiasis were reported; 207 of the infected individuals did not have a travel history within the 2 weeks prior to developing the

illness. One hundred thirty-three patients were from Texas, and their infections were associated with consumption of cilantro from Puebla, Mexico (111). In 2015, 546 cases of cyclosporiasis were reported; 319 of the individuals did not have a history of travel. Cases in Wisconsin and Texas were associated with cilantro as the suspect food vehicle (112).

As a result of these outbreaks, the FDA issued an import alert that indicated that shipments of cilantro (intact, cut, or chopped) from Puebla, Mexico, can be detained without physical examination from 1 April to 31 August of each year if the product is not from a firm listed on the Green List (firms that have been inspected and approved for import) (113). In 2016, 384 cases were reported from 25 states. No suspect food was identified (114). In 2017, there were 1,065 laboratory-confirmed cases in 40 states; at least 597 of the individuals did not report international travel prior to illness. No specific food vehicle was identified (115). Once again, in 2018, two multistate outbreaks of cyclosporiasis were identified in the United States. The first outbreak had 250 laboratory-confirmed cases from four states in which individuals reported consuming prepackaged Del Monte fresh produce vegetable trays that contained cauliflower, broccoli, and carrots. The second was associated with people from 15 states and New York City who reported consuming salads in McDonald's restaurants in the Midwest. The implicated romaine and carrot mix bags were distributed to McDonald's by the Fresh Express processor in Streamwood, IL. A total of 511 laboratory-confirmed cases occurred in this outbreak. So far, in 2018, 2,173 laboratory-confirmed cases of domestically acquired cyclosporiasis have been reported in the United States (116).

The cases reported from 2013 to 2017 occurred during the months of May to August, suggesting that the implicated food commodity was imported from a location where *Cyclospora* is endemic and where contamination occurred and that *Cyclospora* contamination is seasonal. Another possible explanation for this seasonal relationship observed in the United States could be that food commodities grown in the United States are contaminated in the

field by infected field workers. This could also explain the findings of Dixon et al., in which *Cyclospora* was identified in 1.9% of bagged salad mixes assayed. Most of the samples tested (97% of 544) were products from the United States sold in Canada (117). Similarly, in a study conducted in Italy, *Cryptosporidium* spp., *G. lamblia*, *T. gondii*, *C. cayetanensis*, *Blastocystis hominis*, and *Dientamoeba fragilis* were identified in ready-to-eat salads sold at retail (118).

Neither the minimum infectious dose of oocysts nor the sporulation and survival rates under different environmental conditions are known, although human volunteer studies have been attempted without success (119). Because of the potential low number of oocysts present in foods, molecular assays and methods to improve parasite recovery have been studied (83, 120, 121).

Analysis of the intervening internal transcribed spacer 1 (ITS-1) region sequence of *Cyclospora* isolates from the 1996 outbreak revealed that all were identical, suggesting a single source of contamination for the infection (122). Another study examined *C. cayetanensis* and *Cyclospora papionis* isolates. Although high sequence variability was present, conserved species-specific ITS-1 sequences were identified. This consistent and remarkable diversity among *Cyclospora* species ITS-1 sequences suggests polyparasitism and simultaneous transmission of multiple strains (123).

There is strong evidence to suggest seasonality of *Cyclospora* infections. In Peru, more than 6 years of prospective epidemiologic studies investigating endemic *Cyclospora* infections revealed that nearly all infections occurred between December and July (82). In Haiti, most *Cyclospora* cases occurred during the months of January to March (124). Rarely were infections documented at any other time of the year. In the United States, most cases occur between May and August. In Nepal and Honduras, most cases of cyclosporiasis occur between May and August (75, 125). In Mexico, a 10-year study revealed that most cases of *Cyclospora* infections occur during the months of June to August (126), similar to China, where most cases present during July to November (127). The

specific reasons for this marked seasonality have not been elucidated.

The only successful antimicrobial treatment for *Cyclospora* infections is trimethoprim-sulfamethoxazole (TMP-SMX) (82, 128, 129). AIDS patients appear to have higher parasite infestation levels than immunocompetent individuals infected with *Cyclospora*. However, the prevalence of *Cyclospora* infection among HIV patients is not higher than that among immunocompetent populations. This is probably due to the frequent use of TMP-SMX for *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) prophylaxis among HIV patients (128). Ciprofloxacin has also been evaluated as an alternative treatment for sulfa-sensitive patients (129).

Trace-back studies have been hampered by the lack of genotyping tools. Guo et al. (130) described a multilocus sequence typing (MLST) alternative. Sixty-four *Cyclospora*-positive specimens were analyzed using five genetic loci, including CYC3, CYC13, CYC15, CYC21, and CYC-22. Sequence data for 56 of them had at least four loci, and 34 specimens had all five loci. With this MLST method, the authors determined that there were at least 25 multilocus genotypes among these samples. Samples from China were genetically distant from those from the United States and Peru (130). In another study, Chinese investigators assayed 45 *Cyclospora*-contaminated samples from Zhenzhou and Kaifeng using MLST with five microsatellite loci and determined that there were 29 multilocus genotypes among the isolates in the samples. These isolates, including 34 reference isolates, produced three main clusters (131). The whole genome of *Cyclospora* has also been described by various research groups. Using comparative genomics, Liu et al. determined that *C. cayetanensis* and *Eimeria tenella* share similar genome organization, metabolic capabilities, and potential invasion mechanisms. However, *Eimeria* has unique surface antigens, and amino acid metabolism and post-translation modifications of proteins are some major differences between *C. cayetanensis* and other apicomplexans (132)

CYSTOISOSPORA

Cystoisospora is a coccidian parasite that infects humans. It is frequently identified in AIDS patients (133, 134) and can be acquired by ingestion of contaminated food or water. Oocysts excyst in the intestine, and sporocysts are released. The sporocysts in turn release sporozoites that infect intestinal epithelial cells. Asexual and sexual life cycle stages occur in the cytoplasm of enterocytes. Unsporulated *Cystoisospora* oocysts require 12 to 48 h to mature and become infectious outside the host.

Cystoisospora can be detected in stools from infected patients by observing unsporulated oocysts shed in feces. *Cystoisospora belli* oocysts (10 to 19 by 20 to 30 μm) can be detected in direct wet mount preparations in heavy infections during ova and parasite examination (Fig. 25.5). However, most infections are not heavy, and rates of shedding of oocysts may be variable; therefore, it is necessary to examine a series of samples and perform modified acid-fast staining (Fig. 25.3C). *C. belli* infects the entire intestine and produces severe intestinal disease (135). Deaths from overwhelming infections have been reported, especially in immunocompromised patients. Symptoms include diarrhea, nausea, steatorrhea, headache, and weight loss. The disease can persist for months to years (136).

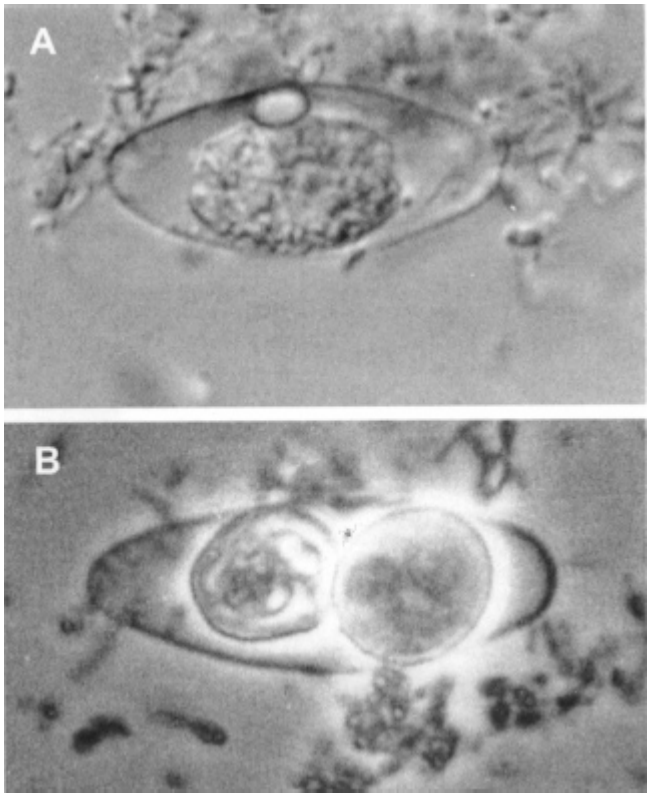

Figure 25.5 Bright-field photomicrograph of unsporulated (A) and sporulated (B) *C. belli* oocysts.

Cystoisospora infection is rare in immunocompetent people but occurs in 0.2 to 0.3% of immunocompromised AIDS patients in the United States and in 8 to 20% of AIDS patients in Africa and Haiti. *Cystoisospora* infection is endemic in many parts of Africa, Asia, and South America. The treatment of choice is TMP-SMX; however, recurrence in HIV patients is common after discontinuation of therapy (136).

TOXOPLASMA

T. gondii is a coccidian parasite that infects a variety of warm-blooded hosts. Cats are the definitive host, and other warm-blooded animals can serve as intermediate hosts. Cats excrete oocysts in their feces. Oocysts are environmentally resistant and can survive several years in moist, shaded conditions. Infections are acquired principally by ingestion of food and water containing oocysts,

ingestion of animal tissues containing cystic forms (bradyzoites), or transplacental transmission (137).

The unsporulated oocysts require 24 h outside the host to differentiate and become infectious. When oocysts are ingested by the intermediate host, the oocyst walls are ruptured and the sporozoites are released (Fig. 25.6). They invade epithelial cells and rapidly multiply asexually, producing tachyzoites. Tachyzoites multiply by endodyogeny, a process in which the mother tachyzoite is consumed by the formation of two daughter forms (Fig. 25.7). Eventually bradyzoites, which are slowly multiplying forms, develop, forming tissue cysts. Cysts persist for the duration of the life of the host. By encysting, the parasite evades the host's immune response and ensures its viability (138).

When animal tissues containing cysts are ingested by cats, proteolytic enzymes digest the cyst walls and the bradyzoites are released. They infect and multiply in the intestinal epithelial cells, transforming into tachyzoites. These in turn disperse via blood and lymph. When tissues of other animal species are ingested by felines, tachyzoites or bradyzoites begin the enteroepithelial cycle, and sexual multiplication also occurs (Fig. 25.6). Macro- and microgametocytes are produced. After fertilization, the zygote differentiates into oocysts, which are passed in the feces (138).

Although most *Toxoplasma* infections occur by ingestion of contaminated meat, other foods, or water, infections can also be acquired by organ transplantation or by blood transfusion (139–142). Disseminated toxoplasmosis may occur in patients who have received organ transplants and are receiving immunosuppressive therapy. Chorioretinitis is frequently observed in adults who acquire the infection. In immunosuppressed patients, toxoplasmosis can reactivate from latent infections (143, 144). It is estimated that 50% of cases of toxoplasmosis in the United States are foodborne, representing 76,840 cases per year (38).

Toxoplasmosis can also be acquired vertically by transplacental transmission when a pregnant woman becomes infected. After

multiplying in the placenta, tachyzoites spread into the fetal tissues. Infection can occur at any stage of pregnancy, but the fetus is most affected when infection occurs during the first months of pregnancy. Most infected children do not show any signs of the disease until later in life, when they may present with chorioretinitis and mental retardation (145–148).

The overall prevalence in humans and animals varies according to eating habits and lifestyle. The prevalence of *T. gondii* is highest in swine with outdoor access. Confined housing reduces swine exposure to cat feces and infected rodents (145, 149).

Toxoplasmosis can be acquired by ingestion of infected lamb, poultry, horse, and wild game meat. Cooking, freezing, or gamma irradiation will kill the *Toxoplasma* cysts and oocysts. Exposure to temperatures of 61°C or higher for 3.6 min inactivates the parasites, and freezing at −13°C kills the cysts (137, 150). *Toxoplasma* has also been identified in fresh produce and ready-to-eat salads (118, 151); however, the oocyst viability was not addressed in this study. Thus, the public health implications remain to be determined (118).

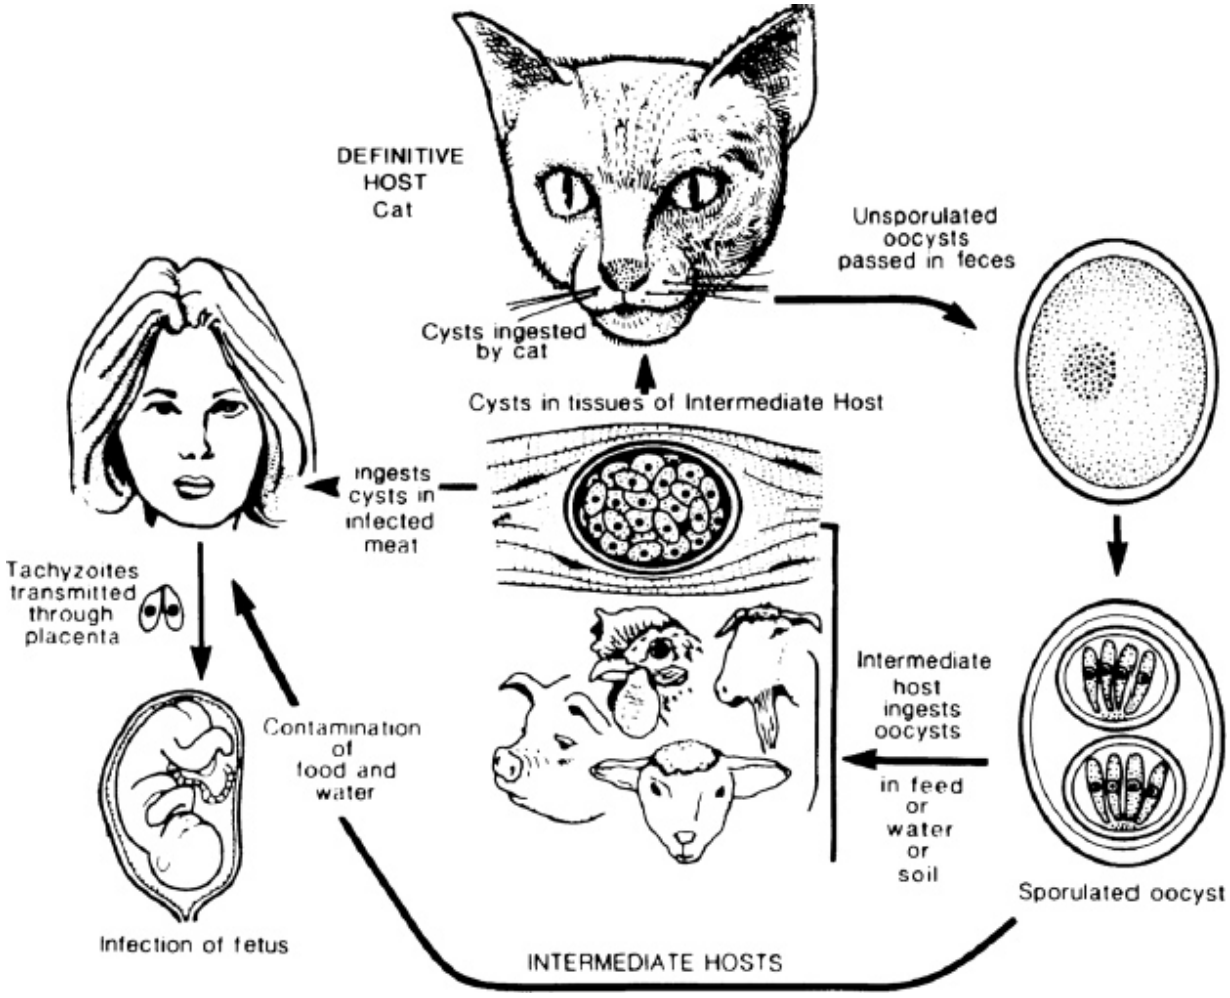

Figure 25.6 Life cycle of *T. gondii*. From Dubey and Beattie (137).

Pyrimethamine in combination with folinic acid or trisulfapyrimidine is the treatment of choice for acute infections. TMP-SMX is effective and frequently used to prevent recurrence of acute infections in AIDS patients (152).

There are several methods for detecting *Toxoplasma* in humans, such as enzyme-linked immunoassays, microarray assays, and molecular assays (153–162), the modified agglutination test, and indirect enzyme-linked immunosorbent assays using recombinant rMAG1 instead of soluble *Toxoplasma* lysate antigens in animals (163–170). For fresh produce, a loop-mediated isothermal amplification lateral flow dipstick was developed to detect *Toxoplasma* oocysts in ready-to-eat salads (171).

SARCOCYSTIS

Sarcocystis is another coccidian that causes a significant number of foodborne infections. Muscular sarcocystosis is caused by several species of *Sarcocystis*. The oocysts, which are excreted in the feces of an infected animal or individual, contain two sporocysts, each with four sporozoites. The oocyst cell wall is thin and usually breaks, and the sporocysts are more commonly identified in the feces. The intermediate hosts are pigs, cattle, sheep, etc., and humans acquire the infection when they ingest meats containing muscle cysts (sarcocysts) full of bradyzoites (172).

Humans can also be definitive hosts for *S. hominis* and *Sarcocystis suihominis*. These sarcocysts are released from the infected muscle and infect the intestinal lamina propria. The bradyzoites differentiate into sexual stages, and after fertilization, oocysts are produced. Oocysts measure 12.3 to 14.6 by 18.5 to 20 μm (172). Patients with muscular sarcocystosis present with musculoskeletal pain, fever, rash, cardiomyopathy, bronchospasm, and subcutaneous swelling. The intestinal infection is characterized by nausea, vomiting, diarrhea, dyspnea, tachycardia, and stomachache (63). The infection can be acquired by ingestion of raw or undercooked meats, other foods including vegetables, and water contaminated with feces of a variety of animals containing oocysts or sporocysts.

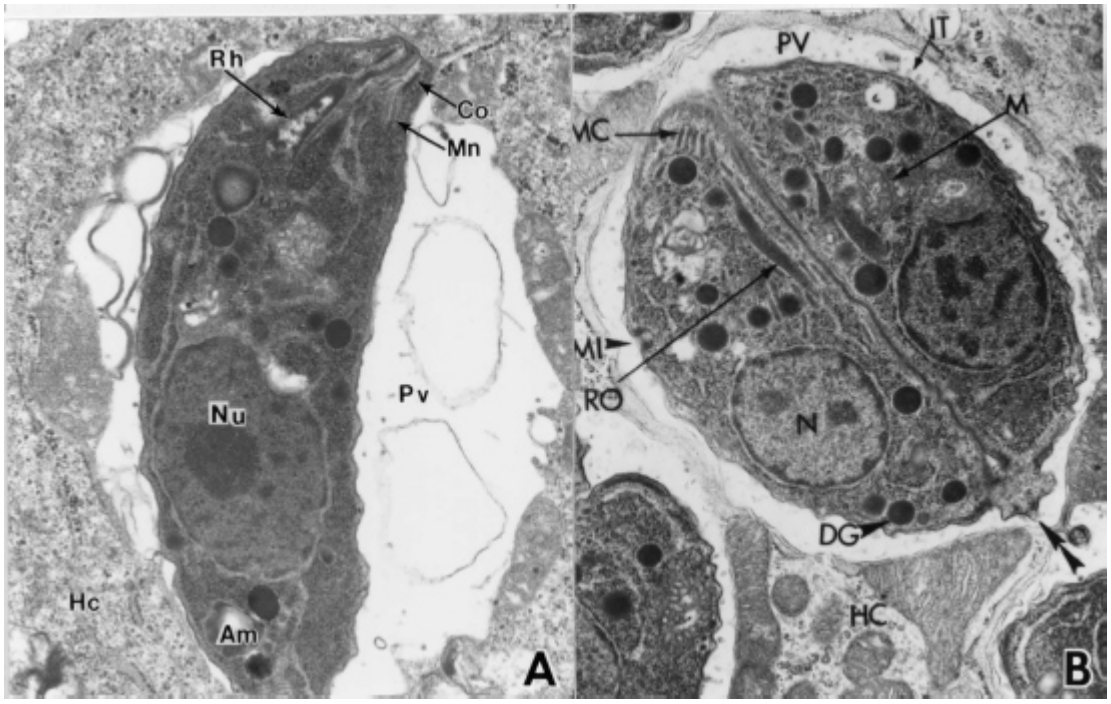

Figure 25.7 Transmission electron micrographs of *T. gondii*. (A) Sporozoite in parasitophorous vacuole (Pv) of host cell (Hc) at 24 h after inoculation. Am, amylopectin granule; Co, conoid; Mn, microneme; Nu, nucleus of sporozoite; Rh, rhoptry. (B) Final stage of endodyogeny to form two daughter tachyzoites that are still attached to the posterior ends (arrowheads). DG, dense granules; HC, host cell; IT, intravacuolar tubules; M, mitochondrion; MC, microneme; MI, micropore; N, nucleus; RO, rhoptry. From Dubey and Beattie (137).

During 2011 to 2012, a cluster of 68 cases of acute muscular sarcocystosis occurred in persons who had traveled to Tioman Island, Malaysia. Of those, six were laboratory-confirmed, and *Sarcocystis nesbitii* DNA was recovered from one muscle biopsy (173). The source of these infections was not determined but was suspected to be raw or undercooked meats (174).

Presumptive diagnosis of human intestinal sarcocystosis is based on symptoms and travel history. Definite diagnosis is determined by identifying sporocysts in the stools of the patients. *Sarcocystis* species cannot be differentiated by direct microscopic observation. Muscular sarcocystosis can be diagnosed by the clinical

presentation and by linking it to the patient's travel history. Muscle biopsies can be used to detect tissue cysts or sarcocysts present; however, this method is not very sensitive. Myositis, myonecrosis, perivascular and interstitial inflammation, vasculitis, and eosinophilic myositis have been observed in cases of muscular sarcocystosis (174). Molecular tools have been developed and used for testing animal tissues and meat for human consumption (175–183).

MICROSPORIDIA

Most microsporidium infections occur in AIDS patients (134). Several species of microsporidia have been associated with human infections, in particular *Enterocytozoon*, *Pleistophora*, *Encephalitozoon*, and *Vittaforma*. *E. bieneusi*, the only species that seems to be tissue specific, is associated only with human enteric infections. Microsporidium spores, which are highly resistant to environmental stresses, vary in size among the different species. They are ovoid or piriform and 1 to 2 μm in diameter. *Encephalitozoon intestinalis* spores are larger than those of *E. bieneusi*. These spores contain a polar filament that is used to eject the sporoplasm and penetrate the host cell cytoplasm. After entering the cell, the parasite multiplies asexually and eventually forms spores, lysing the host cell and invading neighboring cells. Although the mechanisms of transmission are not clear, it is believed that the infection can be acquired by ingesting spores in contaminated water and produce (184).

Infection with microsporidia is characterized by watery and large-volume stools. Microsporidia are occasionally associated with biliary tract disease and may potentially cause cholangiopathy, which occurs in AIDS patients (185).

Microsporidium spores can be histologically identified in tissue, but identification in fecal samples requires special staining methods. Microsporidia can be identified in tissues by using various

conventional stains such as hematoxylin-eosin, Gram, and Giemsa stains. These spores can be detected in fecal samples by using nonspecific staining techniques such as Calcofluor white and a modified trichrome with Chromotrope 2R; however, small structures and yeast spores are also stained by these procedures (149, 186, 187). Identification of microsporidia in the environment presents an additional challenge. Most species of the animal kingdom can be parasitized by species of microsporidia, and noninfectious species can be confused with those infectious to humans. Definitive identification is limited to transmission electron microscopy (188–191). New tests using specific monoclonal antibodies and molecular tools such as PCR assays are being developed to aid in the detection of microsporidia in tissues and in fecal and environmental samples (57, 192–194).

Infections caused by *E. intestinalis* can be treated with albendazole or with metronidazole and atovaquone. To date, there is no effective treatment for infections caused by *E. bieneusi* (195); however, nitazoxanide has been reported to resolve the infection in an AIDS patient (196).

GIARDIA

Giardia is a protozoan flagellate that belongs to the phylum *Sarcomastigophora*. Initially thought to be a commensal organism in humans, *Giardia* is now clearly recognized as a common cause of diarrhea and malabsorption. *Giardia* infects millions of people throughout the world in both epidemic and sporadic forms. Most human infections result from ingestion of contaminated water or food or direct fecal-oral transmission, such as would occur in person-to-person contact in child care centers and in male homosexual activity (197).

Three species of *Giardia* have been described based on differences discernible in cysts and trophozoites by light microscopy: *Giardia agilis* from amphibians; *G. muris* from rodents, birds, and reptiles;

and *G. lamblia* from various mammals, including humans. Two additional species that are indistinguishable from *G. lamblia* by light microscopy, *G. ardeae* from herons and *G. psittaci* from psittacine birds, have been identified based on ultrastructural morphologic differences (198).

G. lamblia is not host restricted, and wild animals such as beavers and muskrats have been implicated in waterborne outbreaks of giardiasis in humans. Molecular classification using small-subunit rRNA has placed *Giardia* as one of the most primitive eukaryotic organisms (199). Two major molecular groups or assemblages (A and B) of *G. lamblia* have been recognized as infecting humans but can also infect nonhuman primates, dogs, cats, and wildlife. Other assemblages infect animals exclusively: dogs and other canids (C and D); cattle, goats, sheep, and pigs (E); cats (F); rats (G); and marine mammals (H) (200).

Giardia can be observed in two forms: the trophozoite and the cyst. The cyst is the infectious form and is relatively inert and environmentally resistant. After cysts are ingested, excystation occurs in the duodenum after exposure to the acidic gastric pH and the pancreatic enzymes chymotrypsin and trypsin. Each cyst releases two vegetative trophozoites. The trophozoites replicate in the crypts of the duodenum and upper jejunum and reproduce asexually by binary fission. Some of the trophozoites then encyst in the ileum, possibly as a result of exposure to bile salts or cholesterol starvation (197). The trophozoites and cysts are excreted in the feces.

Cysts are round or oval. Each cyst measures 4 to 11 by 7 to 10 μm, has four nuclei, and contains axonemes and median bodies. Trophozoites have the shape of a teardrop (viewed dorsally or ventrally) and measure 10 to 20 μm in length by 5 to 15 μm in width. The trophozoite has a concave sucking disk with four pairs of flagella, two axonemes, two median bodies, and two nuclei. The ventral disks act as suction cups, allowing mechanical attachment to the surface of the intestine (Fig. 25.8) (201). Infections may result

from the ingestion of 10 or fewer *Giardia* cysts. Boiling is very effective to inactivate *Giardia* cysts, but cysts can survive after freezing for a few days.

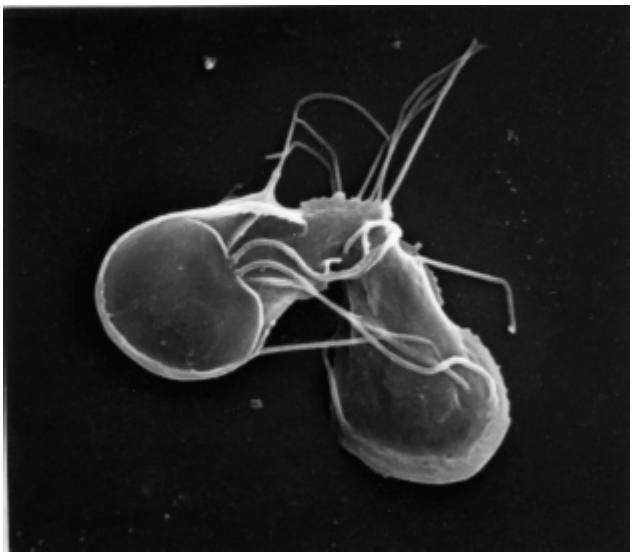

Figure 25.8 Scanning electron micrograph of *G. lamblia* trophozoites. One trophozoite shows the dorsal surface and the other shows the ventral surface with sucking disk and flagella.

Ozone is an excellent disinfectant and can even be used to inactivate microorganisms such as protozoa, which are very resistant to conventional disinfectants. The apparent activation energy for the inactivation of protozoa is 80 kJ/mol. By-products of ozonation include bromate, iodate, and chlorate, which may be of concern depending on the chemical composition of the water to be disinfected. A 2-log reduction of *G. lamblia* and *G. muris* cysts with ozone requires a contact time 2.4 times longer than that recommended by the surface water treatment rule.

A 2-log inactivation of *Cryptosporidium* in drinking water can be achieved using ozone; however, in other waters, including recreational waters, a 3-log reduction can be achieved using 5 mg/ml of free chlorine with or without the addition of 2.6 ml/liter of free chorine at contact times of 105 and 128 min. Ozone has also been evaluated, and 99% oocyst inactivation was achieved when the

integrated ozone residual was 0.5 mg/liter with a 5.2-min concentration time (202–205).

G. lamblia is prevalent worldwide and is especially common in areas where poor sanitary conditions and insufficient water treatment facilities prevail. Seasonality of giardiasis has been reported during late summer in the United Kingdom, the United States, and Mexico. Most *Giardia* infections are asymptomatic, but they can present as chronic diarrhea. Travelers to areas of endemicity are at high risk for developing symptomatic giardiasis. A study in Leningrad (now St. Petersburg), Russia, revealed that 95% of travelers developed symptomatic giardiasis. Hikers and campers are also at increased risk, since *Giardia* cysts, often of animal origin, can be found in freshwater lakes and streams. The prevalence of *Giardia* infection can be as high as 35% in children attending child care centers. Although these children are frequently asymptomatic, they may infect other family members, who may develop symptomatic giardiasis (206–208).

Giardia has been the most common agent in waterborne outbreaks of diarrhea in which the etiologic agent was identified. Waterborne transmission is usually a result of inadequate water treatment or sewage contamination of drinking, well, or surface water. Giardiasis has also been associated with exposure to contaminated recreational water, such as that in swimming pools. *Giardia* cysts can be inactivated by ozone and halogens; however, the concentration of chlorine used for drinking water is not sufficient for inactivation. Inactivation by chlorine requires prolonged contact time, and filtration is the recommended means for purifying water (209–211). It is estimated that 76,840 *Giardia* episodes associated with foodborne illness occur in the United States annually (38).

Symptomatic patients present with loose, foul-smelling stools and increased levels of fat and mucus in fecal samples. Flatulence, abdominal cramps, bloating, and nausea are common, as are anorexia, malaise, and weight loss. Blood is not present in stools. Fever is occasionally present at the beginning of the infection. In

contrast with most other forms of acute infectious diarrhea, *G. lamblia* infection results in prolonged symptoms. Although giardiasis may resolve spontaneously, the illness frequently lasts for several weeks and sometimes for months if left untreated. Those with chronic giardiasis have profound malaise and diffuse epigastric and abdominal discomfort. Although diarrhea may persist, it may be replaced by constipation or even by normal bowel habits (197).

Malabsorption associated with giardiasis may be responsible for substantial weight loss. Even in asymptomatic infections, malabsorption of fats, carbohydrates, and vitamins may occur. Reduced intestinal disaccharidase activity may persist even after *Giardia* is eradicated. Lactase deficiency is the most common residual deficiency, occurring in 20 to 40% of cases (212).

Villous blunting, lymphocytic infiltration, and malabsorption are observed in biopsy samples in symptomatic cases. No tissue invasion is observed, and large numbers of trophozoites are sometimes present in the crypts without obvious pathology. To date, the presence of a toxin has not been identified and no other potential mechanisms by which *Giardia* causes diarrhea have been elucidated.

Giardia infection can be diagnosed by finding cysts or, less commonly, trophozoites in fecal specimens (Fig. 25.9A). *Giardia* in feces can be detected by enzyme immunoassays, indirect and direct immunofluorescence assays using monoclonal antibodies, or PCR assays. All of these procedures are highly sensitive and specific for environmental and stool samples.

Genotyping of *Giardia* has been achieved using 18S ribosomal DNA and triosephosphate isomerase PCR assays, among others. In some patients with chronic diarrhea and malabsorption, results from stool examinations are repeatedly negative despite ongoing suspicion of giardiasis (213–215). *Giardia* cysts were found in 41.5% of nondepurated mussels from the Galician coast that were destined for human consumption (216).

Effective treatment for patients with symptomatic giardiasis is mainly a single treatment course with metronidazole. In refractory cases, multiple or combination treatments have occasionally been required. Tinidazole is widely used throughout the world, and a single dose is effective for the treatment of giardiasis (217, 218).

BALANTIDIUM

Balantidium coli is a ciliate parasite that, although found worldwide, is not highly prevalent. It is a commensal parasite of pigs. The trophozoites reside in the large intestine and multiply by binary fission. In humans, *B. coli* can cause ulcerative colitis and diarrhea. The ulcers differ from those caused by *Entamoeba histolytica* in that the epithelial surface is damaged but with lesions more superficial than those caused by amoebae. The parasite encysts and is excreted in the feces. The cyst, which is the environmentally resistant form, is large and oblong, 45 to 65 μm in diameter (Fig. 25.9B). Both cysts and trophozoites contain two nuclei. Trophozoites move via their cilia and rotate on their longitudinal axis (219). The preferred treatment of infection is tetracycline and, alternatively, iodoquinol and metronidazole.

AMOEBAE

Various amoebae can infect humans as commensals; however, *E. histolytica* is pathogenic to humans. *Entamoeba dispar*, which is

morphologically similar to *E. histolytica*, is not pathogenic. Cysts and trophozoites of *E. histolytica* are excreted in the feces of infected individuals (Fig. 25.9C), with cysts being environmentally resistant. Once cysts are ingested, the trophozoite excysts, colonizes the large intestine, and multiplies by binary fission followed by encystation.

Most infected individuals are asymptomatic even when shedding cysts in their feces. In other instances, parasites can invade the mucosa and cause an ulceration that goes from the luminal surface of the intestine through the lamina propria and to the muscularis mucosae. The parasite then spreads laterally, forming a flask-shaped ulcer. The trophozoites feed on cell debris and red blood cells (220). Infection can progress, producing ulcerative amoebic colitis and causing perforation of the intestinal wall. Patients complain of diarrhea with stools containing blood and mucus, back pain, tenesmus, dehydration, and abdominal tenderness. Fulminant colitis is characterized by severe bloody diarrhea, fever, and abdominal tenderness due to transmural necrosis of the bowel. Another presentation of amoebiasis is formation of amebomas, which resemble carcinomas and are not necessarily associated with pain. Amoebae can also disseminate to the liver. Complications with amoebiasis are observed when the liver parenchyma is gradually replaced with necrotic debris, inflammatory cells, and trophozoites. Patients present with hepatomegaly, weight loss, and anemia (220, 221).

Asymptomatic amoebiasis can be treated with iodoquinol, paromomycin, or diloxanide. If mild to severe infection and hepatic abscesses are present, amoebiasis can be treated with metronidazole or tinidazole followed with iodoquinol to treat asymptomatic amoebiasis.

CONCLUDING COMMENTS

Inactivation of the protozoan parasites is challenging. Enrichment media are not available for cultivating parasites; therefore, isolation and identification methods need to be extremely sensitive and specific to detect small numbers of various forms of parasites that may be present in foods. Molecular tools such as PCR, restriction fragment length polymorphism analysis, and variations of these techniques are being developed to improve the sensitivity and specificity of detection and identification processes.

Treatment of drinking water by chlorination at permissible concentrations is relatively ineffective at inactivating spores, cysts, and oocysts of parasites and cannot be recommended as a sole method for water treatment. Boiling can inactivate cysts, oocysts, and spores. Irradiation of produce to inactivate pathogens that may be present has also been evaluated. This method effectively inactivates *Toxoplasma* cyst forms and oocysts. There has been an increase in consumers' acceptance of purchasing irradiated produce (222), providing additional incentive to use irradiation as a treatment to reduce or eliminate at least some genera of parasites in food and water.

Finally, we face new challenges to ensure the safety of produce and other foods. Foodborne-disease outbreaks caused by parasites are being documented with increased frequency. The consumption of fresh fruits and vegetables in developed countries has increased, and local production cannot meet this demand. Thus, importation of produce and other foods from countries where sanitary standards are minimal or lacking makes it even more difficult to control foodborne diseases (223).

Novel Physical Methods for Food Preservation

There is a growing consumer demand for safe foods that are free of additives, minimally processed, and fresh-like in appearance and taste. While conventional thermal processing methods can address microbial safety considerations, the severity of processing invariably lowers the quality of food. To address these needs, numerous non-thermal processing methods are under investigation. In this chapter, we highlight some of these physical, non-thermal processing technologies and discuss their mechanisms of action, their benefits over conventional technologies, and their potential limitations.

DENSE-PHASE CARBON DIOXIDE

Dense-phase carbon dioxide (DPCD) processing is a non-thermal processing technology. In DPCD processes, carbon dioxide (CO_2) is held under high pressure in the liquid or gaseous phase, as well as in the supercritical state (1). A supercritical fluid can be defined as a substance held at a pressure and temperature at which there is no distinction between the liquid and the vapor phases. Supercritical conditions take place above a specific combination of pressure and temperature known as the critical point. For the case of CO_2, supercritical conditions exist above ~7.38 MPa and ~31°C (2). The use of CO_2 entails some safety benefits due to its thermodynamic stability, as well as its lack of flammability and toxicity (3).

DPCD processing has largely been studied for the processing of liquid foods. The liquid food is often heated to a mild temperature (30 to 50°C) and then is subjected to pressure above the critical point of CO_2. The CO_2 is injected into the liquid food, and these conditions are maintained for a specific holding time, which is followed by the release of CO_2 through depressurization (1, 4–6) (Fig. 26.1). The application of DPCD has also been studied in solid foods. However, this technology is less effective in solid foods than in liquid foods for inactivating microorganisms, possibly due to the lower diffusivity of CO_2 within solid matrices. Additionally, in contrast to what has been observed in liquid foods, in which there is a marginal effect on the sensory and nutritional attributes of the food, solid foods generally experience adverse changes in texture (loss of firmness) and discoloration when subjected to DPCD treatments (1). In general, there are still some limitations for the commercial application of DPCD, such as lower efficiency compared to heat treatments, costly equipment, and environmental concerns related to the release of

CO_2 (1). Table 26.1 shows some examples of studies in which DPCD has been applied.

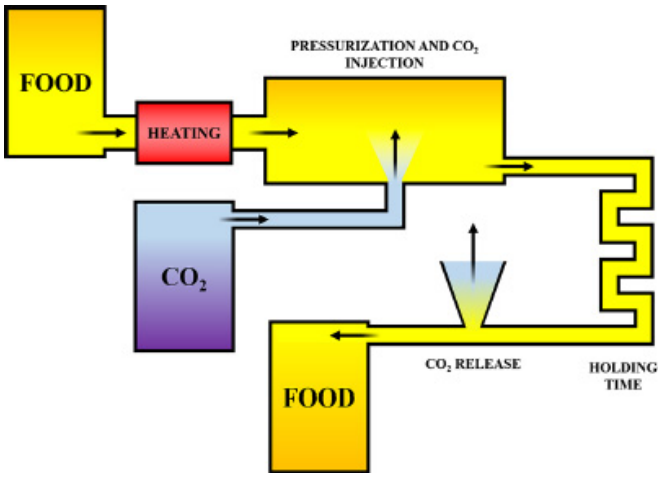

Figure 26.1 DPCD processing diagram.

Different phenomena have been proposed to explain the antimicrobial effect of DPCD. One probable contributing factor could be the decrease of pH caused by the incorporation of CO_2 into the liquid medium. Another mechanism could involve the denaturation of microbial enzymes, caused by the decrease in pH, the formation of bicarbonate complexes with enzymes, or precipitation of metal ions within the enzymes to form bicarbonate salts. Another accepted phenomenon is cell lysis, which may be caused by the expansion of CO_2 within the cells once it is released from the liquid food during the depressurization step. The expansion of CO_2 may also promote the release of vital biomolecules, affecting cell viability (1) (Fig. 26.2).

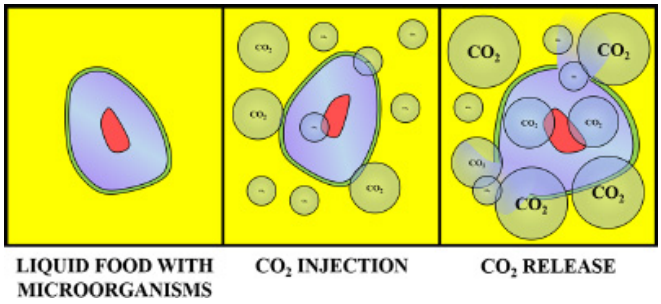

Figure 26.2 Possible mechanism for the antimicrobial effect of DPCD.

FILTRATION

In filtration, particles of different sizes are removed from a liquid medium by forcing the liquid through a porous matrix. The liquid that passes through the filtration medium is called filtrate, and the fraction that contains the removed particles is the retentate. Different mechanisms can serve as the driving force behind the removal of particles, such as a pressure gradient, a concentration

gradient, or an electric field (7). Filtration can be classified into microfiltration, ultrafiltration, nanofiltration, and reverse osmosis. Figure 26.3 shows the capabilities of each classification in terms of the range of particle sizes that can be removed. Microfiltration can be used to remove bacterial cells (8). For filtration to effectively remove microorganisms from the liquid medium, a pore diameter of 0.20 to 0.22 μm is needed, as well as a low initial microbial load in the liquid medium. Filtration offers the advantage of reducing the energy costs of the thermal treatments often used to inactivate microorganisms (7).

For sterilization, a filtration medium must efficiently remove particles that are the size of the different types of microorganisms, be able to have a high flow rate, prevent clogging, possess high thermal stability, possess adequate mechanical properties to ensure stability, be resistant to biofouling, and possess chemical stability to avoid release of chemicals into the filtrate (9). Innovations that have been developed for this technology have largely focused on approaches addressing the latter requirements.

Table 26.1 Recent studies on DPCD applications in foods

Food	Microorganism(s)	DPCD conditions	Logarithmic Reduction	Reference
Coconut water	Total aerobic bacteria	34.5 MPa, 30°C, 13% CO_2 for 6 min	6.18	4
Barley grains	*Penicillium oxalicum*	10 MPa, 44°C, 99.5% CO_2 (with water as cosolvent), 12 min	6.8	37
Bovine milk	Naturally present microflora	25 MPa, 50°C, 70 min	4.96	38
Grape juice	*Saccharomyces cerevisiae*, *Candida stellate*, *Kloeckera apiculata*	6.9–48.3 MPa, 25–35°C, 0–0.17% CO_2, 5 min	<6	
39	Orange juice	Aerobic mesophiles	7.6 MPa, 42°C, 8.5% CO_2, 20 min	2	6

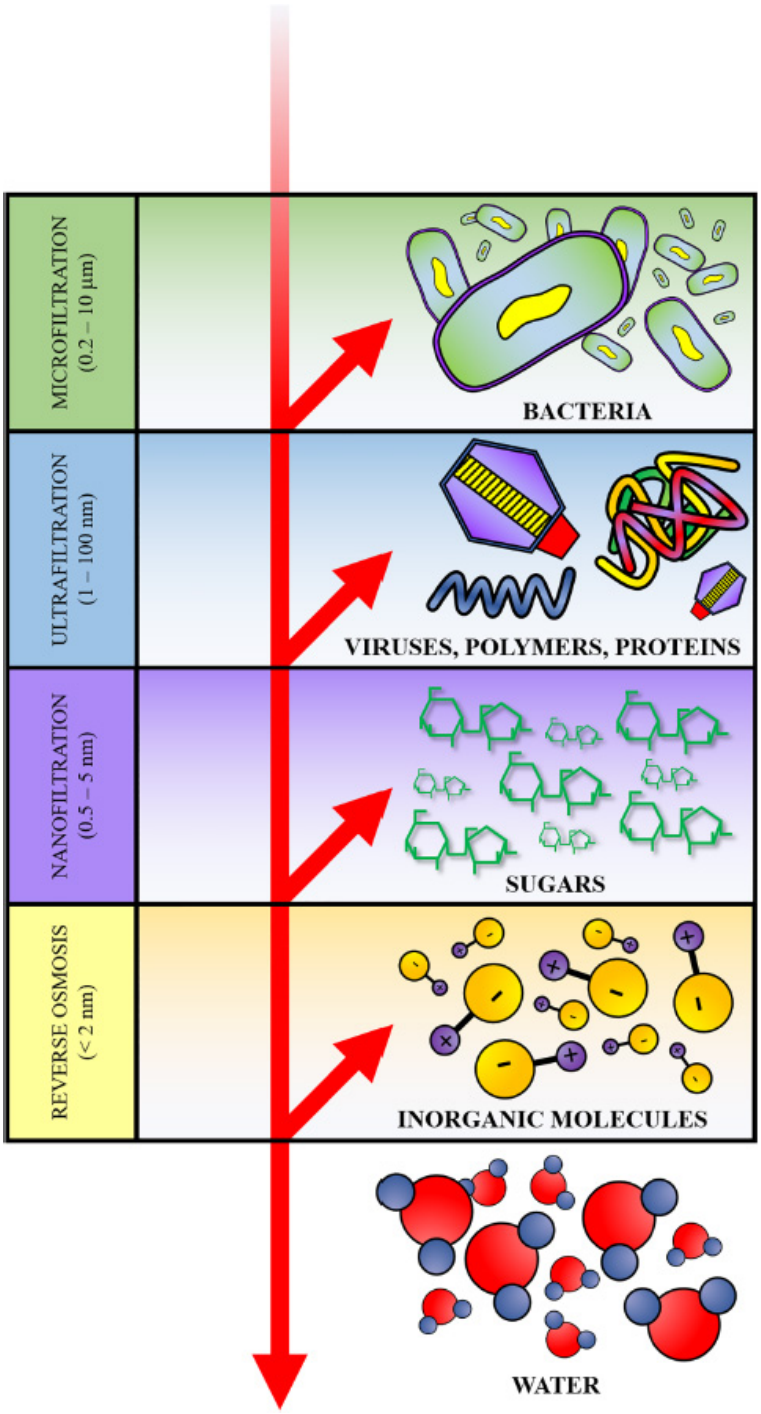

Figure 26.3 Capabilities for removal of different substances by different types of filtration (8, 12).

Most membranes used for filtration are made of polymeric materials which can provide greater flexibility and versatility to control pore size, surface chemistry, mechanical properties, and other functionalities that can help meet a specific objective for filtration. The polymers used for filtration membrane fabrication are normally hydrophobic. This feature has some drawbacks, such as resistance of

water to be filtered, as well as fouling by microorganisms and organic matter, which can subsequently result in microbial contamination of the filtrate or clogging of the membrane (7). Hence, this raises the need to modify the surface chemistry of the bulk materials used to fabricate filtration membranes. The different approaches that have been explored include blending of the bulk material with a variety of compounds that can provide an added functionality. Some of those compounds are amphiphilic substances that may reduce the affinity of organic molecules for the membrane (7), intrinsically antimicrobial polymers such as chitosan (7, 10), and antimicrobial metal nanoparticles (7, 11, 12).

Coating of the bulk material of the filtration membranes has also been used instead of blending (7, 13). Different techniques can be used in coating to incorporate an additional functionality, such as graft polymerization or surface activation to create reactive groups (on the bulk material) followed by covalent immobilization of different types of compounds (7). Another approach involves the fabrication of filtration membranes from electrospun nanofibers (7). During electrospinning, different polymers or compounds may be cross-linked to provide antimicrobial or antifouling properties to the resulting membrane.

Table 26.2 provides a summary of results of recent studies addressing antimicrobial applications of filtration technology.

COLD PLASMA

Plasma can be categorized as the fourth state of matter. Changes of state take place in substances when energy (in different forms, such as heat, radiation, light, or electricity) is applied to them. The transitions from the solid state to the liquid state and from the liquid state to the gas state demand increasing amounts of energy. If more energy is supplied to a substance that has reached the gaseous state, the inter- and intramolecular interactions (as well as the intra-atomic interactions) can be broken, which may result in a mixture of neutral molecules, electrons, and ions. These chemical species carry with them large amounts of energy. When they recombine or collide, that energy is released in the form of UV light (14–16). Plasma is a gas in which molecules and atoms have been ionized. The resulting high electrical conductivity allows a constant supply of electrical energy to be released through a wide range of methods, normally electric discharge (16, 17).

Plasma can be divided into hot and cold plasma (14, 16). Cold plasma refers to the type of plasma that can be generated at or near room temperature, which makes it an attractive nonthermal technology for food processing (14). Cold plasma can also be subdivided into thermal and nonthermal plasma. In thermal plasma, particles have high levels of energy and remain in equilibrium without transferring energy, whereas in nonthermal plasma there is an imbalanced level of energy between particles, which leads to energy transfer through collisions (14, 16). Nonthermal plasmas can be generated by electric discharge at low levels of pressure or at

atmospheric pressure (16). Cold nonthermal plasma at different levels of pressure is most frequently used in research addressing microbial inactivation (18–23). Plasma can also be generated from different types of gases, such as nitrogen, oxygen, mixtures of oxygen and nitrogen, and noble gases (14).

Table 26.2 Results of recent studies on antimicrobial filtration technology applications for foods

Antimicrobial material	Pore size	Microorganism tested	Logarithmic Reductions	Reference
N-Alkylated polyethyleneimine coating polypropylene microfiltration membrane	200 μm	*Staphylococcus aureus*	0.75–1.5	40
N-Chloramines on carboxylated thermoplastic of cardo poly(aryl ether ketone)		*Staphylococcus aureus* and *Escherichia coli* K-12	Inactivation below detection limit	41
Cellulose with chitosan	<1 nm	*E. coli*	Not reported (inhibition zone assay)	42
Quaternized cardo poly(arylene ether sulfone)	5–11 nm	*E. coli*	<1	43
Aminated poly(ether sulfone)		*E. coli*, *Bacillus subtilis*	Not reported (inhibition zone assay)	44

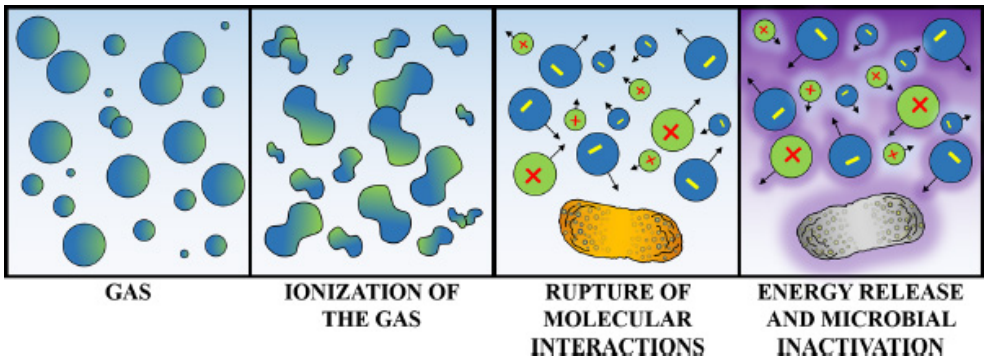

Figure 26.4 Antimicrobial effect of plasma.

The release of energy brought about by the collisions experienced between the different chemical species in plasma inactivates microorganisms (Fig. 26.4). Although the antimicrobial mechanisms of plasma have not been completely elucidated, they generally involve the degradation of cell membranes and essential biomolecules (such as genetic material, proteins, and enzymes) by exposure to the

UV radiation and the reactive species present in plasma (14). The antimicrobial effectiveness of cold plasma can vary widely depending on the plasma generation methods applied and the plasma composition. Some plasma-generating methods include radio frequency discharge, glow discharge, inductively coupled plasma, barrier discharge, plasma jets, and microwave regimes (14, 16). Although different plasma compositions are effective in inactivating microorganisms in different types of foods, the presence of oxygen enhances plasma's antimicrobial action (14).

Cold plasma has shown promise as a nonthermal processing alternative for microbial decontamination of foods. However, given the diversity of methods in which it has been studied (and the small scale in which they have been implemented), more research is needed to evaluate its scalability and applicability in food processing operations.

Table 26.3 summarizes results of studies involving plasma for reducing microbial loads in different types of foods.

COATINGS

The application of coatings to materials commonly used in food processing facilities (and throughout the transport chain) is a concept that has been widely studied and represents an attractive alternative to reduce microbial cross-contamination during the manufacture and distribution of foods (Fig. 26.5). According to the Centers for Disease Control and Prevention, the contamination of surfaces in the food preparation and processing environment is among the top five risk factors responsible for foodborne outbreaks (24).

Table 26.3 Results of studies on antimicrobial plasma applications in foods

Plasma type	Food	Microorganism	Logarithmic Reduction	Reference
Cold atmospheric plasma (air)	Cherry tomatoes and strawberries	*Salmonella enterica* serovar Typhimurium, *Listeria monocytogenes*, *Escherichia coli*	3.5–4.2	18
Cold atmospheric plasma (dry air or nitrogen)	Almonds	*Salmonella*, *E. coli* O157:H7	0–2	45
Cold atmospheric plasma (argon)	Whole black pepper	*Salmonella enterica*, *Bacillus subtilis*, *Bacillus atrophaeus*	2.8–4.1	46
Low pressure cold plasma (nitrogen, argon, helium)	Meat	Psychrotrophs, mesophiles, yeasts, and molds	1–6	21
Atmospheric pressure plasma (argon)	Lettuce, carrots, and tomatoes	*E. coli*	0–2	20

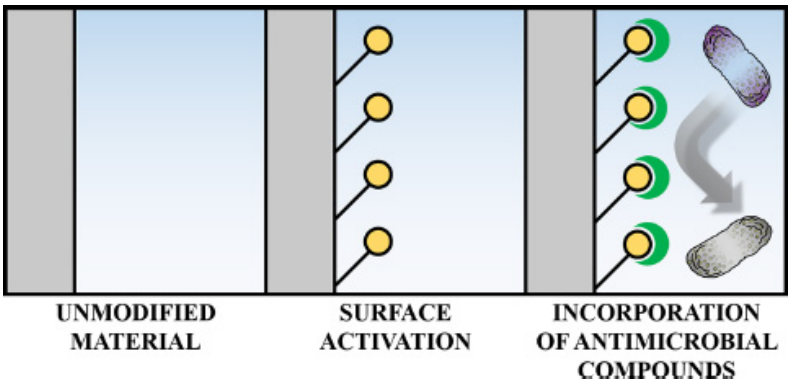

Figure 26.5 Application of a functional compound to an inert surface.

The surfaces of both organic (such as plastics) and inorganic (such as stainless steel) materials can be modified to provide a specific functionality. Most studies conducted in this field have focused on developing antimicrobial or antifouling materials (25). The rationale behind applying a thin coating on the surface of commonly used materials is that a thin coating would allow the bulk materials to retain their mechanical, chemical, and thermal properties, thereby enabling them to preserve their functionality and at the same time serve as an antimicrobial agent

(26). This could thereby decrease the use of chemicals for disinfecting food processing plants.

The materials used in food processing facilities are typically chemically inert. Before any type of coating is applied, the surfaces of these materials should be activated so that they contain functional groups, change their hydrophobicity, or change their topography and surface area. The functional groups (such as carboxylic, hydroxyl, amine, or thiol) can further react with different types of compounds. By changing the hydrophilicity or the topography, these materials can also retain different compounds or polymers on their surface through a variety of surface modification techniques (25, 27). Surface functionalization can be accomplished through the application of UV light irradiation, ozone, plasma, or corrosive chemicals such as chromic acid or piranha solution (25, 27–29).

The surface modification technique to be used depends on the type of material to be coated. For inorganic substrates, such as stainless steel, the most common techniques involve chemical vapor deposition and electroplating. In chemical vapor deposition, a compound is applied to a surface by condensation from a gaseous phase, which is created through high temperatures, with or without vacuum. This condition limits the range of compounds that can be applied, as they can normally be only low-molecular-weight compounds (25, 30). In electroplating, a compound is deposited on the surface of the material through diffusion. The driving force is normally a difference in voltage between the liquid medium that contains the active compound and the material to be coated (25).

Plastic materials are more flexible regarding the surface modification techniques that can be applied to them. After surface functionalization, antimicrobials or other active compounds can be applied through covalent immobilization, graft polymerization, layer-by-layer deposition, self-assembled monolayers, or reactive blending (25, 31). In each of these methods, bioconjugation techniques can be used to promote the formation of covalent bonds (32).

A wide range of antimicrobial compounds have been used to coat different materials (organic and inorganic), such as metal-based compounds, quaternary ammonium compounds, polycations, essential oils, peptides, and light-activated compounds. The mechanisms by which these compounds inactivate microorganisms include damage to the cell membranes and essential biomolecules. Because these antimicrobials are immobilized, they should not be released from the bulk material, thereby preventing contamination and colonization of surfaces by microorganisms (25).

Even though antimicrobial coatings can be effective against Gram-positive and Gram-negative bacteria, as well as against yeasts and molds, their application in food processing facilities has been limited. One of the main drawbacks of this technology is the limited stability and durability of coatings under adverse conditions (high temperatures or extreme pH). In addition, scaling up some surface modification techniques is a challenge (25). Table 26.4 provides examples of

immobilization of antimicrobial compounds on food contact surfaces and their biocidal efficacy.

Table 26.4 Examples of the use of antimicrobial coatings for food applications

Antimicrobial	Support	Microorganism	Logarithmic reductions	Reference
Lysozyme	Silicon rubber	*Micrococcus lysodeikticus*	Not reported (absorbance assay)	47
N-Halamines	Stainless steel	*Listeria monocytogenes*	2.5	29
Nisin	Clay (montmorillonite)	*Enterococcus faecium*	Not reported (inhibition zone assay)	48
Polyethyleneimine (polycation) with or without *N*-halamines	Polypropylene	*Escherichia coli* O157:H7	0.6 to >4	31
Antimicrobial peptide	Titanium	*Porphyromonas gingivalis*	<1	49

UV IRRADIATION

The UV range of the light spectrum includes wavelengths from 200 nm to 400 nm. UV radiation in the range of 200 to 280 nm (UV-C) inactivates microorganisms, which is attributed mainly to the dimerization of pyrimidine units, which alters or eliminates DNA replication, causing cell death (33). In spite of its proven efficacy against microorganisms (predominantly bacteria and viruses, although molds and yeasts may also be affected), the use of UV irradiation in food processing has been limited by its ability to penetrate foods, so the technology has been applied more frequently to the disinfection of surfaces (33, 34), which includes surfaces in the processing environment that have direct contact with foods or raw materials, such as conveyor belts, utensils, and processing equipment (35).

Two of the main factors that influence the antimicrobial efficacy of UV irradiation are the applied dose and its intensity. The intensity is normally expressed in units of energy per unit of time and area. Vegetative cells are more sensitive to UV irradiation than spores. Molds and yeasts require higher doses and intensities than bacteria to be affected. In general, doses high enough to cause irreversible damage in DNA are needed to provide a lethal effect (33). Another factor that determines the efficacy of UV irradiation is the medium that contains the microorganisms. The efficacy of UV irradiation tends to be higher when it is applied to liquid foods

(although the presence of organic matter and suspended particles [Fig. 26.6] may compromise its effect by absorbing part of the light irradiation). In contrast, a shielding effect can be observed in solid foods, where the roughness of the surfaces may leave microorganisms unexposed (33, 35), which may diminish or even eliminate any biocidal effect. However, UV irradiation has the potential to be applied as a complementary treatment to reduce microbial contamination in solid foods, in combination with other antimicrobial agents or technologies (35). This could also lead to a greater preservation of the chemical integrity of macro- and micronutrients, as they can be adversely affected by UV irradiation (33, 35, 36).

Several UV light sources are available. Their effectiveness depends on their intensities, as well as the amount of penetration that can occur through the sample. These light sources have largely been tested on liquid foods. Mercury lamps are among the most common sources and are used for water disinfection. They consist of bulbs that contain mercury and an inert gas (normally argon), which are ionized sequentially (argon excites mercury) through the application of an electric current. The ionization of mercury produces UV light at ~254 nm, which inactivates microorganisms. Mercury lamps are of low or medium pressure, which relates to the partial pressure of the mercury gas. Excimer lamps contain noble and halogen gas mixtures, in which ionization produces UV light in the 120- to 380-nm range. In microwave UV lamps, mercury gas is ionized by a magnetron instead of electrodes. The magnetron is used as the source of the electromagnetic waves that ionize argon and mercury (36).

Different designs of UV lamps have been developed to reduce microbial loads in liquid foods. Most consist of UV mercury lamps protected by a quartz cylinder. The liquid food is circulated around the UV lamps, allowing the liquid to form a very thin film, which allows sufficient penetration of the UV irradiation and greater antimicrobial activity (33, 35). However, some of these designs are still limited in their applicability, due to difficulties in scaling up.

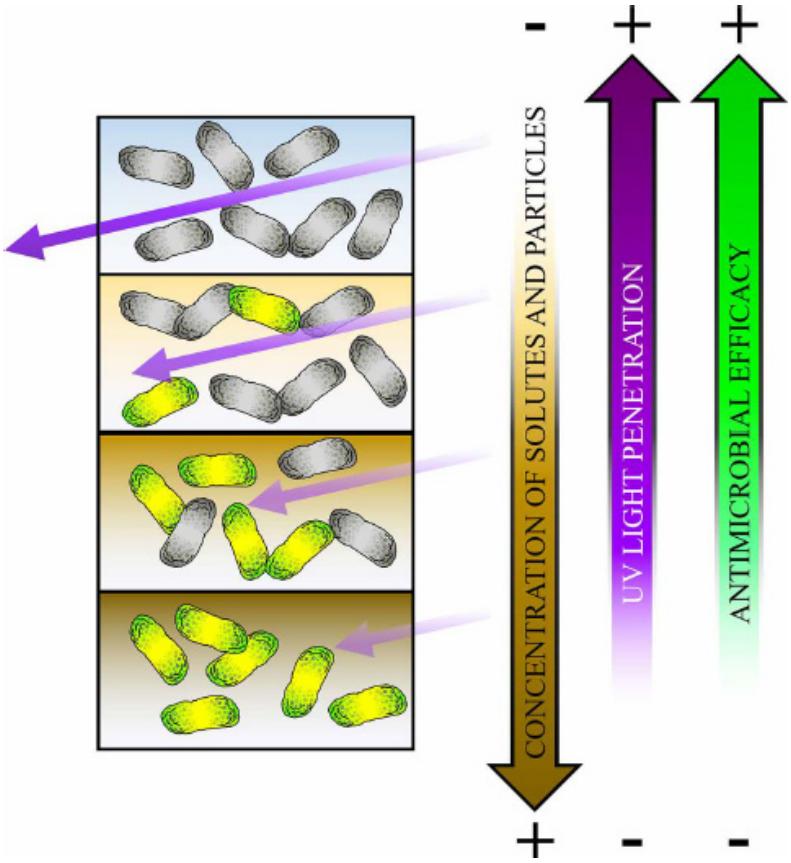

Figure 26.6 Effect of suspended particles and solutes on the antimicrobial activity of UV irradiation.

Table 26.5 provides examples of applications of UV irradiation to inactivate microorganisms in foods.

CONCLUDING COMMENTS

This chapter presents several emerging physical methods for food processing and preservation, such as DPCD processing, filtration, cold plasma treatment, antimicrobial coating, and UV irradiation. For each method, the principle of operation, mechanism of antimicrobial action, types of food products where these methods can be used, their unique benefits, and their potential limitations are discussed. Generally, these technologies have significant potential benefits over conventional processing technologies, such as improved energy efficiency, enhanced quality and safety of food, and longer shelf life. However, while these technologies are effective against pathogenic and spoilage vegetative microorganisms and viral particles, they are not as effective in inactivating spores. This gap can be addressed by a rational combination of two or more complementary processing methods. More research is needed to explore these combinations. Future work is also necessary to scale up these processes to a commercial level and achieve regulatory approval.

Table 26.5 Examples of UV irradiation for inactivating microbes in foods

UV light conditions	Food or medium	Microorganism	Logarithmic Reductions	Reference
UV-A light combined with gallic acid and lactic acid (320–400 nm)	Water	*Escherichia coli* O157:H7	≤4.7	50
UV-A light combined with gallic acid and lactic acid (320–400 nm)	Lettuce and spinach leaves	*E. coli* O157:H7	~2–3	50
UV-C light (254 nm) in combination with ultrasound and acidic electrolyzed water	Salmon	*Listeria monocytogenes*	0.5–0.8	51
UV-C light (200–280 nm)	Cheese	*Pseudomonas* spp.	0.8–2.1	52
UV-C light (specific wavelength not reported)	Cauliflower	*L. monocytogenes*, *E. coli* O157:H7, yeasts, and molds	0.17–1.8	53

Chemical Preservatives and Natural Food Antimicrobials

The quality of food products declines from the point of harvest through animal slaughter and processing to consumption. Quality loss may result from microbiological, enzymatic, chemical, or physical changes to food structure and makeup. Consequences of microbiological changes include the introduction of hazards to consumer health due to the contamination and subsequent growth of microbial pathogens and the secretion of microbially produced toxins (e.g., mycotoxins and staphylococcal enterotoxin). Economic losses may occur through microbiological spoilage and resultant changes to the food, rendering it unpalatable to consumers. Food preservation technologies, including the application of antimicrobial preservatives, protect foods from the deleterious effects of microbial growth and inherent deterioration. Antimicrobial preservatives are often applied as one type of antimicrobial hurdle during food processing, in combination with other forms of food preservation: heating, refrigeration and/or freezing, water activity (a_w) reduction, nutrient restriction, acidification, use of modified-atmosphere packaging, fermentation, or various forms of nonthermal processes (e.g., application of high hydrostatic pressure and irradiation).

For the purposes of this chapter, food antimicrobials are defined as chemical preservatives added to or present in foods that retard growth of or kill microbes, but they do not include therapeutic antibiotic-type compounds used for growth promotion or disease treatment in food animals. Most food antimicrobials are bacteriostatic or fungistatic at usage levels, inhibiting microbial

growth rather than exerting microbicidal effects. Thus, food antimicrobials do not preserve food indefinitely. Food antimicrobials are often used in combination with other preservation procedures; targets for food antimicrobials are pathogenic and spoilage microorganisms. Food antimicrobials are legally defined as preservatives, though the term also describes additives functioning to preserve the food in question, including antibrowning agents (e.g., citric acid) and antioxidants (e.g., butylated hydroxyanisole) [Code of Federal Regulations Title 21 (21 CFR), §101.22(a)(5) (https://www.ecfr.gov/cgi-bin/text-idx?SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&node=pt21.2.101&rgn=div5) and §170.3(o) (2) (https://www.ecfr.gov/cgi-bin/text-idx?SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&node=pt21.3.170&rgn=div5)].

Herein, antimicrobial compounds are divided into the traditional and the naturally occurring. Antimicrobials are classified as traditional when they have been (i) used for many years, (ii) approved by many countries and/or regulatory bodies for inclusion in foods as antimicrobial agents, or (iii) produced by synthetic processes as opposed to natural extracts (e.g., industrial fermentation of nisin from *Lactococcus lactis* subsp. *lactis*). Ironically, many synthetic and traditional food antimicrobials are found in nature; examples include acetic acid from vinegar, lactoperoxidase in fluid milk, and nitrate species in some food crops. Finally, this chapter focuses on recent developments in food antimicrobial research and applications.

FACTORS AFFECTING ACTIVITY

The observed activity of antimicrobials depends on multiple factors related to the food product, its processing and postprocess handling, the antimicrobial itself, and the microorganism(s) targeted. Food preservation is best achieved when the microorganism(s) to be inhibited, antimicrobial type and concentration, food storage

conditions, food pH and buffering capacity, and the presence of other agents that affect shelf life are known and accounted for. Taylor et al. (1) reviewed these factors, differentiating intrinsic, extrinsic, process-related, and microbial factors. Davidson and Branen (2) further differentiated the microbial factors into those associated with the microorganism(s) targeted for inhibition and those related to the antimicrobial's structure and consequent functionality (i.e., physicochemistry).

Intrinsic factors are those inherent to the food product's physicochemistry, including food physical structure, nutrient availability and profile (including, by correlation, the product aw), pH and buffering capacity, the presence of physical barriers to microbial penetration into edible components of the food (e.g., hides, skin, husks, or rinds), the oxidation-reduction potential, and the presence of naturally occurring or fermented antimicrobials and compounds that may interact with these antimicrobials. Extrinsic factors include the temperature of food storage postprocessing, the duration of storage until the end of shelf life or consumption, the atmospheric composition of the storage environment or packaging, and the relative humidity of the storage environment and packaging. Process-related factors include changes in food composition, microbiota shifts, and changes in microbial populations and in food microstructure and/or moisture resulting from processing (e.g., thermal, dehydration, or high-pressure processes). These influence microbial growth in the food in an interactive manner, leading many food processors to apply a hurdle technology approach incorporating the use of antimicrobials in addition to control of other factors in order to prevent microbial growth and product safety or quality loss (3, 4).

Food pH is potentially the most significant intrinsic factor directing the effectiveness of many food antimicrobials, including the organic acids and different antimicrobial peptides (e.g., lysozyme and bacteriocins), though not always through similar mechanisms. The weak organic acids and the fatty acids are most effective in their undissociated state, as they are better able to passively diffuse

through the microbial membrane. This arises from a lack of charge and their organic nature, yielding greater hydrophobicity to the acid species that facilitates access and movement through the lipophilic core of the microbial membrane between its leaflets. Nevertheless, antimicrobial polarity has also been reported as highly important, as it affects the antimicrobial's capacity to be suspended or solubilized into the aqueous phase of a food product. Hence, many antimicrobials must possess both hydrophobicity and polarity for optimal access to, and inhibition of, microbial organisms in foods (2, 5). Finally, it is worth noting that many food antimicrobials discussed herein, particularly many of the spice-derived essential oil components, bearing GRAS (generally recognized as safe) status or affirmation do not do so for their food preservation or antimicrobial properties but for other functionalities in the food (e.g., as a flavorant or stabilizer or for pH control).

TRADITIONAL ANTIMICROBIALS

Organic Acids and Their Derivatives

A review of recent research suggests that the most effective organic acids used as food antimicrobials are monoprotic, including acetic, lactic, propionic, sorbic, and benzoic acids, as well as some of the fatty acids (e.g., caproic acid and butyric acid) (6, 7). Doores (8) reviewed the research available on food antimicrobial applications of organic acids and the tolerances to these preservatives of different foodborne bacteria and fungi, indicating that while some have antimicrobial activity, multiprotic acids (e.g., malic, tartaric, and citric acids) exhibited less antimicrobial activity and/or microbial inhibition than monoprotic acids. The antimicrobial utility of organic acids is thought to result largely from the undissociated acid's penetration into the microbial cytoplasm and the subsequent acidification of the cellular cytoplasm, resulting in initiation of the cell's acid tolerance and stress response systems. Thus, application of organic acids is generally limited to foods with

reduced pH (pH ≤ 5.5), as most organic acids possess at least one pK_a (acid dissociation constant) ranging from pH 3.0 to 5.0 (9).

Research suggests that the enhanced capacity of organic acids to penetrate the microbial membrane in the undissociated state versus the dissociated acid anion state (10). Nonetheless, over the last 2 decades, evidence has accumulated indicating that microbial inhibition is not solely the result of cellular acidification and energy regulation uncoupling (11–13). In fact, Koczoń (14) reported that benzoic acid salt species activity was less affected by pK_a than by the total undissociated-acid content. This would need to be balanced against the content of acid anion extracellularly and the organism's capacity to tolerate the acidulant applied for the microorganism(s) of interest (11). Taylor et al. (1) summarized these mechanisms, working to integrate these explanations for microbial inhibition via organic acid antimicrobials. In addition, perturbation of microbial membranes has been reported to occur, resulting in permeabilization of acid-treated cells, which increases the opportunity for leakage of their contents (15, 16).

It is known that microorganisms surviving sublethal environmental stressors may develop enhanced tolerance to subsequent exposure to antimicrobials, which may be termed tolerance, adaptation, or habituation based on the method of stress application and the cellular responses leading to the cell's enhanced survival (17, 18). In foods, adaptation of cells to sublethal stressors can be of concern also for the development of cross-protective effects against other stressors (19, 20). Although there is little evidence of antimicrobial adaptive responses being sustained over multiple generations, there is a recent report of foodborne *Escherichia coli* strains that possess and share mobile genetic elements carrying genes encoding resistance to quaternary ammonium sanitizers (21). Nonetheless, application of a more severe antimicrobial challenge to contaminating microbes will result in a lower likelihood of microbial survival during extended holding, even despite previous adaptation (22).

Acetic Acid and the Acetates

Acetic acid (pK_a, 4.75; 60.05 Da) (Fig. 27.1) is the primary component of vinegar and also may be microbially oxidized from ethyl alcohol, and its cationic salts, as well as diacetate salts and dehydroacetic acid, are some of the oldest known food antimicrobials and preservatives (23). In the United States, acetic acid and calcium and sodium acetates are identified by the FDA as direct food substances affirmed as GRAS (21 CFR §184) (https://www.ecfr.gov/cgi-bin/text-idx?SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&node=pt21.3.184&rgn=div5), while dehydroacetic acid is approved for direct addition to certain foods (21 CFR §172) (https://www.ecfr.gov/cgi-bin/text-idx?SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&node=pt21.3.172&rgn=div5). for pH control in foods, or as a pickling and brining agent. With respect to meat, poultry, and egg product manufacture, the U.S. Department of Agriculture (USDA) Food Safety and Inspection Service approves the use of multiple commercial products containing acetic acid or diacetate for pH control during meat animal harvest, in further product manufacture, or as antimicrobial agents for application onto or in formulations of various further processed meat products (e.g., fully cooked sausages) (24). Doores (8) summarized research that indicated that fungal microbes, including *Saccharomyces* and *Aspergillus*, were inhibited at higher concentrations than were the Gram-positive bacteria *Bacillus*, *Clostridium*, and *Staphylococcus*, as well as indicating that multiple Gram-negative bacteria were also susceptible to the acid. Geng et al. (25) recently reviewed the literature discussing the gene expression-mitigated tolerance of *Saccharomyces cerevisiae* to acetic acid, indicating over 300 genes encoding proteins participating in the organism's tolerance responses to the antimicrobial, including cell wall reconstruction, acetate efflux for detoxification, and metabolism of acetate to acetyl coenzyme A, as well as pH and proton efflux. However, Svoboda et al. (26) reported the inability to reduce yeast and mold counts on

melons following application of a surface sanitizer containing 0.78% acetic acid, peracetic acid, and hydrogen peroxide.

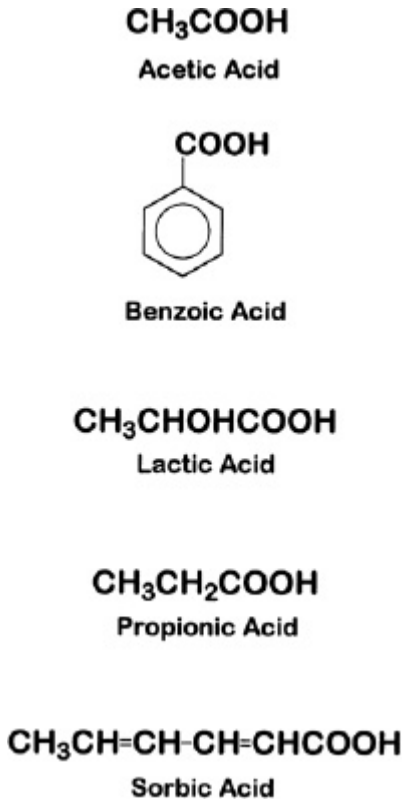

Figure 27.1 Organic acids used as antimicrobial food preservatives.

Bacteria sensitive to acetic acid application include both Gram-positive and -negative microbes (including pathogenic organisms), specifically *Listeria monocytogenes*, *Shigella flexneri*, *Salmonella enterica*, *Staphylococcus aureus*, *E. coli* O157:H7, and Shiga toxin-producing *E. coli* (STEC) (27). Sullivan et al. (28) likewise reported no differences in the inactivation of *L. monocytogenes*, *S. enterica*, and *E. coli* O157:H7 in egg pickling brine formulated to contain 2% acetic acid at pH 4.0 over 10 days' storage, though the Gram-positive *S. aureus* was still detectable after 5 days, whereas other pathogens were reduced to nondetectable levels. Similar results were obtained where *S. enterica*, *L. monocytogenes*, *E. coli* O157:H7, and *S. aureus* were reduced by 4.6 to 5.0 $\log_{10}$ CFU/g following 24 h of brining in a pickle solution containing 1.0 M acetic acid, 0.9 M NaCl, and 5 mM benzoate (29).

Bacterial pathogens have been reported to tolerate the application of nonlethal concentrations of acetic acid and the acetates by multiple mechanisms, including general stress response systems (e.g., *rpoS*) as well as various chaperone-type proteins and other acid tolerance response systems. Burin et al. (30) reported from a study of 79 isolates of *Salmonella enterica* belonging to multiple serotypes that *rpoS* was activated following 24 h of acid stress (4% [vol/vol] acetic acid, pH 6.0 and 5.0), but no stress response operon expression was detected in cells challenged with the acid adjusted to pH 4.0, presumably due to inactivation. These authors also reported that *Salmonella* cells were better able to withstand equivalent pH and concentration of lactic acid challenge, presumably due to a higher relative content of dissociated lactate versus acetate based on different pK_as of the acidulants and relative concentrations of dissociated and undissociated acids at the lowest experimental pH. Similar trends were also observed for *L. monocytogenes* isolates challenged with multiple organic acid and acid anion salts at pH 5.0 to 8.0, where acetic acid exhibited a lower MIC than did lactic, citric, malic, or propionic acid or salts of benzoate and sorbate at pH 5.5 (31).

Similar to *Salmonella* and other Gram-negative enteric pathogens, *L. monocytogenes* possesses the capacity for acid tolerance, possessing multiple systems for activating sublethal acid tolerance and cross-protection against other environmental stressors following acid shock (32, 33). Nonetheless, genetically encoded antimicrobial resistance systems and multidrug resistance systems identified for this pathogen, like others, do not appear to confer protective effects against food preservatives, including acetic acid and/or the acetates at concentrations sufficient to produce inhibition (34). *Campylobacter jejuni* possesses multiple stress-responsive systems, including acetic acid stress response and tolerance, though it has been reported to possess systems other than RpoS (35, 36).

Recently published research detailing the utilization of acetic acid or the acetates has focused on exploring novel methods of

antimicrobial delivery to the food system, as well as determining the capability of multipreservative and multihurdle processing technologies to produce microbial inhibition and control in various foods. Gaseous acetic acid application between 0.3 to 4.7 mM to surfaces of fenugreek seeds reduced *Salmonella enterica* serovar Enteritidis counts by 3.3 to 4.1 $\log_{10}$ CFU/g, and reductions of 3.6 to 4.0 $\log_{10}$ CFU/g in numbers of the pathogen were similarly achieved on black peppercorns following gaseous acid application (37). Greater reductions were observed on identically treated samples inoculated with *E. coli* O157:H7 following treatment, including a >5.0-$\log_{10}$-cycle reduction in *E. coli* O157:H7 on fenugreek seed and peppercorn surfaces treated with 0.6 or 4.7 mM gaseous acid for at least 3 h (37). Supplementation of 1% acetic acid with 8 mM zinc oxide nanoparticles produced 1.0- to 4.0-$\log_{10}$-cycle differences in numbers of *S. aureus*, *E. coli*, and *L. monocytogenes* organisms on fresh sheep meat surfaces following 12 days of refrigerated storage posttreatment, with no discoloration detected on treated meat for samples inoculated with Gram-positive pathogens (38). Bae and Lee (39) reported antagonistic effects between organic acids, including acetic acid, and NaCl when the acid was combined with 3% NaCl in a pickle brine against *E. coli* O157:H7 and *Salmonella*, though a synergistic inhibition effect between acid and NaCl was observed against *L. monocytogenes*. These authors concluded that acid structure in combination with osmotic pressure impacted subsequent interaction of antimicrobials, replicating similar effects achieved in previous research, though the impacts of dual membranes in the Gram-negative versus the Gram-positive pathogens were not fully elucidated (39). Conversely, 0.5 mg/ml acetic acid in combination with 5,000 ppm of the anionic surfactant sodium dodecyl sulfate (SDS) produced reductions in *S.* Typhimurium on blueberry surfaces equivalent to that produced by 200 ppm free chlorine, without significant changes to berry anthocyanin content or firmness (40).

Apart from acetic acid, the acetates and diacetates possess utility as food preservatives and continue to be incorporated into research

determining the efficacy of antimicrobial technologies for food safety and quality preservation. In comparing the inhibition of multiple Gram-positive and -negative bacterial pathogens, 3% acetic acid and potassium acetate subjected to electrolysis demonstrated equivalent reductions in *S. enterica* and *L. monocytogenes* populations, though the potassium acetate application produced significantly greater reductions in numbers of *S. aureus* during processing than protonated acid (41). Recent research has focused on the utilization of pH-buffered acetic acid-containing vinegar antimicrobial interventions for pathogen inhibition in fully cooked cured and uncured meat and poultry products. McDonnell et al. (42) reported that the addition of 2% buffered vinegar or 3% cultured sugar vinegar products to uncured sliced roast beef prevented *L. monocytogenes* growth over 12 weeks' storage at 4°C, though growth of the pathogen was observed for alternatively cured hams and turkey breast products similarly inoculated and formulated with antimicrobials. Similar inhibition of *L. monocytogenes* inoculated onto uncured ready-to-eat (RTE) turkey breast was reported with application of potassium and sodium-buffered vinegar antimicrobial solutions during 9 weeks of refrigerated storage, with a <1.0-$\log_{10}$ increase in pathogen loads detected (43). Nonetheless, outgrowth of *Clostridium perfringens* spores was inhibited in naturally cured (50 ppm ingoing NO_2) turkey breasts formulated with various clean-label antimicrobial products, including dry vinegar and lemon-vinegar blend products, although a fruit extract product appeared to be superior to acetate-containing products for spore germination prevention (44). Pork bologna products formulated with 0.0625, 0.1875, or 0.25% sodium diacetate and sodium lactate and surface treated with the bacteriocin pediocin demonstrated reduced *D* values at cooking temperatures for *L. monocytogenes*, indicating reduced survival of the pathogen (45).

Diacetates, similar to acetic acid and the acetates, have been explored in recent years for antimicrobial utility via multihurdle applications in animal-and plant-derived foods. Ahn et al. (46) summarized the research investigating the combination of

irradiation (ionizing) with antimicrobials for manufacture of RTE poultry products, identifying the combination of sodium diacetate with irradiation processing as effective for *L. monocytogenes* inhibition during postprocessing storage. More recently, incorporation of 5,000 ppm sodium diacetate into calcium alginate films along with plant-derived antimicrobial essential oil and the antifungal natamycin produced synergistic inhibition of *L. monocytogenes* on broccoli, enhanced by the application of 0.8 kGy gamma irradiation (47).

Benzoic Acid and the Benzoates

Chipley (48), citing Jay (49), identified sodium benzoate as the first federally approved food preservative in the United States. Currently in the United States, the acid species and the benzoates are identified as GRAS and approved for use at up to 0.1% in foods (21 CFR §184). Benzoic acid has a pK_a of 4.19 and is very poorly water soluble, while the sodium salt possesses significantly greater water solubility (66% [wt/vol]). Benzoic acid naturally occurs in cranberries, plums and prunes, cinnamon, and cloves, as well as many other berries (50). Koczoń (14) reported that while benzoate salt pK_a alone did not fully describe the antimicrobial activity against the yeast *Pichia anomala*, efflux mechanisms were activated upon benzoate application, resulting in large amounts of high-energy molecules being expended to combat cellular acidification, negatively impacting energy management within the cell. Critzer et al. and Creamer et al. (51, 52) also described multiple genetically encoded mechanisms for benzoate tolerance in bacterial pathogens including *E. coli* O157:H7 and *L. monocytogenes*. Nonetheless, recently reported data indicate that the pathogen surrogate *E. coli* K-12 can lose antibiotic resistance capacity through sacrifice of inducible multiple antimicrobial resistance (*mar*) operon elements following adaptation to benzoic acid (20 mM) stress over the course of multiple generations of the cell line (53).

Currently in the United States, the benzoates are primarily employed as antifungal agents during processing of foods, though research has also reported antibacterial effects. As cited by Davidson et al. (50), Chipley (48) identified benzoic acid as inhibitory towards yeasts at concentrations ranging from 20 to 700 μg/ml, with higher concentrations required for mold inhibition (20 to 2,000 μg/ml). In recent years the benzoates and benzoic acid have been repeatedly tested for foodborne microbe inhibition efficacy in combination with other processing interventions. Er et al. (54) reported that the minimum biofilm-inhibiting concentrations of sodium benzoate against poultry-recovered *Salmonella* capable of forming biofilms were 20- to >60-fold greater than the MICs of sodium benzoate and the *p*-hydroxybenzoate derivatives methyl- and propylparaben. Addition of 1,000 ppm sodium benzoate to orange and apple juices followed by application of ultrasound processing reduced the time to a 5.0-$\log_{10}$-cycle reduction in *E. coli* O157:H7 numbers by 22.4 and 35.6 min versus control juices, respectively (55). Sewlikar and D'Souza (56), however, reported no inhibition of the O157 and non-O157 STEC isolates by the application of 0.1% sodium benzoate (non-acidity controlled) or 0.1% pH 3.75 sodium benzoate versus controls at 25 or 37°C. These authors did detect reductions in STEC isolates of >6.0 $\log_{10}$ cycles following application of a commercial plant essential oil extract containing pH-adjusted (pH 3.75) benzoate antimicrobial product, indicating that the antimicrobial effects were primarily due to interaction of the acidulant and essential oil fractions of the antimicrobial product.

In addition to novel combinations of benzoate and other chemical and physical processing hurdles, innovations in delivery methods of benzoic acid and plant extracts containing benzoic acid were recently reported. Sagoo et al. (57) found that the coapplication of chitosan with benzoate enhanced the antifungal activity of the organic acid against spoilage yeasts. Recently, the encapsulation of benzoic acid and essential oils of spice plant extracts containing benzoic acid demonstrated similarly enhanced activity of the organic acid against foodborne bacterial and fungal microbes.

Khalili et al. (58) demonstrated inhibition of the mycotoxigenic mold *Aspergillus flavus* by the use of chitosan-benzoic acid nanogels, with and without encapsulated thyme essential oil, reporting that 1,500 mg/liter of nanogel is capable of fully inhibiting mold growth in medium. Encapsulation of cinnamon oil (0.05 or 0.1%) in chitosan nanoparticles produced significant bacteriostatic effects versus nonencapsulated essential oil or control-treated samples in beef patties during posttreatment refrigeration against *Enterobacteriaceae*, yeasts and molds, and *S. aureus* (59). Similar findings were obtained with beef cutlets treated with benzoic acid-chitosan nanogels entrapping rosemary essential oil against *S.* Typhimurium on fresh beef surfaces during 6 days of refrigerated storage posttreatment (60).

The benzoates, like other organic acids discussed herein, have been explored for their utility in limiting the shedding of human fecal pathogens in food animal production systems, allowing more comprehensive food safety management across the farm-to-fork continuum. Lynch et al. (61) reported that supplementation of a standard pig diet with benzoic acid did not result in significantly reduced *Salmonella* shedding versus controls but in a small subset did improve the recovery of *Salmonella* from animal lymph nodes (50% recovery from the treated group versus 77% recovery from the control group) following animal euthanasia and sample collection. Broom (62), reviewing the available literature on the use of organic acids in poultry production, noted similar findings indicating limited utility of benzoic acid in reducing pathogen shedding in turkeys and broiler chickens, though significantly less detection of the pathogen was mentioned. Benzoic acid, along with other antimicrobial organic acids, may exert multiple useful effects in modulating gut health of the livestock animal, resulting in reduced pathogen shedding and/or immuno-modulatory effects, leading to reductions in the risk of pathogen contamination during animal harvest and slaughter (62).

Lactic Acid and Lactates

Lactic acid possesses a pK_a of approximately 3.8 (90.08 g/mol) and occurs in both d- and l-isomers, though the l-isomer of the acid has been reported to be more effective than the d-form for inhibiting bacterial pathogens (63). Lactic acid is anaerobically fermented from glucose by the lactic acid bacteria through pyruvate via lactate dehydrogenase and the reducing equivalent NAD. Depending upon the application, lactates and lactic acid have been incorporated into food products as antimicrobials, antioxidants, acidulants, and/or flavorants, though they are described as having a clean flavor, not necessarily contributing significantly to product flavor at normal usage concentrations.

Similar to other organic acids, lactic acid and the lactates are reported to inhibit microbial growth by uncoupling of cellular metabolism regulation through cytoplasmic accumulation of acid molecules (64). Graves et al. (65) reported reduced ethanol production by fermentative yeast following 4% lactic acid exposure at multiple test pH values in a corn mash fermentation. Alakomi et al. (15) also described membrane permeabilization effects of lactic acid on Gram-negative bacterial membranes. Papadopoulos et al. (66) reported that lactate addition to processed meats discouraged lipid oxidation and product discoloration. More recent research has reported similar findings, where addition of 1.5% lactate to sausages resulted in reduced oxidation product formation compared to control sausages (67). The USDA Food Safety and Inspection Service currently approves the use of lactic acid to decontaminate meat animal carcasses and intact cuts up to 5% (application solution temperature may not exceed 55°C), a concentration previously reported to enhance the antimicrobial efficacy of lactic acid for pathogen reduction (68, 69). Additionally, lactic acid may be applied at up to 2.8% to beef heads and tongues, topically as a mixture with other organic acids to RTE meat products, to comminuted beef products, or as an antimicrobial fermentate-type product containing acetic acid and microbially fermented lactic acid for formulation of further processed meat and poultry products (24).

A great deal of research has explored the antimicrobial utility of lactic acid and the lactates for the manufacture of processed meat, poultry, and seafood items to prevent the growth of bacterial pathogens, including *L. monocytogenes*, *S. aureus*, *Salmonella*, and the clostridia (30, 70–73). As with other organic acid antimicrobial applications, recent research has sought to quantify the antimicrobial utility of the acidulant in combination with other antimicrobial hurdles. Mohan and Pohlman (74) applied organic acids with a nonionic surfactant to decontaminate beef trimmings and reported that the application of 30 g/liter lactic acid and surfactant did not outperform the application of lactic acid alone. Additionally, *E. coli* O157:H7 counts were not reduced by 30 g/liter lactic acid compared to controls (74). *E. coli* O157:H7 and non-O157 STEC were reduced by 1.2 and 1.6 $\log_{10}$ cycles on beefsteaks following application of 3 and 4% lactic acid to steak surfaces (75). Similar reductions were observed on pork surfaces following 4% lactic acid application (75). Verotoxin-producing *E. coli* was reduced by >3.0 $\log_{10}$ CFU/g on beefsteaks following application of 5% lactic acid and 0.8 to 0.9 kGy; similar reductions in *Salmonella* counts were also achieved (76). Aymerich et al. (77) likewise demonstrated synergistic inhibition of *L. monocytogenes* and *Salmonella* when applied in combination with high hydrostatic pressure. Finally, *L. monocytogenes* on carp fillets was prevented from growth by the application of thymol and 1 or 2% sodium lactate over 5 days at 4°C, while *S.* Typhimurium numbers declined on carp fillets following treatment (78).

García-Díez et al. (79) reported that the combined application of 3.3% sodium lactate and essential oils of oregano and garlic produced bacteriostatic effects on *Salmonella* and *L. monocytogenes* in frankfurters. Utilization of a cultured sugar-and-vinegar antimicrobial produced listeriostatic inhibition of *L. monocytogenes* in franks over 4 weeks of refrigerated storage, resulting in a 0.4-$\log_{10}$-cycle decline in pathogen numbers versus controls formulated with 1.68% lactate and nitrites (42). Combining 2.8% potassium lactate and 107 PFU/cm^2 anti-*L. monocytogenes*

phages produced a 4.0-$\log_{10}$-cycle reduction in pathogen numbers on sliced turkey held at 4°C after 28 days (80). Similarly, 0.75 to 3% sodium lactate and 10.5 or 21 g/kg lactic acid inhibited *L. monocytogenes* growth in queso fresco, resulting in a 3.0-$\log_{10}$-cycle reduction in pathogen growth versus treatments with caprylic acid, nitrite, and combinations of antimicrobials (81).

Sorbic Acid and the Sorbates

Sorbic acid and the sorbates are unsaturated small fatty acid and acid salts useful for the preservation of multiple types of human foods against fungal and bacterial microorganisms. Luck (82) and Stopforth et al. (83) provided reviews of the utilization of sorbic acid and its salts in the U.S. and European food industries. Stopforth et al. (83), citing previous works, indicated that sorbic acid was first recovered from the mountain ash tree, possesses a pK_a of 4.75, and, similar to benzoic acid, has much greater water solubility (32 to 50% depending upon sorbate salt species) as the dissociated acid anion than as the protonated weak acid (0.15 g/100 ml) (84, 85). A great deal of research has been published detailing the antimicrobial utility of the sorbates against foodborne microbes, bacterial and fungal alike, the concentrations and conditions of microbial inhibition in differing foods, and the potential mechanisms of microbial inhibition *in vitro* and in food product systems. Multiple fungal microbes, both yeasts and molds, are effectively inhibited by the sorbates, leading to their widespread utilization in various food products susceptible to fungal spoilage or mycotoxigenic mold growth and toxin secretion (83, 86–88). In the United States, sorbic acid and its calcium, potassium, and sodium salts bear GRAS status for use in foods (21 CFR §181 [https://www.ecfr.gov/cgi-bin/text-idx?SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&node=pt21.3.181&rgn=div5] and §182 [https://www.ecfr.gov/cgi-bin/retrieveECFR?gp=&SID=0f2002a44dc3b3296966c07b0f4aadb6&mc=true&r=PART&n=pt21.3.182]). The World Health Organization's Codex

Alimentarius indicates that the sorbates are useful for inclusion in various products to maximal levels ranging from 200 to 3,000 mg/kg depending upon the food product and up to 10,000 mg/kg in edible casings used in various meat products (89).

In addition to the antifungal activity of the sorbates, antibacterial activity has been reported to occur against both Gram-positive and Gram-negative bacterial pathogens and food spoilers, including spore-forming bacteria. The sorbates have been repeatedly tested for their capacity to inhibit toxigenic clostridia, particularly *Clostridium botulinum*, and as preservatives in cured and uncured meat and poultry products, due to spore germination inhibition activity of the acids for both *Clostridium*- and *Bacillus*-produced spores (90–94). As short-chain fatty acids, sorbic acid and the sorbates may, in addition to their uncoupling-type mechanism of microbial inhibition, act on the membranes of targeted microbes in foods to enhance dissipation of transmembrane electrical potential, demonstrated previously in *Bacillus subtilis* cells (95–97). Lues and Theron (31) indicated that while at pH 5.5 the MICs of sorbate did not differ from those of other organic acids against *L. monocytogenes* strain CC77, as the pH of the test medium was increased to pH 7.0, the MIC of sorbate increased, ultimately requiring the greatest content of acidulant to inhibit *L. monocytogenes*.

Davidson et al. (50) described the sorbates as possessing useful inhibitory capacity against the clostridia and listeriae. The organic acid can prevent the germination of clostridial spores, a useful form of food safety and spoilage prevention for application in processed meats, cheeses, and other foods susceptible to these pathogens (92, 98–100). Ronning and Frank (90, 91) previously reported that sorbates dissipated or disrupted electrochemical potentials across cytoplasmic membranes in sporulating bacteria. As with other organic acid antimicrobials discussed herein, recent research has focused on the determination of sorbic acid and the sorbates' utility in food systems when combined with other preservatives and/or with different processing treatments. Combinations of salt, nisin,

and potassium sorbate at concentrations up to 4% at pH 5.5 and 7.0 yielded increasing inhibition and reduced predicted germination and growth of *Clostridium sporogenes* spores in nutrient broth as sorbate content was increased while other preservatives were held constant (101). Similar studies combining heat application (85°C, 10 min) and 3 mM sorbic acid significantly reduced the fraction of *B. subtilis* spores exhibiting germination and outgrowth versus no treatment and even 3 mM sorbic acid alone, declining from 83.3% of spores demonstrating germination and outgrowth down to 27.0% of spores demonstrating outgrowth (102). Non-spore-forming bacteria are also inhibited by sorbate application. Psychrotolerant *Lactobacillus sakei* organisms were inhibited by sorbic acid at 12.6 mM, a higher requirement for inhibition versus benzoic and citric acids (1.51 and 10.3 mM, respectively) (103). Use of sorbic acid in processed meat and fish products was described as not optimal for control of spoilage lactobacilli compared to benzoic acid or acetic acid, given the absence of maximal-use requirements for foods produced in European companies for sorbic acid versus acetic acid (103). Species of *Eurotium* and *Aspergillus* were inhibited by sorbic acid at pH 5.0 and an aw of 0.85 at levels of 0.05% (wt/wt), whereas MICs of sorbic acid at pH 6.0 and the same aw were between 0.1 and 0.3% (wt/wt), indicating the utility of food safety and spoilage prevention by hurdle processing (88).

Propionic Acid and the Propionates

Propionic acid, also identified as propanoic acid (CH_3CH_2 COOH; 74.08 g/mol), is a short-chain volatile fatty acid produced by multiple microbes residing in the human and animal guts (104–107). While the propionates are primarily applied as antifungal agents, particularly for mold inhibition, they also exert antibacterial effects against both Gram-positive and -negative spoilage and pathogenic genera (108–110). In the United States, the propionates are approved for use up to a concentration of 0.5% in RTE meat and poultry foods (24) and bear GRAS status (21 CFR §181 and §184). As with other organic acid antimicrobials, while its acid anionic salts

are more water soluble, propionic acid is the most potent antimicrobial form of the preservative (111).

Cronobacter spp. were inhibited by the application of sodium propionate in microbiological medium and in whole milk, where inoculated pathogen strains were inhibited in medium at 0.4% propionate. In milk samples, the addition of 0.1, 0.2, or 0.3% propionate reduced *Cronobacter* counts compared to controls, although the addition of the bacteriocin nisin or lacticin did not afford additional pathogen reductions compared to application of propionate alone (112). Application of mixed organic acids, including propionic acid, at 0.4 and 0.8% reduced *S.* Typhimurium to nondetectable levels 24 h after application on chicken skin; similar reductions in *E. coli* O157:H7 numbers were also achieved by exposure to acids (113). Likewise, reductions of *S.* Typhimurium and *E. coli* O157:H7 on celery surfaces achieved with application of propionate were enhanced by thermoultrasound treatment (114). The Gram-negative halophile *Vibrio harveyi* was inhibited by 0.05% propionic acid up to 100 h, in contrast to controls, at ambient temperature, while application of 0.06% acid completely inhibited organism growth up to 300 h of sample incubation (115).

L. monocytogenes isolates were reportedly inhibited by propionic acid in a pH- and strain-dependent manner, with MICs increasing 16- to 64-fold as the system pH was increased from pH 5.0 to 8.0 (31). Glass et al. (116) reported that propionic acid addition to the formulations of a cured deli turkey product at levels of 0.3 to 0.5% produced inhibition of *L. monocytogenes* growth to <1.0 $\log_{10}$ cycle on product stored at 4°C for 9 weeks, though the data did not indicate differences between treatments with respect to pathogen counts during storage. Other researchers indicated that the blending of levulinate and propionate into an uncured turkey deli product significantly outperformed propionate alone with respect to *L. monocytogenes* inhibition during refrigerated product storage (117).

Citric Acid and the Citrates

Citric acid (192.12 g/mol; $C_6H_8O_7$) and the citrates naturally occur in multiple sources, including food plants; calcium, iron (Fe^{3+}), and sodium citrates are considered GRAS alongside citric acid (21 CFR §184). Research has indicated that inhibition of Gram-positive and -negative pathogens occurs in microbiological media and in food products such as meat and fish at relatively low concentrations, in concentration- and pH-dependent manners (118–122). In a recent study of the impacts of feed additives on pathogen shedding in food animals, *Salmonella* shedding 2 days after treatment in pigs fed a citric acid-containing feed was significantly lower than that in control pigs, indicating that the acid could be safely fed and reduce pathogen fecal load, a risk factor for subsequent carcass and meat contamination (61). Kim et al. (123) demonstrated that citric acid application to sodium chloride solutions to produce acidified sodium chlorite functioned effectively to inactivate multiple bacterial pathogens through the acid-driven formulation of antimicrobial chloride species. As has been reported for other organic acid antimicrobials, citric acid exhibits greater activity against bacterial pathogens at reduced system pH, likely due to increased protonation of the acid molecule (31).

Byelashov et al. (124) reported that citric acid in combination with tripolyphosphate and NaCl performed as well as acetic acid or lactic acid in combination with tripolyphosphate with respect to inhibiting *E. coli* O157:H7 in beef knuckle following inoculation and refrigeration. Nevertheless, others reported minimal reductions (~1.0 $\log_{10}$ cycle) in STEC (O157 and non-O157) counts following exposure to citric acid at pH 3.75 (below the pK_a of citrate), indicating that acidity alone was insufficient to significantly reduce pathogen counts (56). Most recently, the application of 30 mM citrate to infant formula (pH 6.8), alone or in combination with the antimicrobials carvacrol and nisin A, produced reductions in *Cronobacter sakazakii* between 1.0 and 1.5 $\log_{10}$ CFU/ml (125). Similar experiments were conducted in apple juice (pH 3.2) and

showed that *C. sakazakii* was reduced to nondetectable levels after treatment with citric acid and nisin (125).

Given its occurrence in citrus fruits, citric acid has gained attention in recent years for its potential utility in decontaminating fresh produce. Sagong et al. (126) reported moderate sensitivity of *E. coli* O157:H7, *S.* Typhimurium, and *L. monocytogenes* on lettuce leaves to the application of citric acid. In studies evaluating the dose-dependent impacts of the acid on the pathogens, reductions for allthree pathogens at the maximum applied concentration of acid (2.0%) were less than 2.0 $\log_{10}$ CFU/g. Coapplication of citric acid with power ultrasound treatment (40 kHz, 30 W) for 5 min led to reductions for all pathogens, with populations of *Salmonella* being reduced at 2% citric acid by 3.2 $\log_{10}$ CFU/g following acid and ultrasound application. Adler et al. (127) reported that the application of a lactic acid–citric acid blend (1%) or sodium hypochlorite acidified to pH 6.7 with citric acid to surfaces of jalapeno peppers reduced counts of aerobic bacteria by 1.1 to 1.3 $\log_{10}$ CFU/g. *Salmonella* counts, however, were not reduced to the same degree, with pathogen counts on inoculated peppers approximating 0.8 to 1.1 $\log_{10}$ CFU/g. Reductions in numbers of *Salmonella*, *E. coli* O157:H7, and *L. monocytogenes* ranged between 1.6 and 2.2 $\log_{10}$ cycles on lettuce leaves following application of a commercial citric acid preparation (128).

With respect to citric acid inhibition of foodborne molds, including mycotoxigenic molds, previous research indicated that the acid prevents toxin synthesis in the aspergilli (129). Recent research reported the ability of citric acid to reduce mycotoxin content in various foodstuffs. Five percent citric or lactic acid applied to feed experimentally inoculated with *Fusarium*-produced mycotoxins reduced deoxynivalenol by approximately half (130). The addition of 0.5 to 2.0% citric acid produced dose-dependent reduction in aflatoxin B1 in wet distiller's grains, producing a maximum reduction of 31%. Researchers compared citric acid to other decontamination strategies, reporting that while hypochlorite

outperformed citric acid in toxin reduction, it also produced undesirable bleaching of the feedstock (131). Likewise, application of lemon juice to whole pistachio kernels contaminated with 268 ng/g aflatoxin B1 followed by 4 days' storage and roasting at 120°C resulted in a 50% toxin reduction; application of lemon juice alone also effectively reduced toxin content by 23% (132).

Miller et al. (133, 134) reported that citric acid possesses enhanced buffering capacity and chelation activity versus other organic acids. Nielsen and Arneborg (135) reported that growth of *S. cerevisiae* and *Zygosaccharomyces bailii* in pH 3.0 citric acid reduced the maximum growth rate from 0.14 to 0.05 h^{-1}, though both organisms were inhibited to a greater extent in citric acid solutions adjusted to pH 4.0 and 4.5. Biomass output and ethanol fermentation by the yeast decreased in citric acid solutions, with lower output of biomass at pH 4.0 and 4.5 versus pH 3.0. Application of citric acid to medium-suspended cells of *S. aureus* and *L. monocyte-genes* resulted in physical damage to cells, but the coapplication of nisin and citric acid increased the extent of damage to cells, as indicated by scanning electron microscopy and cytoplasmic constituent release analysis (136).

Miscellaneous Organic Acid and Fatty Acid Antimicrobials

In addition to the organic acids described above, a number of other weak organic acids have been explored for microbial inhibition in media and in differing foodstuffs. Malic acid in particular has enjoyed much attention in recent years, particularly for decontamination of fresh food systems from bacterial pathogens. Lues and Theron (31) reported pH-dependent MICs for *L. monocytogenes* isolates in medium following application of malic acid. Dipping of pathogen-inoculated lettuce in malic acid (2.0%) produced reductions ranging between 1.6 and 1.7 $\log_{10}$ CFU/g for *E. coli* O157:H7, *S.* Typhimurium, and *L. monocytogenes* (126). Over et al. (137) described bacteriostatic effects of malic acid (37.5 mM, pH

3.3) application *in vitro* against *L. monocytogenes* and *S.* Typhimurium, with bactericidal impacts against pathogens when the acid concentration was increased to 75 mM. Kang and Kang (138) reported reductions in *Salmonella*, *E. coli* O157:H7, and *L. monocytogenes* on paprika following submersion in 2% malic acid solution to nondetectable levels within 5 min of exposure. Multi-$\log_{10}$-cycle reductions of enteric pathogens on leafy green produce items have been reported in experiments in which malic acid was applied at different concentrations (139, 140). Mohan and Pohlman (74) reported that application of 30 g/liter malic acid to surfaces of beef trimmings reduced coliforms and inoculated *E. coli* O157:H7 numbers by 2.2 and 2.3 $\log_{10}$ CFU/g.

Levulinic acid (4-oxopentanoic acid; 116.2 g/mol) has been repeatedly tested in combination with surfactants for decontamination of foods and food process surfaces from viral and bacterial microbes. Cannon et al. (141) reported that the combined application of 0.5% levulinic acid and SDS reduced numbers of human norovirus surrogates to nondetectable levels within 5 min of application. Coapplication of 0.5% levulinic acid and 0.05% SDS reduced *E. coli* O157:H7 by 7.4 $\log_{10}$ CFU/ml following 30 min of application time, whereas no reductions in numbers of *Cryptosporidium parvum* oocysts were reported following application of higher concentrations of levulinate (2 or 3%) in combination with SDS (142). A combination of acetic, lactic, and levulinic acids (2% each) reduced *S.* Typhimurium counts by >5.0 $\log_{10}$ cycles following treatment of cherry tomato skin (143). Similar reductions in *S.* Enteritidis on unsprouted seeds treated with carvacrol-containing, 50 mM levulinate-acidified nanoemulsions were also reported, though following seed germination, the pathogen count returned to numbers that were not different from those following seed inoculation pretreatment (144). Researchers have also reported the utility of levulinic acid plus SDS to reduce the numbers of bacterial pathogens contaminating food contact surfaces, in some instances reducing pathogen counts by >5.0 $\log_{10}$

cycles versus controls or treatments using only sterile water (145, 146).

Multiple medium-chain fatty acids have been determined to possess antimicrobial activity against Gramnegative and -positive bacterial microbes, as well as fungal microbes, when applied alone or in combination with other intervention technologies. Previous reports have indicated the inhibition of pathogens such as *L. monocytogenes* and *Listeria ivanovii*, as well as other members of *Listeria*, following application of the fatty acids caprylate and caproate (6, 147). Chang et al. (148) demonstrated the susceptibility of Gram-negative enteric bacterial pathogens to caprylic acid. Patel et al. (149) reported similar activity against *E. coli* O157:H7 and *Salmonella* on lettuce treated with 25 or 50 mM caprylic acid, where pathogen loads were reduced to nondetectable levels following treatment. As with other antimicrobials, recently published research has focused on the coapplication of fatty acids in combination with other antimicrobials for purposes of enhancing foodborne microbe inhibition. Kim and Rhee (150) reported that the combined application of 0.5 or 1.0 mM caprylic acid with multiple plant-derived essential oil components, including thymol, carvacrol, and *trans*-cinnamaldehyde, produced 6.0- to 7.0-$\log_{10}$-cycle reductions in counts of *E. coli* O157:H7, whereas a single antimicrobial application resulted in only a 0.5- to 1.0-$\log_{10}$-cycle reduction. These researchers suggested that the membrane degradation activity of the fatty acid antimicrobial permitted easier access to the cytoplasm of plant essential oil components for subsequent pathogen inactivation. Combinations of caprylic acid and sodium caprylate with other antimicrobials inhibited the growth of *L. monocytogenes* in microbiological medium adjusted to pH 5.5 or 7.4, requiring significantly less fatty acid in acidified medium versus neutral pH medium (151). Nonetheless, combinations of sodium caprylate with ε-poly-l-lysine and acidic calcium sulfate were reportedly capable of synergistic *L. monocytogenes* inhibition in acidified medium (151).

Fatty Acid Esters

Monolaurin and Monocaprylin

In addition to the fatty acid antimicrobials, monoesters of multiple fatty acids are known to exert antimicrobial activity against microbial pathogens and spoilage microbes. Of those studied, monolaurin and monocaprylin have each been repeatedly tested and characterized for antimicrobial activity. Monocaprylin and monolaurin were evaluated for inhibition of *C. sakazakii* and *Cronobacter malonaticus*; monocaprylin was more effective as an inhibitor, requiring 1.6 to 1.7 mg/ml for bacterial inhibition, in contrast to monolaurin, which required >5.0 mg/ml (152). Lower MICs of the monoester of laurate were reported for various molds, including *Aspergillus niger*, *Alternaria alternata*, and *Penicillium roqueforti*, where MICs ranged from 0.16 to 1.5 mg/ml and were reported to not be greatly influenced by test medium pH (153, 154). *S. aureus* growth was reportedly inhibited at a 10-fold-lower concentration *in vitro* by monolaurin, and monolaurin interacted additively with other antimicrobials for pathogen inhibition on meat surfaces (155).

Synergistic interactions were observed for combined carbonation (1 to 5 MPa, 30 min), heat (80°C), and monolaurin for the inhibition of *Bacillus* and *Geobacillus* spores. Synergistic inhibition of *L. monocytogenes* by a combination of monolaurin and essential oils of tarragon and spearmint in broth medium was reported, while the combination of pennyroyal essential oil (0.6%) and 400 ppm monolaurin produced a 1.45-$\log_{10}$-cycle reduction in pathogen counts in inoculated white cheese (156). Currently, monolaurin is applied via engineered delivery systems for pathogen inhibition on foods. Nanoparticle-constructed monolaurin inhibited *S. aureus* cells at 0.1 mg/ml, not very different from previously reported free-monolaurin-specific MICs for *S. aureus* (155, 157). Entrapment of the bacteriocin nisin (10 μg) in monolaurin nanoparticles suppressed *S. aureus* growth over 175 h at 37°C (157). Zein-derived films impregnated with essential oil of *Zataria multiflora* (2%) and monolaurin (1%) produced inhibition zones of 74 and 57 mm against *L. monocytogenes* and *E. coli* O157:H7 cells in agar diffusion

testing (158). On minced-beef surfaces, antimicrobial encapsulates produced a 1.0-$\log_{10}$-CFU/g reduction in *L. monocytogenes* versus untreated controls (158).

LAE

Lauric arginate ester (LAE; *N*α-lauroyl ethyl ester) is a cationic surfactant antimicrobial compound, demonstrating inhibition of both Gram-positive and Gram-negative bacteria, as well as some fungal organisms, particularly yeasts belonging to the genera *Saccharomyces* and *Zygosaccharomyces* (159–162). Recently completed research indicated a synergistic inhibition of bacterial pathogens by the combined application of LAE with plant-derived antimicrobial essential oil components or extracts (162, 163). An additive interaction was recently reported by researchers applying 400 mg/kg LAE with an antimicrobial intervention containing anti-*L. monocytogenes* bacteriophages, where reductions in pathogen numbers on inoculated chicken breasts remained at >1.0 $\log_{10}$ cycle throughout 72 h of refrigerated holding posttreatment (164). Recent reports of combination application of eugenol and LAE against bacterial spoilage organisms (Gram-positive and -negative) indicated that the simultaneous application of sublethal concentrations of antimicrobials functioned synergistically to produce 6.0- to 6.5-$\log_{10}$-cycle reductions, whereas the application of antimicrobials in sequence produced smaller reductions in bacterial numbers (165). Ruengvisesh et al. (166) reported that eugenol-loaded micelles produced from a commercial LAE-containing antimicrobial product exhibited minimum bactericidal concentrations of 0.063% LAE-containing surfactant for both *S.* Typhimurium and *E. coli* O157:H7, indicating that the essential oil component and surfactant antimicrobial work effectively together for pathogen destruction. Ma et al. (163) and Nubling et al. (167) both reported enhanced sensitivity of Gram-positive bacteria to LAE versus Gram-negative bacteria, as indicated by differences in MICs, though differences in MICs vary only 2- to 4-fold.

It is suggested that LAE functions as a cationic surfactant, destabilizing membrane components of targeted microbes (lipopolysaccharide and membrane phospholipids) and allowing respiration and metabolism disruption and cytoplasmic content leakage; LAE was also recently reported to complex with DNA to produce large aggregates, thereby preventing proper transcription (168, 169).

Similar to the results of the studies described above, LAE has shown great utility when paired with one or multiple antimicrobials, as the compound functions to sensitize microbial membranes to subsequent or simultaneous attack by other preservatives. Fisher et al. (170) reported that an antimicrobial beef-marinating solution containing 5% chitosan, 2% (each) acetic, lactic, and levulinic acids, and 4% LAE reduced *L. monocytogenes*, *Salmonella*, *E. coli* O157:H7, and non-O157 STEC isolates to nondetectable counts within 6 h at 4°C. Pathogens were nondetectable throughout 48 h of refrigerated marination. In addition to applications utilizing multiple antimicrobials applied together or sequentially to a food product (i.e., hurdle processing), recent work has demonstrated the usefulness of LAE for food surface disinfection as a component of antimicrobial films or coatings. Application of chitosan-attached LAE to *L. monocytogenes* on frozen and thawed shrimp reduced pathogen counts by over 4.0 $\log_{10}$ CFU/g versus untreated controls (171). Similar reductions against *Listeria innocua* on deli turkey meat surfaces were achieved by application of chitosan-based films loaded with both LAE (0.388 mg/cm^2) and nisin (486 IU/cm^2) (172). Combining LAE at the same content with chitosan film and then applying a steam-type flash pasteurization produced a 5.1-$\log_{10}$-CFU/cm^2 reduction in numbers of the microbe on meat surfaces, thus demonstrating the opportunity for postlethality treatment of exposed meat and food surfaces for surface decontamination (173).

DMDC and DEDC

Dimethyl dicarbonate (DMDC) (Fig. 27.2) and diethyl dicarbonate (DEDC) are clear, colorless compounds with low aqueous solubility (DMDC: 3.6% water solubility). Whereas DEDC is not currently approved for use in foods in the United States, DMDC is currently approved for use in various beverages (wines and carbonated beverages) as an antimicrobial agent at concentrations not exceeding 250 ppm (21 CFR §172). The antimicrobial is added primarily as an antimycotic for the inhibition of wild yeasts in wines and spoilage yeasts in other beverages, including members of *Saccharomyces*, *Brettanomyces*, *Zygosaccharomyces*, *Candida*, and other genera. Research has also shown significant antimicrobial activity of both compounds against bacterial pathogenic and spoilage microbes (172). Basaran-Akgul et al. (174) reported that the application of 125 or 250 ppm DMDC in apple juice prepared from different cultivars of apples reduced *E. coli* O157:H7 to nondetectable levels within 24 h of application. Similarly, DEDC application at 1% in solution reduced numbers of nonpathogenic *Yersinia pestis* in liquid whole eggs over 40 days' storage at 4°C (175).

Research into the antifungal activity of DMDC for the preservation of wine and beverage quality has continued in recent years, using multihurdle strategies for inhibition of wine spoilage and beverage spoilage yeasts. A level of 200 ppm was fungicidal for the wine spoilage yeasts *S. cerevisiae* and *Rhodotorula mucilaginosa*, producing a 4.0-$\log_{10}$-CFU/ml reduction in yeast counts (176). Zuehlke et al. (177) reviewed the utility of DMDC in wines for spoilage yeast control, indicating its current use as a processing aid due to its short active period in the wine. The exact nature of the antimicrobial mechanisms of DMDC and DEDC is not known, given their rapid disintegration in food systems, but both are thought to inhibit cells by protein attack (172, 178).

NATURAL ANTIMICROBIALS

Phytoantimicrobial Agents

Research on plant-based antimicrobials is gaining attention in recent years due to the preferences of health-conscious consumers who want natural ingredients and processes in food production. These compounds are well known for their antimicrobial activity, including antiviral, antimycotic, antiparasitic, insecticidal, antitoxigenic, and antibacterial properties (179–181). Phytocompounds can be used in various forms, including essential oils and their active components, plant extracts and powders, and spices and herbs. These are designated GRAS by the U.S. Food and Drug Administration (182) and are applied by the food industry as part of the multiple-hurdle approach to better maintain the freshness, sensory attributes, and nutritional quality of the processed food products. These compounds can add unique flavors to foods and are also known for their health benefits and medicinal values (180, 183).

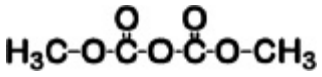

Figure 27.2 DMDC.

Since phytocompounds have multiple components responsible for antimicrobial activity, each compound could have multiple targets in a microbial cell. The exact mechanism of action for several phytocompounds is not yet clear. The mechanisms of action of some active components of essential oils are known. Cinnamaldehyde, the active component present in cinnamon oil and eugenol and the active component of clove bud oil, has been shown to interfere with the activity of enzymes. In *Enterobacter aerogenes*, cinnamaldehyde was found to interfere with the action of amino acid decarboxylases (184), and it also inhibited the separation of *Bacillus cereus* cells after cell division (185). Studies have shown that eugenol can inhibit ATPase, amylase, protease, and histidine decarboxylase (184, 186, 187). Carvacrol, the active component of oregano oil, is a lipophilic compound that can dissolve in the phospholipid bilayer of bacterial cell membrane and can cause

expansion and destabilization of the membrane, resulting in an increase in membrane fluidity and passive permeability (188, 189). Carvacrol was observed to cause leakage of phosphate ions from the treated cells of *S. aureus* and *Pseudomonas aeruginosa* (190). Carvacrol was also observed to cause disruption of the cell membrane and leakage of adenosine triphosphate in *E. coli* cells (191).

Plant essential oils and their active components have shown antimicrobial activity *in vitro* against microorganisms in numerous investigations. Carvacrol and cinnamaldehyde, at 0.1% or higher concentrations, demonstrated strong antimicrobial activity against both antibiotic-resistant and nonresistant *C. jejuni* strains (192) and *Salmonella* serotypes (193) in phosphate-buffered saline. Elgayyar et al. (9) evaluated the antimicrobial activity of numerous essential oils, including those from anise, angelica, basil, carrot, celery, cardamom, coriander, dill weed, fennel, oregano, parsley, and rosemary, against *L. monocytogenes*, *S. aureus*, *E. coli* O157:H7, *Yersinia enterocolitica*, *P. aeruginosa*, *Lactobacillus plantarum*, *A. niger*, *Geotrichum*, and *Rhodotorula*. Oregano, basil, and coriander essential oils showed strong inhibitory activity against both bacteria and fungi, while anise essential oil was effective only against the fungi (9). Lemongrass oil was effective against *Candida albicans*, *E. coli*, *S.* Typhimurium, *Serratia marcescens*, *S. aureus*, and other potential pathogens *in vitro* (194–197). Lemon, orange, and bergamot essential oils and their active components were found to be effective against *C. jejuni*, *E. coli* O157:H7, *L. monocytogenes*, *B. cereus*, and *S. aureus in vitro*, and among the compounds tested, bergamot, citral, and linalool showed the greatest activity (198).

The antimicrobial activity of plant extracts and plant powders *in vitro* against microorganisms has been the subject of research by many investigators. The survival of *E. coli* O157:H7, *S. enterica*, and *L. monocytogenes* in roselle (*Hibiscus sabdariffa*) calyx aqueous extracts or roselle leaf aqueous extracts over 72 h at 4, 8, and 25°C was investigated (199). No surviving *E. coli* O157:H7 or *Salmonella* organisms were detected in either of these extracts at 24 h at all

temperatures. *L. monocytogenes* populations were reduced by 5 and 3 log in the calyx and the leaf extract, respectively, at 24 h and at all temperatures, by 4 to 6 log at 4°C and 8°C, and to undetectable levels at 25°C, at 48 h (199). Roselle extracts were also effective against *S. aureus*, *Bacillus stearothermophilus*, *Micrococcus luteus*, *S. marcescens*, *C. sporogenes*, *E. coli*, *Klebsiella pneumoniae*, *B. cereus*, and *Pseudomonas fluorescens in vitro* (200). Olive leaf extracts exhibited antimicrobial activity against *P. aeruginosa* and *K. pneumoniae* as well as fungi including *C. albicans* and *Cryptococcus neoformans* (201). Olive pomace and olive juice freeze-dried extracts were effective against *E. coli* O157:H7, *S. enterica*, *L. monocytogenes*, and *S. aureus* (202). Commercial green tea leaf and rosemary powders were effective against *B. cereus*, *S. aureus*, and *L. monocytogenes in vitro* (203). Grapeseed extract was effective against *B. cereus*, *B. coagulans*, *B. subtilis*, *S. aureus*, *E. coli*, and *P. aeruginosa*; however, the concentrations required to inhibit Gram-negative bacteria (1,250 to 1,500 ppm) were higher than those required to inhibit Gram-positive bacteria (850 to 1,000 ppm) (204).

Plant antimicrobials can be applied in meat products as ingredients to improve the microbiological safety of these products. Roselle aqueous extract exhibited antimicrobial activity against *L. monocytogenes*, *E. coli* O157:H7, *S. aureus*, and *B. cereus* in ground beef (205). Grape-seed, pine bark, and rosemary extracts were added to raw ground beef at a concentration of 1%, and they brought about a 1-log reduction in populations of *S.* Typhimurium, *L. monocytogenes*, and *E. coli* O157:H7 after 9 days of storage (206). Oregano and cinnamon bark extracts were added to raw pork at a concentration of 4% as part of the curing juice and caused 2- and 3-log reductions in *S. enterica* populations, respectively, during storage at 20°C for up to 9 days (207). Garlic, ginger, and turmeric pastes inhibited the growth of multidrug-resistant *S.* Typhimurium DT104 in heat-treated ground beef stored at 4°C for 10 days (208). The antimicrobial effects of garlic, ginger, carrot, and turmeric pastes against *E. coli* O157:H7 were evaluated in ground beef;

commercial ginger paste demonstrated a 1- to 2-log-CFU/g reduction after 3 days of storage at 4°C (45). Cinnamon oil and olive extract were effective against multidrug-resistant *S.* Typhimurium in heated ground pork, resulting in 1.3- and 3-log-CFU/g reductions, respectively, after 7 days of storage at 4°C and these compounds were stable during cooking at 70°C for 5 min (209). Lemongrass oil inhibited the growth of foodborne pathogens in minced meat products (210). Carvacrol and cinnamaldehyde were effective against antibiotic-resistant *S.* Newport on oysters stored at 4°C for up to 3 days, exhibiting reductions of about 2 and 5 log CFU/g, respectively (193).

Plant antimicrobials have demonstrated dual benefits—antimicrobial and antioxidative activities—in grilled meats. Grilled ground beef patties are heated to reach an internal temperature of 71.1°C at the geometric center to inactivate *E. coli* O157:H7. The periphery of the patty can reach temperatures as high as 200°C, which can induce the formation of potentially carcinogenic compounds called heterocyclic amines. Epidemiological studies have shown a close correlation between consumption of well-done meats containing heterocyclic amines and incidence of cancer in humans (211, 212). Carvacrol simultaneously inactivated *E. coli* O157:H7 (2.5- to 5-log-CFU/g reduction) and reduced the formation of heterocyclic amines (58 to 78% reduction in the three major amines) in heated ground beef patties (213). Olive extract at 5% and lemongrass oil at 1% reduced *E. coli* O157:H7 population to below detection limits, and olive extract reduced the heterocyclic amines MeIQx and PhIP by 79.5% and 84.3%, respectively, in heated ground beef patties, while onion powder reduced PhIP by 94.3% (214). Olive and apple extracts, clove bud oil, and onion powder exhibited concentration-dependent effects against *E. coli* O157:H7 and the carcinogenic heterocyclic amines MeIQx and PhIP during grilling of ground beef patties (215).

Plant antimicrobials can be added to the wash water for washing produce postharvest, and this application may be particularly useful for organic produce, since growers of organic produce have limited

options. Oregano, lemongrass, and cinnamon essential oils were added to the wash water for organic leafy greens, including romaine and iceberg lettuces and mature and baby spinaches; concentration-, storage time-, and exposure time-dependent activities against antibiotic-resistant *S.* Newport were observed during storage at 4°C for 3 days (216–218). The antimicrobial activities of olive and apple powder extracts as well as hibiscus aqueous extract against *S.* Newport on organic iceberg lettuce, romaine lettuce, baby spinach, and mature spinach stored at 4°C for 3 days were concentration and storage time dependent, with olive, apple, and hibiscus extracts showing 2- to 3-log, 1- to 2-log, and 1-log reductions, respectively, while hydrogen peroxide (control) showed a 1-log reduction (219). On organic leafy greens (romaine lettuce, iceberg lettuce, and baby and mature spinaches), the concentration-dependent reductions in *S.* Newport populations by hibiscus tea, grape-seed, and green tea extracts ranged between 0.7 and 2.3 log CFU/g, 0.4 and 2.0 log CFU/g, and 0.2 and 1.6 log CFU/g, respectively (220). Carvacrol and cinnamaldehyde at 1% were effective against antibiotic-resistant *S.* Newport on celery (193). Cinnamaldehyde was effective against *E. coli* O157:H7 on baby spinach leaves (221). Carvacrol, cinnamaldehyde, and thymol exhibited antimicrobial activity against *B. cereus* strains in carrot broth (222).

Plant compounds can enhance product shelf life by inhibiting the growth of spoilage organisms. Basil essential oil was found to be effective against spoilage microorganisms such as *Aeromonas hydrophila* and *P. fluorescens* on lettuce (223). When applied to romaine lettuce, clove and tea tree essential oils demonstrated antimicrobial effects against various types of background microflora, including bacteria, yeasts, and molds (224). Cinnamon oil inhibited spore production and the hyphal growth of molds, including *Colletotrichum coccodes*, *Cladosporium herbarum*, *A. niger*, *Botrytis cinerea*, and *Rhizopus stolonifer* (225). Olive, apple, and hibiscus extracts were effective against background microflora of organic iceberg and romaine lettuce and baby and mature spinach, with reductions ranging from 0 to 2.8 log CFU/g (219).

A unique way to apply plant-based antimicrobials to food is by means of edible films (Fig. 27.3) that can be made from the pulp of a plant part, such as fruits, vegetables, leaves, or flowers. Edible films could help alleviate some of the adverse effects that plant antimicrobials may have on the sensory properties of the treated products. Antimicrobial edible films can be used as wrappings on meat and poultry products to improve the microbial safety and quality of these products. Edible films made of apple pulp containing three concentrations of carvacrol and cinnamaldehyde and used to wrap chicken breast with storage for 72 hours at 4 and 23°C and ham and bologna with storage at 4°C for up to 7 days were effective against *S.* Enteritidis, *E. coli* O157:H7, *C. jejuni*, and *L. monocytogenes* (226–228). Antimicrobial edible films can be added as ingredients in salad bags to inactivate foodborne pathogens. Apple-, carrot-, and hibiscus-based edible films containing carvacrol or cinnamaldehyde (Fig. 27.3) added to salad bags with organic leafy greens stored at 4°C for up to 7 days were effective against antibiotic-resistant *S.* Newport (229). When an alginate-based edible coating containing essential oils and their active components along with malic acid was applied on fresh-cut melons, the populations of *S.* Enteritidis were significantly reduced (230). Alginate-based films containing essential oils and their active components reduced the populations of *E. coli* O157:H7 on fresh-cut Fuji apples (231). Methylcellulose coatings containing chitosan applied to fresh-cut cantaloupe reduced the populations of mesophilic aerobes, psychrotrophs, lactic acid bacteria, and total coliforms by 3 to 4 log CFU/g (232). Plant antimicrobials have the potential to improve food safety, and commercial-scale trials will help the industry to determine the most effective applications of these healthful commodities in foods.

Natural Antimicrobials from Animal Sources

Lactoferrin and Lactoferricin

Lactoferrin is an iron-binding glycol-protein (molecular mass, 76.5 kDa) in milk and colostrum; it is also present in other physiological fluids and polymorphonuclear leukocytes (233). Lactoferrin is approved for application to beef in the United States (234). Lactoferrin exists in milk primarily as a tetramer with Ca^{2+} and possesses two iron-binding sites per molecule. For each molecule of Fe^{3+} bound by the enzyme, one bicarbonate (HCO^{-}) is required. Lactoferrin must be low in iron saturation and bicarbonate must be present for the protein to exert antimicrobial activity (132, 235). The exact biological role of lactoferrin is unknown; however, it may act as a barrier to infection of the nonlactating mammary gland and aid in protecting the newborn against gastrointestinal infection (236, 237). The lactoferrins exhibit antimicrobial activity through iron sequestration, modification of microorganism motility, disruption of biofilms, modification of virulence factors, and due destabilization of microorganism cell membrane (238). Lactoferrin can inhibit numerous foodborne microorganisms, including *B. subtilis*, *B. stearothermophilus*, *Carnobacterium viridans*, *L. monocytogenes*, micrococci, *E. coli*, and *Klebsiella* species (235, 239–241).

Payne et al. (242) found that bovine lactoferrin had to be reduced to 18% iron saturation to have bacteriostatic activity against four strains of *L. monocytogenes* and an *E. coli* strain at concentrations of 15 to 30 μg/ml in ultrahigh-temperature-treated (UHT) milk. At 2.5 mg/ml, it exhibited no activity against *S.* Typhimurium or *P. fluorescens* and little activity against *E. coli* O157: H7 or *L. monocytogenes* (243). Branen and Davidson (244) studied the interactive antimicrobial effects of combinations of lactoferrin with monolaurin, nisin, or lysozyme against *L. monocytogenes*, *E. coli*, *S.* Enteritidis, and *P. fluorescens* in culture medium and fluid milk. In culture medium, lactoferrin combined with nisin inhibited *L. monocytogenes* and lactoferrin combined with monolaurin inhibited *E. coli* O157:H7. None of the antimicrobial combinations with lactoferrin were effective in UHT milk incubated at 25°C; this

was attributed to interactions of the antimicrobials with food components and to the storage temperature (244).

Figure 27.3 Apple-, carrot-, and hibiscus-based antimicrobial edible films containing carvacrol and cinnamaldehyde that can be used as wrappings for meat products or added as ingredients in salad bags.

Lactoferricin B (i.e., hydrolyzed lactoferrin [HLF]) is a small polypeptide (25 residues) obtained from pepsin digestion of lactoferrin (245). Unlike bovine lactoferrin, lactoferricin is inhibitory to multiple genera of the lactic acid bacteria, including *Lactobacillus* and *Pediococcus* (246). Incubation of *S. aureus*, *E. coli* O157:H7, and enteropathogenic *E. coli* in 20 to 40 μM HLF resulted in only 10 to 15% growth of targeted microbes compared with untreated controls (247). Jones et al. (248) determined that HLF at concentrations of 1.9 to 125 μg/ml has bacteriostatic and/or bactericidal activity against *Shigella*, *Salmonella*, *Y. enterocolitica*, *E. coli* O157:H7, *S. aureus*, *L. monocytogenes*, and *Candida*. These

findings were recently confirmed and reviewed (249, 250). The addition of the chelator EDTA enhances the activity of HLF in liquid medium, indicating that decreases in the antimicrobial activity of HLF may be in part due to excess cations (251). Venkitanarayanan et al. (241) found that adding HLF to ground beef at 100 μg/g reduced *E. coli* O157:H7 populations by ~1.0 $\log_{10}$ CFU/g after 5 days at 4°C, whereas the pathogen populations in non-HLF-treated beef decreased by only 0.5 $\log_{10}$ CFU/g. In minimal culture medium, however, a decrease in *E. coli* O157:H7 populations of nearly 2.0 $\log_{10}$ CFU/ml was observed compared with medium containing no HLF (241).

Lactoperoxidase

Lactoperoxidase is an oxidoreductase in milk which plays an important role in protecting the lactating mammary gland and the intestinal tracts of newborn infants against pathogenic microbes. Lactoperoxidase is inhibitory towards both Gram-negative and Gram-positive bacteria (252). Lactoperoxidase contributes to the keeping quality of raw and pasteurized milk (253, 254). The combination of pasteurization at 60°C for 15 s with naturally occurring lactoperoxidase in goat milk inhibited the growth of *E. coli* O157:H7 for 6 hours postprocessing, resulting in a reduction in pathogen populations of 0.7 to 1.2 $\log_{10}$ CFU/ml compared with goat milk samples receiving the heat treatment but no antimicrobial (255). Adding the lactoperoxidase system (lactoperoxidase, potassium thiocyanate [KSCN], glucose oxidase, and glucose) to skim milk inoculated with *L. monocytogenes* and held at 25°C resulted in a 50-h lag phase, compared with an ~3-h lag phase in untreated control milk (256). The lactoperoxidase system also can inhibit growth of *S. aureus*, *L. monocytogenes*, *E. coli* O157:H7, *Salmonella*, and *Y. enterocolitica* in products such as beef, vegetable juices, milk, and liquid whole eggs (257, 258). For this reason, the lactoperoxidase system has been suggested as a preservative in foods. It has been applied in combination with alginate coating on chicken breast fillets during cold storage (259).

Lysozyme

Lysozyme is a powerful antimicrobial enzyme found in egg white, milk, and blood. It is classified as GRAS (234). It has been reported to act efficiently against food spoilage microorganisms. Its main target is Gram-positive bacteria, as it attacks the peptidoglycan in the cell wall (260, 261). Lysozyme is the predominant protein in egg albumen, being present at approximately 3.5% (262). Hen egg white lysozyme is the primary antimicrobial substance in albumen, although its activity is enhanced by ovotransferrin, ovomucoid, and alkaline pH (~9.3). Lysozyme possesses greater stability to heat at acidic pH (30 min at 80°C), but its thermal stability is reduced as pH is increased, an interesting phenomenon given the natural alkalinization of eggs during their storage after laying. The enzyme is most active from 55 to 60°C but maintains up to 50% of its activity at lower temperatures (10 to 25°C) (262). Lysozyme catalyzes hydrolysis of the α-1,4-glycosidic bond between C-1 of *N*-acetylmuramic acid and C-4 of *N*-acetylglucosamine, resulting in cell wall degradation and lysis in hypotonic systems.

The efficacy of lysozyme in inhibiting spoilage and pathogenic microbes on fresh and processed meat has been studied by several researchers. A combination of 250 or 500 ppm lysozyme, 250 or 500 ppm nisin, and 5 mM EDTA suppressed aerobic bacterial mesophile growth on ground ostrich patty surfaces during 7 days of aerobic or vacuum storage at 4°C (263). Applying 0.5 U of lysozyme/cm^2 on surfaces of turkey bologna followed by in-package pasteurization (65°C, 32 s) reduced *L. monocytogenes* to below detectable limits within 10 weeks of refrigerated vacuum-packaged storage; a combination of lysozyme and nisin inactivated the pathogen more rapidly, reducing *Listeria* populations to below detection limits after only 2 weeks of storage at 4°C (264). Conversely, adding lysozyme (100 or 200 μg/ml), EDTA (1.0 to 2.5 mg/ml), or a combination of these antimicrobials to UHT milk did not significantly inhibit *S.* Typhimurium or *P. fluorescens* but did exert a significant inhibitory effect on *L. monocytogenes* (243).

Likewise, growth of heat-shocked *L. monocytogenes* cells was significantly inhibited by 100 mg of lysozyme/ml of demineralized fluid milk, although fortification with divalent cations removed the observed inhibition (265). Lysozyme is approved for use in cheeses, frankfurter casings, and cooked meat and poultry products. It has been applied against *L. monocytogenes* Scott A in both plant and animal foods (266).

Ovotransferrin

Ovotransferrin is major iron chelating protein of egg (267). It is equivalent to lactoferrin in milk, as it has approximately 49% sequence homology with lactoferrin (268). There are two iron-binding sites, and anions such as bicarbonate or carbonate are bound alongside iron. Antimicrobial efficacy must be preceded by iron deficiency and alkaline pH (269). Ovotransferrin antimicrobial peptide (OTAP-92) kills bacteria through a membrane damage mechanism (270). For this reason, Gram-positive bacteria are generally more sensitive to its activity than Gram-negative bacteria. *Micrococcus* and *Bacillus* species are especially susceptible, as are some yeasts (268, 271). Recent research has sought to enhance the antimicrobial efficacy of ovotransferrin by applying it in foods with other antimicrobials. Ko et al. determined that 20 mg of ovotransferrin per ml in brain heart infusion broth completely inhibited the growth of *E. coli* O157:H7, as did ovotransferrin combined with 2 to 2.5 mg EDTA per ml (272). Ovotransferrin is also applied in K-carrageenanbased edible coating for its antimicrobial effect on fresh chicken breast stored at 5°C (273).

Avidin

Avidin is a tetrameric glycoprotein present in egg albumen. Its concentration varies with the hen's age but is approximately 0.05% of the total albumen protein (269). Avidin is stable to heat and a wide pH range. Avidin binds up to four molecules of biotin with high affinity. While its exact biological function is not known, it is thought that avidin is a nonspecific defense mechanism, inhibiting

function of biotinylated enzymes and thereby slowing the growth and spread of microbial contaminants (274, 275). Avidin is capable of inhibiting the growth of biotin-requiring yeast and bacteria (276). Applications of avidin in food models have not been reported. However, an avidin-biotin complex is used in a wide variety of bioanalytical applications (277).

Chitosan

Chitosan is the *N*-deacetylated derivative of chitin. Chitin is a mucopolysaccharide which is a natural component of fungal cell walls and the most abundant polysaccharide found in nature after cellulose (278). It is also a by-product of shellfish processing. Its derivative chitosan contains a series of polymers with different ratios of glucosamine and *N*-acetylglucosamine. Chitosan inhibits growth of foodborne fungi and bacteria (279–281) and is reported as nontoxic, biodegradable, and biocompatible by several researchers (282).

MICs for bacteria and yeasts vary widely depending on the molecular weight of the polymer, degree of acetylation, pH, temperature, and presence of interfering compounds, such as proteins and lipids (280). Nevertheless, when chitosan is combined with other antimicrobials, such as organic acids or antimicrobial polypeptides, the MIC of chitosan can be reduced. Zivanovic et al. (283) reported that chitosan dissolved in acetic acid was bactericidal to *S.* Typhimurium and *L. monocytogenes* strains, although the rate of inactivation was strain and concentration dependent. Combining chitosan with divergicin M35, a class IIA bacteriocin fermented by *Carnobacterium divergens* M35, halved the MICs of antimicrobials for *L. monocytogenes* (284).

Several studies have incorporated chitosans into edible films with antimicrobials for enhanced inhibition of microorganisms. Combining 2 mg of lysozyme with chitosan films significantly increased the size of the zones of inhibition against *E. coli* O157:H7 and *L. monocytogenes* and significantly reduced pathogen

populations in culture medium (285). Incorporating garlic essential oil, sorbic acid, or nisin into chitosan films significantly inhibited growth of *L. monocytogenes*, *Bacillus* spp., *Staphylococcus*, *Salmonella*, and *E. coli* (286). Park et al. (287) found that chitosan-based coatings containing potassium sorbate and applied to strawberries produced significant reductions in *Rhizopus* and *Cladosporium* populations compared with controls. Vandyousefi and Bhargava (288) applied an emulsion containing cinnamon oil and chitosan to shelled eggs to determine its effect on internal quality and shelf life. The study demonstrated that coatings with cinnamon oil-chitosan ratios of 9:91 and 12:88 could preserve the internal quality of eggs and prolong their shelf life under refrigeration conditions.

CONCLUSIONS

Chemical preservatives and natural food antimicrobials continue to be important tools for preserving food against microbiological spoilage and the growth of pathogens. The general trend is moving towards clean labels, with consumers demanding foods with fewer synthetic additives or foods with natural ingredients that are deemed more environmentally friendly. The natural antimicrobials will likely continue to grow in popularity. Additional research is needed to determine the levels of natural antimicrobials required for successful inhibition of foodborne pathogens, their mechanisms of action, and their safety. Novel applications of existing antimicrobials, including encapsulation, incorporation into edible polymers, and use of combinations of antimicrobials capable of synergistic inhibition of foodborne microorganisms, are being investigated. Major challenges include demonstrating the efficacy of antimicrobial compounds in food products at concentrations that do not have adverse sensory effects, as well as controlling the cost of these interventions.

Biological Control of Food-Challenging Microorganisms

Before we dive into the intriguing and challenging world of biological (i.e., natural) preservatives, it is important to first understand why these antimicrobials are emerging as a novel approach for the control of undesired microorganisms in food products.

Over the course of the evolution of the food industry, food preservation has evolved from simple methods such as drying, salting, and using sugars and/or natural acidification to more sophisticated technologies. It is not in the scope of this chapter to discuss the terminology and legal classification of food preservatives, as they are defined by various regulatory agencies. However, the term "natural" has emerged as a way to distinguish substances of an unmodified origin (as determined by the FDA) in food formulation from "artificial" substances, i.e., those of a chemical or synthetic origin. That is why, according to the FDA Code of Federal Regulations Title 21 (revised as of 1 April 2017; https://www.ecfr.gov/cgi-bin/text-idx?SID=bb4e846ae19064cc1b87826409b86470&mc=true&node=se21.2.101_122&rgn=div8), "… common salt, sugars, vinegars, spices or oils extracted from spices…" are excluded from the list of chemical preservatives. In addition, FDA approval in 1988 for the use of nisin as a preservative in cheese spreads established a legal precedent for the further application of biological preservatives in food products (1). Therefore, naturally derived and unmodified proteinaceous antimicrobials (such as bacteriocins) and more complexly organized multimolecular structures (such as bacteriophages) belong to the group of natural preservatives, provided that they can control undesired microorganisms in food products. In this chapter, the terms "biological" and "natural" are used interchangeably.

It is also important to mention that the rapidly growing interest in biopreservatives is driven largely by our constantly increasing knowledge of possible negative health effects of some of the chemical preservatives and by the consumers' awareness of these negative effects.

BIOPRESERVATION WITH LIVE MICROORGANISMS

One way to categorize microorganisms is by the major metabolic products resulting from the utilization of various carbohydrates. A broad group of Gram-positive, non-spore-forming cocci or rod-shaped microorganisms producing lactic acid as the end product of glucose fermentation are defined as lactic acid bacteria (LAB). Some reports on LAB of importance for both beginners and fundamental and applied science investigators have been compiled by Wackett (2). LAB include several genera: *Lactococcus*, *Lactobacillus*, *Enterococcus*, *Streptococcus*, *Pediococcus*, *Carnobacterium*, *Leuconostoc*, *Oenococcus*, *Tetragenococcus*, *Vagococcus*, and *Weissella*. Numerous strains of microorganisms taxonomically related to the first six genera have been known for centuries to be safe and are commonly used as starter cultures in food fermentation. It is important to mention that while some strains are safe for humans and are utilized in a variety of food products as starter cultures, live preservatives, or both, there are plentiful reports on potential human pathogens which belong to the LAB (e.g., references 3 and 4). Strikingly, most reported cases of lactobacillus-related bacteremia (including cases caused by probiotic strains) are seen in the elderly or infants, age groups with either a declining or incompletely developed immune system. Therefore, safety is neither a genusnor species-specific feature—it is something that must be determined for each individual strain.

Many LAB produce one or a combination of several substances with antimicrobial properties, including lactic acid, hydrogen peroxide, bacteriocins, and diacetyl, with LAB-produced bacteriocins and diacetyl being more active against Gram-negative than Gram-positive pathogens (5). Moreover, a combination

of diacetyl with reuterin (a broad-spectrum antimicrobial produced by some isolates of *Lactobacillus reuteri*) can result in increased antimicrobial activity (6).

Weak organic acids have been recognized for their antimicrobial properties for more than a century and are used as antimicrobial agents in many food and personal care and hygiene products. Lactic acid produced by LAB during the fermentation of food directly contributes to the lowering of the pH, which becomes a significant factor in the control of food safety and quality. For example, a desirable acidification of the food product, provided by a fermenting LAB, is an effective replacement for nitrites in cured meat (reviewed in reference 7). The acidic pH of LAB-fermented food products is reported as inhibiting numerous foodborne pathogens, such as *Clostridium botulinum*, *Listeria monocytogenes*, *Escherichia coli*, etc. (for reviews, see references 8 and 9).

Bacteriocinogenic strains of LAB are capable of inhibiting the growth of foodborne pathogens and spoilage microorganisms, mostly Gram-positive species, thus increasing the safety and shelf life of food products (for example, see reference 10). When used as starter cultures or live preservatives, bacteriocinogenic microorganisms may be categorized as GRAS (generally recognized as safe), provided that they have a history of safety and use by the food industry prior to the 1958 Food Additives Amendment (as outlined in 21CFR170, FDA Code of Federal Regulations, Title 21, volume 3, revised 1 April 2017; https://www.ecfr.gov/cgi-bin/text-idx?SID=58ae784cf65acac9f530a3fbec916fbe&mc=true&node=pt21.3.170&rgn=div5). According to amendment 21CFR170, the bacteriocinogenic starter, the live preservative, or a (partially) purified bacteriocin may have the manufacturer's self-affirmed GRAS status or a GRAS status affirmed as a result of evaluation by an independent surveyor. However, in any of these cases, the FDA may request justification.

It is important to mention that while some strains of LAB may have GRAS status, it does not mean that a self-proclaimed or FDA-affirmed status may be expanded to the entire species or genus. Regrettably, this is a rather common mistake, observed in numerous publications.

The existing FDA regulations clearly state that natural antimicrobials used as food preservatives and live preservatives should have GRAS status affirmed for specific application(s). Additionally, the Food Safety and Inspection Service of the U.S. Department of Agriculture (USDA FSIS) evaluates and approves the efficiency and safety of novel food preservatives, including live, GRAS preservatives and their products. The use of novel bacteriocins requires an integrated review by both the FSIS and the FDA before any applications are possible (11, 12).

Some of the more common commercially available bacteriocin-producing food-grade microorganisms are listed in Table 28.1 (13). When a food preservation strategy utilizing live preservatives is being designed, numerous essential variables must be taken into consideration. These variables are determined by the food environment and include water activity, pH, temperature, atmospheric composition, fat content, presence of nutrients and inhibitors, other microorganisms, etc., and are comprehensively reviewed by Gálvez and coauthors (Fig. 28.1) (14).

BIOPRESERVATION WITH NATURALLY DERIVED ANTIMICROBIALS

Every living creature produces antimicrobial substances to protect itself from invading microorganisms. In order to present the entirety of biopreservatives as a cohesive picture, we have divided these antimicrobials into several groups, as depicted in Fig. 28.2, with some examples given for each subgroup. This figure is intended as an approximation to guide the reader through the chapter and is not meant to suggest an attempt at classification.

Nonproteinaceous Antimicrobials of Plant Origin: Challenges Are Many

In addition to the nonproteinaceous antimicrobials mentioned in Fig. 28.2, plants, like other eukaryotic organisms, produce antimicrobial proteins (AMPs). Plant-derived antimicrobials have been thoroughly reviewed by Cowan (15) and more recently by other investigators (e.g., reference 16), and there are also studies with some emphasis on plant antimicrobials of proteinaceous origin (17). Many

identified plant-derived crude extracts and purified substances have been studied and reported as safe and active against foodborne pathogens such as *L. monocytogenes*, even in the challenging food processing and formulated-food environments. For instance, *Psoraleae semen* L. (Bogolji) and *Sophorae radix* L. (Gosam) antimicrobial extracts still possessed their antilisterial activity after exposure to pH 4.0, NaCl concentrations up to 6%, and high-temperature treatment (80°C and 100°C for 10 min). Interestingly, these antimicrobial activities were observed in the water-insoluble fractions of the studied plant extracts (18).

Table 28.1 Examples of commercially available bacteriocin-producing food-grade microorganisms[a]

Product name	Microorganism(s)	Bacteriocin(s)	Manufacturer	Application
BioSafe	*Lactococcus lactis* subsp. *lactis* BS-10	Nisin A	Chr. Hansen	Cottage, feta, and ripened cheeses, prevention of late blowing and off flavors due to clostridia
HOLDBAC (formerly Bio Profit [Valio]; same species but different strains)	*Propionibacterium freudenreichii* subsp. *shermanii* DSM 706 and *Lactobacillus rhamnosus* DSM 7061	Undefined bacteriocins; see U.S. patent application US 20150150298 A1 (4 June 2015)	DuPont Nutrition Biosciences ApS	Inhibition of mold and psychrotrophs in cottage cheese
Bactoferm F-LC	*Pediococcus acidilactici*, *Lactobacillus curvatus*, and *Staphylococcus xylosus*	*L. curvatus* produces sakacin A, and *P. acidilactici* is likely to produce pediocin PA-1/AcH	Chr. Hansen	Control of *L. monocytogenes* and as a meat starter
ALCMix1	*Lactobacillus plantarum* and *Staphylococcus carnosus*	Produce plantaricin and carnocin bacteriocins, respectively	Danisco DuPont	Antilisterial cultures for fermented sausages and cooked ham
Bactoferm B-SF-43	*Leuconostoc carnosum*	Leucocin	Chr. Hansen	Control of listeria in vacuumand modified-atmospherestored meat products
Bactoferm B-2	*Lactobacillus sakei*	Sakacin	Chr. Hansen	Control of listeria in vacuumand modified-atmospherestored meat products
Bactoferm B-FM	*Staphylococcus xylosus* and *L. sakei*	Sakacin	Chr. Hansen	Control of listeria in vacuumand modified-atmosphere-fresh meat products

[a] Table is from reference 13.

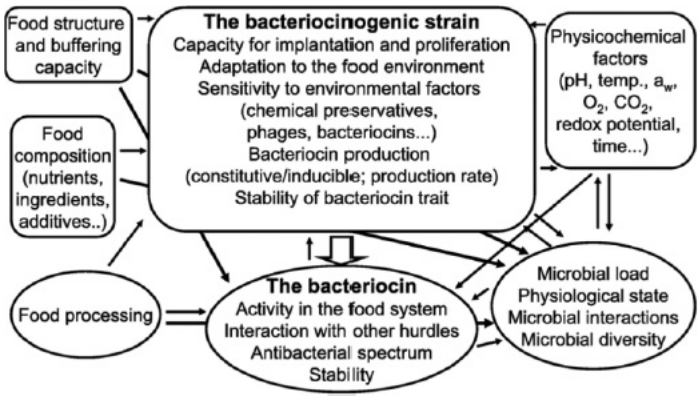

Figure 28.1 Environmental factors essential for biopreservation by bacteriocinogenic GRAS microorganisms. Image from reference 14.

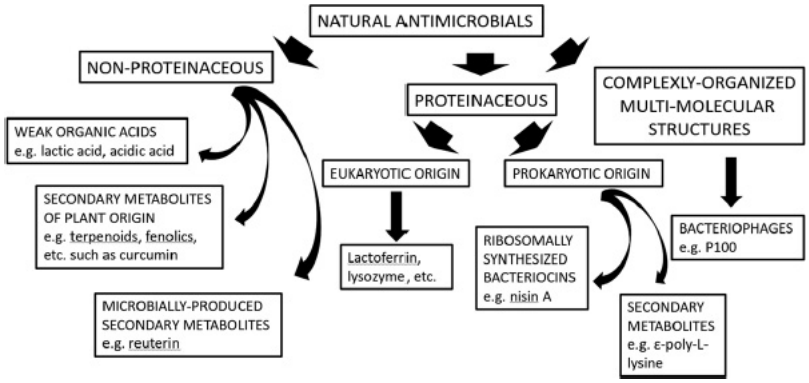

Figure 28.2 Natural antimicrobials of interest for food preservation.

Plant-derived nonproteinaceous antimicrobial substances are often described as having multiple mechanisms of action against targeted microorganisms. Additionally, one of the major challenges for food application of many of these substances (extracts) is their limited water solubility (19). This challenge has been addressed by many investigators with suggested approaches for micro- or nanoencapsulation of plant-derived antimicrobials. While microencapsulations may be useful in the preservation and enhancement of antimicrobial activity (20), nanoencapsulation seems to be more effective in delivering the substances' antimicrobial function (21). In fact, nanotechnology is currently under intense investigation for use in many food-related applications (22–24).

In their study (21), Topuz and coauthors utilized highpressure homogenization to produce a nanoemulsion of anise oil. This formulation delivered 2-log-better inhibition of the common foodborne pathogens *E. coli* O157:H7 and *L. monocytogenes* Scott A than pure anise oil. Additionally, nanoformulated anise oil produced 1-log-better inhibition of these pathogens than the coarse emulsion. In a different study, plant-derived terpenes and d-limonene were nanoencapsulated and evaluated for antimicrobial activity against three model microorganisms representing Gram-positive bacteria (*Lactobacillus delbrueckii*), Gram-negative bacteria (*E. coli*), and yeasts (*Saccharomyces cerevisiae*). The objective of this study was to effectively control a broad range of microorganisms in juices without significant negative impact on the food product's qualities (25). The formulations' MICs and minimum bactericidal concentrations (MBCs) were determined, and in allcases, the nanoencapsulated for In their study (21), Topuz and coauthors utilized highpressure homogenization to produce a nanoemulsion of anise oil. This formulation delivered 2-log-better inhibition of the common foodborne pathogens *E. coli* O157:H7 and *L. monocytogenes* Scott A than pure anise oil. Additionally, nanoformulated anise oil produced 1-log-better inhibition of these pathogens than the coarse emulsion. In a different study, plant-derived terpenes and d-limonene were nanoencapsulated and evaluated for antimicrobial activity against three model microorganisms representing Gram-

positive bacteria (*Lactobacillus delbrueckii*), Gram-negative bacteria (*E. coli*), and yeasts (*Saccharomyces cerevisiae*). The objective of this study was to effectively control a broad range of microorganisms in juices without significant negative impact on the food product's qualities (25). The formulations' MICs and minimum bactericidal concentrations (MBCs) were determined, and in allcases, the nanoencapsulated formulations were found to have MICs and MBCs lower than or similar to those of nonencapsulated preparations. Also, high-pressure-homogenized emulsions of the studied formulations at 10 g/liter effectively inhibited 10^3 CFU/ml of *L. delbrueckii* in orange and pear juices for 16 days at 32°C. It should be mentioned that while MICs of nanoformulated plant-derived antimicrobials such as essential oils are often reported as being 10 to 20 times lower than those of pure (nonencapsulated) substances, their performance in food product models is still far from being acceptable for any food application. In a recent study, chitosan-benzoic acid nano-gel-encapsulated *Rosmarinus officinalis* essential oils were evaluated for their ability to control *Salmonella enterica* serovar Typhimurium-challenged beef cutlets. After 12 days of incubation, 2 mg of nanoformulated essential oils per g of beef cutlet produced an approximately 2-log reduction of the pathogen compared to untreated meat, which is approximately 1 log better than the activity delivered by 100 mg of the nonformulated (pure) essential oil (26).

In addition to the above-mentioned challenges with the effectiveness of plant-derived antimicrobials (alone and nanoformulated) in food model systems, their safety should be seriously considered, especially because nano-formulations, while delivering better bioavailability for many substances, also raise concerns about potential health risks due to their ability to easily penetrate various biological barriers (27).

Biopreservatives of a Proteinaceous Nature

As depicted in Fig. 28.2, proteinaceous biopreservatives are a diverse group of substances of both prokaryotic and eukaryotic origins. The natural source and proteinaceous structure of these substances are why these biopreservatives are particularly favored by consumers concerned with the health and safety of food products. Indeed, proteins are normally subjected to digestion by the proteolytic system of the human gastrointestinal tract (28), and while some of them, such as lactoferrin and its derivative lactoferricin, can cause various responses in eukaryotic hosts, these effects are generally reported as positive (for example, see reference 29; also see the excellent review in reference 30). The proteinaceous food biopreservatives included in this chapter are presented in Table 28.2.

Table 28.2 Proteinaceous food biopreservatives examples

Name	Dosage (mg/kg)	Microbial targets	Food applications	Comments
Polylysine	100–1,000	Gram-positive and -negative bacteria, yeast, molds	Sliced fish, rice, noodles, cooked vegetables (Japan)	FDA GRAS notice GRN no. 135, with intended use as a antimicrobial agent in cooked rice and sushi rice at lev from 5 to 50 parts per million (https://www.accessdata.fda.gov/scripts/fdcc/?set=GRASNotices&id=135; last accessed 24 January 2018)
Lactoferrin	1,000	Gram-positive and -negative bacteria	Infant formulas	FDA GRAS notice GRN no. 465, with intended use as a ingredient in infant formulas (https://www.accessdata.fda.gov/scripts/fdcc/?set=GRASNotices&id=465; last accessed 24 January 2018)
Lysozyme	125–250	Gram-positive bacteria	Used in milk, wine and in casings for frankfurters	FDA GRAS notice GRN no. 191, with intended use as a ingredient in infant formulas (https://www.accessdata.fda.gov/scripts/fdcc/index.cf set=GRASNotices&id=191; last accessed 24 January 2018)
Nisin A	5–200	Gram-positive bacteria	Canned foods, dairy products, cooked meats, poultry	FDA GRAS notice GRN no. 65, with intended use on casings for frankfurters and on cooked meat and poult products as an antimicrobial agent (https://www.accessdata.fda.gov/scripts/fdcc/index.cf set=GRASNotices&id=65; last accessed 24 January 20

Polylysine: a Broad-Range Antimicrobial Polypeptide

ε-Poly-l-lysine (polylysine) is a secondary metabolite isolated from the soil microorganism *Streptomyces albulus* subsp. *lysinololymerus* strain 346 (31). It is composed of 25 to 35 l-lysine residues and has a net positive charge. In this molecule (Fig. 28.3), l-lysine residues are connected via isopeptide bonds between ε-amino and *R*-carboxyl groups (32). Polylysine is produced with the assistance of a membrane-associated nonribosomal peptide synthetase, and the producer cell is partially protected from polylysine's antimicrobial activity by an aminopeptidase, a product of the *pld* gene (33). Polylysine is particularly attractive as a food preservative due to its broad range of antimicrobial activity, covering Gram-positive and Gram-negative bacteria as well as yeast and molds (34). Equally compelling is its safety: in a rodent oral toxicity study, it caused no adverse effects or mortality when delivered at a dose of 5 g/kg of body weight (35).

The mechanism of antimicrobial action for polylysine has been studied and modeled using *E. coli* (36). Polylysine initially acts on the cellular membrane. The primary interaction between polylysine and L-glycero-D-mannoheptose of the membrane lipopolysaccharides is driven by electrostatic forces leading to the detergent-like removal of lipopolysaccharides. It is still unknown whether polylysine is active in periplasmic space or whether it simply transitions to the inner membrane. When the inner membrane is reached, a so-called "carpet-like interaction" (reviewed in reference 37) takes place in which polylysine interacts with the membrane's leaflets, gradually removing them and causing thinning of the inner membrane. Once inside the cell, polylysine has multiple mechanisms of action causing downregulation of the expression of virulence genes, as well as negative effects on the SOS response and the regulation of oxidative stress, etc. (38).

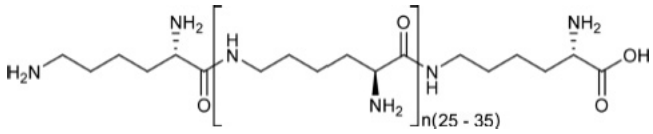

Figure 28.3 Chemical structure of polylysine.

Metabolomic analysis of polylysine-treated *S. cerevisiae* revealed several different, concentration-dependent mechanisms of antimicrobial action (39). At high levels, close to the MBC, polylysine caused multiple, clearly identifiable damages to the yeast membrane. When used at 40% of the MBC, polylysine did not cause the death of the yeast population; however, the yeast's life cycle was much slower than that of untreated cells. Finally, when used at 10% of the MBC, polylysine did not have any negative effects on yeast viability, but significant negative changes in cellular biochemistry and physiology (e.g., inhibition of glycolysis) were observed, most likely in relation to disruption of the membrane's integrity.

The antimicrobial activity of polylysine against the foodborne pathogens *Salmonella* Typhimurium, *L. monocytogenes*, and *E. coli* O157:H7 was evaluated in laboratory nutrient medium (40) and in several food models (41). In the latter experiments, tryptic soy broth was supplemented with 10% (wt/wt) of fat-free or whole milk or 10% (wt/wt) extracts of beef, bologna, rice, and vegetables. These experiments were designed as a preliminary evaluation of the possible effects of various food formulations on polylysine's antimicrobial activity. These experiments were conducted at 12°C, mimicking temperature-abused storage of refrigerated foods. Interestingly, after 6 days of incubation, 0.2% polylysine caused, on average, a 7-log reduction of the viable cell count of *E. coli* O157:H7 in food model systems and an approximately 2-log reduction of the pathogen when incubated in tryptic soy broth. Comparable results were achieved against *Salmonella* Typhimurium; however, these required 0.04% polylysine. An approximately 1-log reduction in the number of the pathogen's viable cells was observed when the cells were incubated in tryptic soy broth. Finally, similar results were obtained with *L. monocytogenes*: 0.02% polylysine was effective in delivering an approximately 8- to 9-log reduction of the pathogen in every food-mimicking system, while there was a 3-log reduction in the viable cells that had been grown for 6 days in the presence of the antimicrobial in broth alone. It is important to mention that the observed inhibition of allthree foodborne pathogens developed gradually over the 6-day storage period. This interesting study produced several conclusions, two of which are very important: (i) food composition may positively influence the preservative's activity and ability to control foodborne pathogens, and (ii) some preservatives may work well during extended storage time but should be intelligently formulated with other antimicrobials capable of more immediate action against foodborne pathogens.

Lactoferrin: a Milk-Derived Multifunctional Protein with Antimicrobial Activity

Eukaryotic iron-binding glycoproteins of approximately 80 kDa are found in various biological fluids, such as milk, saliva, vaginal secretions, tears, etc., and are known as lactoferrins (42). The amino acid sequence of bovine lactoferrin is 69% identical to that of lactoferrin of human origin, while porcine lactoferrin is 72.6% identical to bovine lactoferrin and shares 70.7% sequence identity with human lactoferrin (43).

Lactoferrins possess activity against a broad range of human pathogens, including Gram-negative (e.g., *E. coli* and *Salmonella*) and Gram-positive (e.g., *Streptococcus* spp., *L. monocytogenes*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*) bacteria and yeasts (e.g., *Candida albicans*). Several modes of action, most likely initiated during the antimicrobial's interaction with the cellular membrane, have been reported for lactoferrins against various microorganisms, including several expected interactions with iron, lytic activity, interference with adhesion, inhibition of multiple cellular functions, etc. (44). Lactoferrins are also active against enveloped and nonenveloped viruses (reviewed by Jenssen and Hancock [45]).

Food-grade lactoferrin is produced from fresh cow's milk or from by-products of dairy fermentation, such as milk whey. Some examples include the commercial products Bioferrin (Glanbia; Kilkenny,

Ireland), Vivinal (FrieslandCampina; Amersfoort, Netherlands), and lactoferrin from Ferrin-Tech (Phoenix, AZ), Synlait (Rakaia, New Zealand), and Fonterra Group (Auckland, New Zealand). Possible food applications of lactoferrin have been reviewed by Duran and Kahve (46).

An iron-free formulation (apo-lactoferrin) resisted pH 4.0 during a 5-minute treatment at 90 and 100°C (47). However, lactoferrin's activity is reduced by various factors, including divalent cations (Fe^{2+}, Mg^{2+}, and Ca^{2+}). These and other activity-inhibiting challenges have been addressed by Naidu, who immobilized lactoferrin on food-grade polysaccharides (such as carrageenan) (48). The resulting patented technology produced highly active lactoferrin capable of inhibiting various foodborne pathogens, including *E. coli* O157:H7, even on meat surfaces and in iron-rich environments. This technology has received FDA-affirmed GRAS status for use as an antimicrobial spray (processing aid) on beef carcasses (FDA GRAS notice GRN no. 130; https://www.accessdata.fda.gov/scripts/fdcc/index.cfm?set=GRASNotices&id=130).

Interestingly, while noting the structural instability of lactoferrin treated for 5 min at pH 3.0 and 100°C, Abe and coauthors observed increased antimicrobial activity (47). Lactoferrin-derived peptides with increased antimicrobial activity can also result from proteolytic digestion (49). It is important to mention that proteolytic digestion of bovine lactoferrin can produce a diverse group of peptides with antimicrobial activity: LF1-11 (the N-terminal part of lactoferrin), lactoferrampin (lactoferrin residues 268 to 284), and lactoferricin (lactoferrin residues 17 to 41). These derivatives have been reviewed by Sinha et al. (50). Remarkably, lactoferricins of a bovine origin were reported as having higher antimicrobial activity than lactoferricins of human, goat, or rodent origin (51). The antimicrobial action of bovine lactoferrin hydrolysate is likely to be attributed to its function on the cellular membrane, as was shown with the foodborne pathogen *E. coli* O157:H7 (52). Similar to lactoferrin, the hydrolysate's antimicrobial activity is negatively influenced by numerous factors, including divalent cations, pH, temperature, food product constituents (e.g., low activity in ultra-high-temperature-pasteurized milk, as reported by Murdock and Matthews [53]).

Lysozyme: One of the Cohort of Antimicrobial Enzymes

Antimicrobial enzymes are a diverse group of proteinaceous substances and include many representatives with activity against both food spoilage and infectious microorganisms. These include antifungal chitinases; broad-antimicrobial-spectrum glucose oxidases, inhibiting *S. aureus*, *Clostridium perfringens*, and *S. enterica* serovar Infantis; and lactoperoxidases with documented bacteriostatic or bactericidal activity (depending on the microorganism and environment) against *P. aeruginosa*, *E. coli*, *Salmonella* Typhimurium, etc. (for a review, see reference 54).

Lysozymes are a relatively conserved group of cationic antimicrobial enzymes produced by virtually alleukaryotic organisms and capable of killing a broad range of Gram-positive and Gram-negative bacteria by hydrolyzing peptidoglycan in the cell wall (55). There are three major groups of lysozymes: chicken type, goose type, and invertebrate type. These groups differ biochemically, enzymatically, and structurally. Egg white lysozyme is suitable for food processing technologies, as it can survive 100°C treatment for up to 30 min at acidic pH (but not at neutral or basic pH, which are not so common for food products).

Lysozyme is generally active against Gram-positive bacteria and not particularly active against Gram-negative microorganisms, which present an additional barrier, the outer membrane. However, when used in combination with a chelating agent, such as EDTA, lysozyme is recorded as having improved activity against Gram-positive pathogens while also killing Gram-negative foodborne microorganisms and most spoilage bacteria. While a substantial amount of data on lysozyme's antimicrobial activity (alone and in various combinations in laboratory media and food systems) is available, these different studies are difficult to compare because of the many variables which have a significant influence on the outcome of these studies.

Hughey et al. investigated the antimicrobial activity of lysozyme (alone at 100 mg/kg or combined with 5 mM EDTA) against *L. monocytogenes* in Camembert cheese and reported no complete inhibition of the foodborne pathogen under the studied conditions with an initial inoculation of 104 CFU/g of

cheese (56). The reported 1-log reduction in the viable cell count of the pathogen is not sufficient for adoption of this treatment as a preservation method. Some food products may even act as "pathogen protectants." For instance, lysozyme is ineffective against *L. monocytogenes* in milk. However, the pathogen can be "sensitized" to lysozyme by sublethal heat treatment at 62.5°C for 15 s (57), which is likely to produce temporary changes in the cellular membrane, making it susceptible to the antimicrobial's action (58).

Sinigaglia and coworkers studied the effect of lysozyme combined with EDTA on waterborne mozzarella spoilage coliforms and *Pseudomonas* (59). The authors reported effective inhibition of both groups of microorganisms during a 7-day period of storage at 4°C, with no significant inhibition of lactic acid bacteria. Gill and Holley evaluated the combined action of lysozyme, EDTA, and the AMP nisin (discussed below) against spoilage and foodborne microorganisms in meat products (ham and bologna) that were subjected to treatment with combinations of these antimicrobials by dipping (60) or coating (61). In a different study, these investigators explored the activity of selected combinations of antimicrobials relevant to the food industry against spoilage and pathogenic microorganisms grown in laboratory media (62). Interestingly, dipping ham in a formulation with 500 mg/kg lysozyme-nisin (1:3) and 500 mg/kg EDTA effectively controlled *Salmonella* Typhimurium for 3 weeks and both *Brochothrix thermosphacta* (a common meat spoilage microorganism) and *E. coli* O157:H7 for 4 weeks of storage at 4°C. Under the same experimental conditions, the Gram-positive pathogen *L. monocytogenes* was effectively suppressed for only 2 weeks.

These microorganisms were effectively inhibited in the same food systems when the antimicrobial treatment was delivered in a gel formulation. However, the results were strikingly different for the experiments conducted with the microorganisms grown in nutrient broth: the antimicrobial formulations were significantly less active than in the challenged food systems. This important observation indicates the necessity to thoroughly investigate novel food preservatives in real food systems to avoid false-positive and false-negative interpretations of their activities.

Bacteriocins: Food Preservatives, Not Antibiotics

Bacteriocins' place in the world of AMPs: definition and classification

AMPs are naturally produced by allliving organisms: the skin of the African clawed frog (*Xenopus laevis*) is rich with magainins, the salivary glands of humans generate histatins, white blood cells produce defensins, etc. (for a review, see reference 63). In eukaryotes, AMPs are believed to be an ancient functional group of molecules, often serving as one of the first lines of defense against various microbial intruders. The mechanism of antimicrobial action by AMPs is determined by their secondary structure: they can form α-helices, β-sheets, or extended/random-coil structures (reviewed in reference 64). Like eukaryotes, bacteria also produce various AMPs, such as nonribosomally synthesized polylysine (described above) and bacteriocins, which are generally defined as "ribosomally synthesized antimicrobial peptides produced by one bacterium that are active against other bacteria, either in the same species (narrow spectrum), or across genera (broad spectrum) and, as with host defense peptides, cell signaling mechanisms can also be involved" (65).

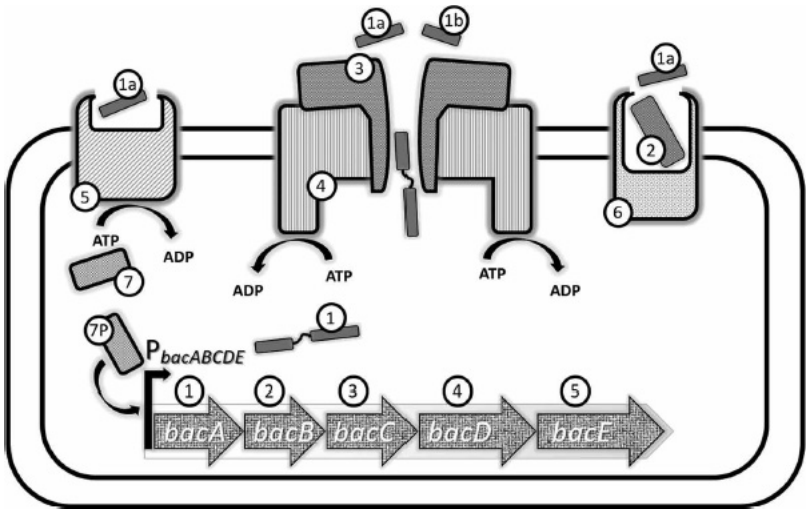
The ability of virtually allbacteria to produce bacteriocins was first postulated by Tagg in 1992 (66) and then solidified with more recent evidence (67). The apparent simplicity of isolating new bacteriocin-producing microorganisms has resulted in numerous reports on "novel producers" and "novel bacteriocins," many of which have not provided sufficient evidence to confirm these claims. Indeed, the initial tests are very simple and straightforward: a potential bacteriocin producer's colony grown on solid nutrient medium is overlaid with soft agar containing the targeted microorganism. Alternatively, the supernatant of the tested isolate can be added to a well in solid nutrient medium seeded with the targeted strain. The appearance of an inhibition zone with sharp edges and sensitivity of this activity to proteolytic enzyme(s) are supposedly considered evidence of antimicrobial activity that can be attributed to proteinaceous substances. However, this is absolutely insufficient and results in premature claims regarding the microorganism's and antimicrobial's novelty. In fact, the strain must

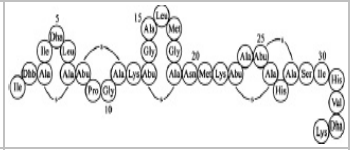
also be taxonomically identified and the nature of the proteinaceous substance should be elucidated to the point of confirming both its ribosomal nature of synthesis and sequence identity.

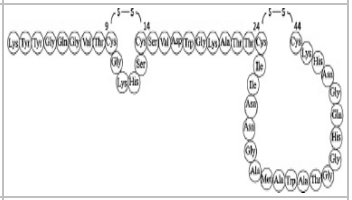
It is important to mention that the definition of bacteriocins has changed several times since it was first proposed in the 1970s, especially with a need to separate the rather different bacteriocins of Gram-negative bacteria from those synthesized by Gram-positive microorganisms. This resulted in even further subdivision, with a separate classification proposed for bacteriocins produced by LAB as well (68), many of which are considered important for various food applications (starter cultures, live preservatives, flavor producers, etc.). According to the proposed classification, bacteriocins from LAB are divided into three major classes: class I contains small (less than 10 kDa) posttranslationally modified proteins, class II contains small but unmodified proteins which may still require processing to remove the leader region during the molecule's translocation across the membrane, and class III contains molecules larger than 10 kDa with various mechanisms of action. These classes are then further divided into subclasses. For the purpose of this chapter, it is important to mention that nisin A belongs to subclass Ia, the lanthipeptides, which contains unusual posttranslationally generated amino acids, such as lanthionine or methyl-lanthionine. Another bacteriocin of importance in current food applications is pediocin PA-1 (also known as pediocin AcH), which belongs to class IIa, or pediocinlike bacteriocins, also referred to as antilisterial bacteriocins or YGNGVXC motif bacteriocins (for reviews of class IIa bacteriocins, see references 69 and 70).

Genetic organization of a "generic" bacteriocin operon, with nisin A and pediocin PA-1 as examples

Genes with different functions and in different numbers are involved in the production of these classes and subclasses of bacteriocins. However, a "generic" bacteriocin operon may consist of several genes whose products are essential for a bacteriocin's production and the normal physiology (healthy status) of a bacteriocin-producing cell (Fig. 28.4). These genes encode (i) a prebacteriocin, (ii) an immunity protein protecting the producer cell from its own product, (iii) possibly an accessory protein, which is engaged in the bacteriocin's translocation across the membrane, (iv) an energy-dependent peptidase-ABC transporter, and (v) possibly signal transduction-regulated production of a bacteriocin, which may involve multiple genes.







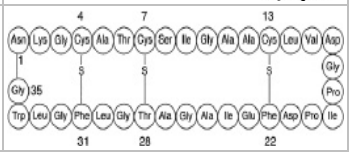


Figure 28.4 Generic bacteriocin operon. The operon's structural gene *bacA* codes for a prebacteriocin (numbered 1). The bacteriocin processing and transport are carried out with assistance of the products of *bacC*, coding for the accessory protein (3), and *bacD*, coding for the ABC transporter (4). The bacteriocin producer cell's immunity to its own product is ensured by the *bacB* gene product, the immunity protein (2). The bacteriocin translocation machinery is engaged in the energy-dependent process, resulting in the cleavage of the bacteriocin's leader region (1b) and release of the mature bacteriocin (1a). The immunity protein (2) protects the bacteriocin recognition site (6) by preventing the bacteriocin (1a) from interacting with this site. The *bacE* gene codes for the histidine protein kinase (5), which is activated by the mature bacteriocin molecule working as a pheromone. The phosphorylated response regulator (7P) interacts with the bacteriocin operon's promoter region, triggering transcription.

Interestingly, when produced, unprocessed prebacteriocins have no or very low antimicrobial activity (71, 72), which may also serve as a mechanism for protection of the producer cell from damage by its own bacteriocin within the cell membrane. Moreover, overexpression of a bacteriocin's processing/translocation machinery may lead to a higher extracellular production of this AMP, indicating that perhaps, under normal physiological conditions, not all of the ribosomally produced bacteriocin molecules leave the cell, and some of them are proteolytically digested inside the producer cell (71).

Processing and translocation of a bacteriocin across the membrane are guided by products of two genes and eventually result in formation of a mature (processed) bacteriocin molecule in the extracellular environment. One of these proteins is an ATP-dependent ABC transporter (encoded by *nisT* in the case of nisin [73] and *pedD* in the case of pediocin PA-1), an ATP-binding cassette translocator which belongs to the hemolysin B (HlyB) type of proteins (74). Also, class IIa bacteriocins' ABC transporters contain an N-terminal domain which is involved in the proteolytic cleavage of the N-terminal leader region from prebacteriocin molecules. The accessory protein is encoded by *pedC* (in the case of pediocin PA-1) and *lcnD* (in the case of lactococcin A) (75) and is similar to the *E. coli* hemolysin A secretion protein HlyD (76). It is involved in bacteriocin translocation across the membrane and is likely needed to ensure that the correct disulfide bridges are formed in the mature pediocin PA-1 molecule (77). In the case of nisin, the serine protease coded by *nisP* is involved in cleavage of the N-terminal leader region of nisin, and the propeptide's posttranslational modification is conducted with the assistance of two membrane-associated proteins encoded by *nisB* and *nisC* (78).

Table 28.3 Bacteriocins: AMPs with varying charges, structures, and targets

Name	Class and/or type	Source	Overall charge	Target	Sequence
Nisin A	Class Ia, lantibiotic	*Lactococcus lactis*	Positive	Lipid II	
Pediocin PA-1	Class IIa	*Pediococcus acidilactici*	Positive	Phosphotransferase system	
Subtilosin A	Cyclopeptide, Sactibiotic	*B. subtilis*	Negative	Under Investigation	

Bacteriocin immunity genes and their products are very specific and provide the producer cell with immunity against its own or very similar bacteriocins (79). For instance, *nisI*, *nisF*, *nisE*, and *nisG* gene products confer immunity to the bacteriocin nisin A. Specifically, *nisI* codes for an extracellular lipoprotein whose C terminus protects the membrane's lipid II, thus providing immunity to the cell's own product (80). Additional genes (*nisEFG*) code for an ABC transporter (for a review, see reference 81). All four gene products are required for the effective protection of the producer cell against antimicrobial action by nisin (82).

It is also important to mention that by default, when we or other authors discuss "nisin," we generally mean nisin A, which is one of a family of nisins consisting of several highly similar lantibiotics (e.g., nisin A, Z, F, Q, etc.; for a review, see reference 83).

Pediocin-like operons contain immunity genes coding for α-helical immunity proteins ranging in size from 9.7 to 12.7 kDa, with the C-terminal region reported as recognizing the corresponding bacteriocin's C terminus, although this physical interaction has not yet been shown (for reviews, see references 84 and 85).

The production of nisin is self-regulated by the bacteriocin's presence in the environment, where it serves as a pheromone, interacting with the producer cell's membrane-localized sensor kinase, a constituent of the socalled EnvZ-OmpR-type two-component regulation system. The intracellular response regulator (second component) is activated by phosphorylation, which occurs with a phosphor transfer from the sensor kinase's transmitter domain. Finally, the activated response regulator's output domain interacts with the promoter regions (P_{nisA} and P_{nisF}), triggering transcription (for a review, see reference 86). Some of the pediocin-like operons were reported as being regulated by a two-component signal transduction system (87, 88); however, this has not been reported for pediocin PA-1 (89).

Bacteriocins' mode of action as multifunctional AMPs

Many studied bacteriocins have multiple functions (in addition to being antibacterial) and often have more than one mechanism of antimicrobial action (for a review, see reference 13). At sub-MIC concentrations, bacteriocins are likely to serve as environmental signals that repel possible intruders in the bacteriocin producer's ecological niche, also preventing these intruding bacteria from settling in the environment—both activities target inhibition of microbial quorum sensing, which is essential for biofilm formation (reviewed in reference 90).

In sensitive cells, lethal interactions with bacteriocins start at the membrane, where both the charge and the AMP's hydrophobicity may be essential for the initial contact between the antimicrobial and

the cell membrane. It is important to mention that while many bacteriocins have a net positive charge (including nisin and pediocin PA-1), not all of them are cationic (Table 28.3). This is particularly important because some authors still suggest a generalized definition of bacteriocins, which includes a statement on their cationic nature. A good example of an anionic bacteriocin is subtilosin A, a cyclopeptide produced by *Bacillus subtilis* which has three aspartates and glutamates and just one lysine in its sequence (91). This bacteriocin belongs to the group of sactibiotics (for a review, see reference 92), also classified by some authors as class V bacteriocins, and has recently received a lot of attention as a potential alternative to conventional antimicrobials for various applications or as antibacterials which are studied as a complementary treatment together with conventional antibiotics (93).

The next stage of interaction may involve a cell membrane-located recognition site, such as the lipid II anchor in the case of nisin (94), and a mannose-specific phosphotransferase system as a “receptor” for pediocin-like bacteriocins (95). These are not receptors in the true sense; a receptor-like function has been reported so far with only one membrane-located protein in *Streptococcus pyogenes*, which is recognized by a two-component bacteriocin from *Streptococcus mutans*, designated lantibiotic Smb (96). In fact, the existence of specific bacteriocin recognition sites for some bacteriocins (without diminishing the role of the primary electrostatic interaction) was proposed in the early 1990s (97).

The next phase of the bacteriocin-cell membrane interaction involves pore formation. Wedge-like and barrel-stave models were proposed during the late 1990s (98) and have been thoroughly studied over the years; these were recently reviewed, with specific examples for three classes of bacteriocins and with some emphasis on food applications (for example, see reference 65). Bacteriocin-induced pore formation causes multiple devastating damages to the targeted cell, starting with dissipation of one (99, 100) or both (101) components of the proton motive force (transmembrane potential and transmembrane pH gradient). The bacteriocin-induced transient pores allow leakage of various cellular constituents, although some bacteriocins may form specific channels, for instance, causing leakage of potassium ions (102). Also, depending on the specific bacteriocin-target interaction, ATP can leak outside the cell, as in the case of nisin (103), or it can be predominantly hydrolyzed intracellularly (104).

In addition to being active against vegetative cells, some bacteriocins have been reported to kill microbial spores. The accumulated knowledge on bacteriocinspore interactions is rather limited, and the molecular mechanisms of these processes have not been elucidated. However, this topic was recently critically reviewed (105), with several significant conclusions. So far, of all the studied bacteriocins, only enterocin AS-48 was reported as having sporicidal activity against *Alicyclobacillus acidoterrestris*, as confirmed by electron microscopy, which showed pronounced damage to the endospore structure (106). Nisin activity against spores is likely to be species dependent: it promotes germination of spores of the foodborne pathogen *C. botulinum* (107) but inhibits germination of the spores of a spoilage microorganism, *Bacillus sporothermodurans* (108). Also, allof the reviewed bacteriocins required germination to start acting against the tested spores. This was thoroughly studied for nisin, and Gut and coworkers, using several mutated and truncated nisin derivatives, showed that pore formation is crucial for nisin’s action against germinating spores of *Bacillus anthracis* (109, 110; reviewed in reference 105). It should be mentioned that while gastrointestinal anthrax resulting from ingestion of *B. anthracis* is rather rare, it is reported as causing mortality in about 40% of the treated patients (for a review, see reference 111).

As was justly emphasized by Egan and coworkers in their comprehensive review (105), there is very limited information on bacteriocin action against spores of food spoilage microorganisms and foodborne pathogens. While the advance in control of spore-forming food-related bacteria is of great importance, the slow progress in these studies is likely due to the limited number of reliable methodological approaches available for mechanistic elucidation of bacteriocin-spore interactions, and it is hoped that the development of novel methods (for example, see reference 112) will accelerate progress in this field of research.

Resistance to bacteriocins

Numerous sophisticated approaches are utilized by microorganisms to survive in competitive environments. These can be divided into two groups of survival approaches: adaptations and mutations. Microbial adaptation to the presence of a bacteriocin in the environment can take various forms: biofilm-associated microorganisms will likely be more tolerant to bacteriocin action, spores are likely to survive the bacteriocin's presence in the environment, and vegetative cells can adapt by modifying their membrane composition. Positive mutations leading to bacteriocin resistance lead to various changes in the cellular membrane and intracellular processes, making the cell resistant to bacteriocin action. It is noticeable that some authors loosely use the term "resistance," which should be attributed only to mutation-determined changes, while the term "tolerance" is more appropriate for adaptation-driven changes.

Bacteriocin resistance should be considered a positive quality for microorganisms which are expected to stay alive and to perform normally in various environments while protected by the action of bacteriocins (e.g., food-fermenting microorganisms and healthy microbiota of the gastrointestinal tract). However, resistance can create some challenges in food products preserved with bacteriocins. Microbial resistance to nisin (along with other lantibiotics) (113) and pediocin PA-1 (89) was recently reviewed. In the case of nisin resistance, several major cellular components were highlighted as contributing to resistance. For instance, the DltB protein is required for d-alanine incorporation into the monomers of the microbial wall's teichoic acid, which can be modified with positively charged d-alanine (114). In turn, this results in a more positively charged membrane, which repels nisin molecules, as in the case of *Lactococcus lactis* with overexpression of the *dlt* operon (115). d-Alanination of lipoteichoic acid also causes a decrease in microbial sensitivity to nisin (116). Nisin-resistant bacteria may produce nisin-specific proteolytic enzymes, such as a nisin resistance protein in lactococci or nisinase in bacilli, enterococci, and some other microorganisms.

Broad-range lantibiotic resistance approaches utilized by various microorganisms are compiled in Table 1 of reference 113. Similar to nisin resistance, d-alanination of lipoteichoic acid ultimately leads to a more positively charged membrane, and this was found to be a factor in increasing resistance to class IIa bacteriocins (including pediocin PA-1) (117). Based on this group's previous studies (118), class IIa bacteriocin resistance in the foodborne pathogen *L. monocytogenes* can also be attributed to the higher fluidity of the cell membrane than that of the membranes of sensitive cells, which is caused by higher levels of unsaturated phosphatidylglycerol.

Microbial resistance to food preservatives should be considered a serious challenge. However, bacteriocin resistance has not yet been reported to be associated with any outbreaks. Moreover, a study has shown that the multiple-stress exposure approach in food preservation may allow the sensitization of bacteriocin-resistant foodborne pathogen (119). In this study, nisin-resistant *L. monocytogenes* was treated with sublethal heat (55°C) and nisin and was found to regain its sensitivity to the bacteriocin.

Utilization of bacteriocins as food preservatives with multiple forms of delivery

The rapidly growing number of studies on bacteriocin activity against pathogens indicates a growing interest among researchers and industries in these antimicrobial substances for various applications expanding beyond food preservation (e.g., personal care products, new antimicrobials for health care). To avoid confusion, it is important to make clear that bacteriocins are different from conventional antibiotics (see Table 28.4, which is adapted from reference 120).

Bacteriocins act as food preservatives in three major forms of delivery. For convenience, some examples have been compiled in the tables, instead of being presented in a narrative manner. The first category contains partially purified formulations, mostly derived from milk fermentation by the producing microorganism. Many of the commercially available food-grade formulations of nisin contain 2.5 to 5% (depending on the manufacturer) nisin, with the rest being NaCl and insoluble milk constituents. While over the last half-century numerous bacteriocins were investigated for their ability to control foodborne pathogens and spoilage microorganisms in model and food systems, nisin is the only GRAS bacteriocin used as a partially purified formulation on an industrial scale around the world. Still, in addition to nisin, several other bacteriocins have been studied in model and food systems and showed promising results in their ability to control undesired microorganisms (Table 28.5). The

second category contains the crude products of fermentation of food-grade substrates by bacteriocinproducing LAB with GRAS status (e.g., MicroGARD [121]). Finally, the third category is an assortment of bacteriocin-producing protective cultures (Table 28.1).

Table 28.4 Bacteriocins are not antibiotics[a]

Characteristic	Bacteriocins	Antibiotics
Application	Food	Clinical
Synthesis	Ribosomal	Mostly secondary metabolites
Activity	Mostly narrow spectrum, few broad spectrum	Varying spectrum of activity, mostly broad
Host cell immunity	Yes, different mechanisms	No
Mechanism of target cell resistance or tolerance	Mostly various adaptations or mutations causing changes in the cellular membrane	Various modifications or mutations affecting different sites depending on the mechanism of action
Interaction requirements and phases	Sometimes docking or recognition sites, possibly in combination with the primary electrostatic interaction with the membrane	Mostly specific targets in the cell
Mode of action	Mostly at the microbial membrane, resulting in pore formation; some may have multiple concentration-dependent mechanisms of action: quorum sensing inhibition, bactericidal, lytic	Cell membrane or intracellular target
Toxicity/side effects	None known at the concentrations used	Yes

[a] Adapted from reference 120.

Table 28.5 Bacteriocins' activity in food products (recent publications)

Bacteriocin	Origin	Target	Food product	Achieved result	Reference
Nisin	*Lactococcus lactis* subsp. *lactis*	*L. monocytogenes*	Red-pepper seasoned cod roe	*L. monocytogenes* was undetectable in samples after 28 days of storage at 15°C (600 μg/g Nisaplin treatment); lower concentrations showed strain-specific activity.	148
Nisin	*Lactococcus lactis* subsp. *lactis*	Total microbial population	Yogurt	Total microbial population was lower in nisin-containing yogurt than in controls over a 40-day period at 10–15°C, with nearly a 1-log difference on day 35. Interestingly, growth in the nisin-treated yogurt peaked at 25 days, while growth in the control continued to increase.	149
Pediocin PA-1	*Pediococcus pentosaceus* NCDC 273	Various	Raw buffalo (*Bubalus bubalis*) milk	Significant reduction in the total count of viable bacteria, *S. aureus*, and lactic acid-producing bacteria. Treatment was less effective against coliform bacteria, and no effect was seen against yeasts and molds.	150
Enterocin AS-48	*Enterococcus faecalis* A-48-32	*B. cereus* LW1, S. *aureus* CECT 976	Liquid egg	Notable inhibition of both pathogens, after incubation at 4°C and 96 h and 28°C and 48 h. For *B. cereus*, 5 μg/ml was able to reduce the pathogen count to undetectable levels, while 15 μg/ml was required for *S. aureus*.	151
Enterocin AS-48	*E. faecalis* UGRA10	*L. monocytogenes*	Raw and smoked fish	Reduction in listeria with respect to the untreated control by 3.13 and 2.8 CFU/cm^2 in raw hake and salmon, respectively, after 7 days at 4°C. For smoked salmon, a 4.25-log CFU/cm^2 reduction was observed after 30 days at 4°C.	152
Enterocin MR10A	*Enterococcus faecalis* N1-33/N41-51	*B. cereus*	Steamed rice	After inoculation and storage at 25°C for 48 h, a 4.0% N41-51 culture supernatant showed a 6-log reduction in CFU/g compared to the untreated sample, and a 4.0% N1-33 culture supernatant showed an approx 1-log reduction.	153

Bacteriocin	Origin	Target	Food product	Achieved result	Reference
Enterocin	*Enterococcus faecalis* L3B1K3	*L. monocytogenes* ATCC 7466	Fresh cheese	Semipurified enterocin was effective in inhibiting *L. monocytogenes* during incubation at 4°C for 72 h; treatment with 134 μg/g of cheese caused a 10-fold reduction, while 536 μg/g reduced *Listeria* counts below detectable limits.	154
Paracin C	*Lactobacillus paracasei* CICC 20241	*A. acidoterrestris*	Apple juice	30 μg/ml was effective against 14 of 19 tested strains, with lethality between 85 and 99% after 24 h. Treatment of *A. acidoterrestris* DSM 3922 spores did not reduce viable-cell counts but did increase sensitivity to heat treatment.	155
Sakacin P, sakacin X	*L. curvatus* MBSa2	*L. monocytogenes* Scott A	Salami	2-log and 1.5-log reductions in viable-cell counts after 10 and 20 days, respectively	156
Aureocin A70	*S. aureus* A70	*L. monocytogenes* L12	Skim milk	5.51-log reduction in *L. monocytogenes* cell counts compared to the control after 7 days of storage at 4°C	157

Major approaches for the improvement of bacteriocin efficacy in food applications

As was already mentioned, in the food environment, the activities of various bacteriocins can be challenged by numerous physical, chemical, and biological factors. Therefore, significant attention is given to the improvement of bacteriocin performance in real foods. These efforts can be divided into several categories, which may ultimately be used either alone or in combination. First, improvement of bacteriocin efficacy is addressed by enhancing its stability against proteolytic digestion (122) and/or enhancing and broadening antimicrobial action resulting from directed mutagenesis (123, 124). Second, possible synergies between bacteriocins and food-grade antimicrobials and/or physical stressors (e.g., temperature, pressure, and irradiation) interacting with different targets is considered a valid approach (for example, see reference 125) (Table 28.6). Finally, the effectiveness of antimicrobial action delivered by bacteriocins can be finely tuned with their controlled delivery. For instance, in a model study with nisin, Balasubramanian and coworkers showed that the most effective inhibition of a targeted model microorganism occurs in the case of bimodal release of the antimicrobial into the environment (126). In this case, the prompt release of a large quantity of the antimicrobial from the carrier contributes to the effective inhibition of the targeted microorganisms. The second phase of slow release over the extended period of time delivers much smaller quantities of the bacteriocins into the environment, contributing to efficient control of possible survivors. For reviews on controlled delivery and antimicrobial packaging, see for instance references 127 and 128.

Table 28.6 Increased activity of bacteriocins when combined with synergistically acting stressors[a]

Bacteriocin	Other stressor(s)	Effect	Reference
Nisin A	Bacteriophage mixtures LM-103 and LMP-102 (5 × 107 PFU/ml)	Reduced *L. monocytogenes* by 5 log on honeydew melon slices stored at 10°C for 7 days compared to control (nisin alone; 400 IU) 3-log reduction	158
Nisin A	Endolysin LysH5	Synergistic action in pasteurized milk at 37°C against *S. aureus*	159
Nisin and/or enterocin AS-48	HIPEF	Bacteriocins were more active when used sequentially after HIPEF, delivering 6-log reduction of S. *aureus*	160
Nisin A	Reuterin and lactoperoxidase	Three antimicrobials synergized in controlling *L. monocytogenes* and *S. aureus* in the semisolid dairy product cuajada, delivering approx. 4-log reduction of foodborne pathogen after 12 days of incubation at 10°C compared to combinations of any two antimicrobials	161
Nisin A	Lactoferrin	Combination of nisin (250 IU/ml) and lactoferrin (500 μg/ml) inhibited *E. coli* O157:H7; combination of nisin (10 IU/ml) and lactoferrin (250 μg/ml) inhibited *L. monocytogenes*	162
Nisin A	Cinnamaldehyde	Nisin in combination with the cinnamon bark's essential oil synergistically acted against 13 foodborne isolates of *S. aureus* when tested in milk	163
Nisin A	Thymol and lactobionic acid	Synergistic action against *L. monocytogenes* reported in reduced-fat and whole milk with nisin used at 250 and 500 IU/ml, respectively. Thymol and lactobionic acid were used at 2 and 10 mg/ml, respectively.	164
Pediocin PA-1	Sodium diacetate	Pediocin PA-1 at 5,000 AU/ml synergized with 0.5% diacetate at 25°C in delivering 7-log reduction of *L. monocytogenes* in turkey slurries	165
Pediocin PA-1	Hydrostatic pressure and high temperature	Combination of pressure (345 MPa), temperature (50°C), and bacteriocin acts synergistically on *S. aureus*, *L. monocytogenes*, *E. coli* O157:H7, *Lactobacillus sakei*, *Leuconostoc mesenteroides*	166
Pediocin PA-1 sakacin P, or curvacin A	Pleurocidin Synergistic action of each of the three class IIa bacteriocins with the fish AMP against the lab strain *E. coli* ATCC 14763	167	

[a] HIPEF, high-intensity pulsed electric field. AU, arbitrary units.

Bacteriophages: Selectively Acting Natural Killers

Bacteriophages are complex, highly organized, multimolecular structured viruses of bacteria, which infect bacterial cells and utilize the cells' resources for multiplication. There are numerous reviews on bacteriophages, and some are suggested here, with an emphasis on the use of bacteriophages as rapidly developing and promising therapeutic antimicrobial agents (e.g., references 129 and 130; the latter provides a good overview of the history of bacteriophage discovery, classification, and research efforts). Whether these strict parasitic predators (bacteriophages and viruses in general) should be considered living creatures is beyond the scope of this chapter, although it is an interesting and controversial topic, and we recommend some studies addressing the issue (131, 132).

Bacteriophages follow their prey and consequently are as ubiquitous in food environments as bacteria themselves. Bacteriophages are just as much of a challenge to the biotech industry, which often relies on microbial fermentation, as they are a threat to the food industry, where microorganisms' role is essential in food processing, safety, etc. (133). On the other hand, bacteriophages targeted at spoilage and infectious microorganisms in the dairy industry are considered a promising tool for improving the safety and quality of fermented dairy products (134). In addition, bacteriophages can contribute to the development of a new generation of protein- and DNA-based vaccines and function as antimicrobials protecting biotechnological fermentation against most common spoilage challenges (135). Bacteriophages are considered a promising aid in the improvement of the health, safety, and quality of animals of agricultural importance and their by-products, helping to control pathogens such as *E. coli* O157:H7, *Salmonella*, *Campylobacter*, *L. monocytogenes*, etc. (for reviews, see references 136 and 137). Clearly, bacteriophages can be utilized as quality- and safety-controlling antimicrobial agents at every step of the food chain, "from the farm to the fork" (138).

Using bacteriophages as food preservatives is somewhat similar to their use as "antibiotic agents" targeted at pathogens in infected human subjects (or animals), although the differences are many and striking. Some of these similarities and differences are summarized in Table 28.7.

The effectiveness of bacteriophages' action as food preservatives is determined by both external factors (environment and targeted pathogen) and the bacteriophage's intrinsic qualities. The latter includes the multiplicity of infection (MOI), which is defined as "the ratio of infectious virions to cells in a given culture" (further reading on the limitations of MOI as a parameter used in microbiology is suggested) (139). It is generally assumed that higher MOIs correspond to enhanced efficacy. MOIs determined in the lab environment differ from those reported in *in vivo* studies. They also vary across multiple studies, making the results confusing and difficult to compare, perhaps because MOI by definition assumes a homogeneously infected cell population, which is not always achievable in practice. Some reports indicate that while lab studies showed the effective control of *E. coli* O157:H7 with bacteriophages, the *in vivo* results were not as impressive, pointing to ineffectiveness of bacteriophages in ruminants under the chosen experimental conditions (140). Moreover, cocktails of bacteriophages targeting different serotypes of several foodborne pathogens would have to be formulated into an all-inclusive bacteriophage-based food preservative to effectively control a broad range of pathogenic microorganisms that may vary greatly based on the food product in question.

L. monocytogenes was one of the first foodborne pathogens whose control in food systems was attempted with the assistance of bacteriophages. This may have been driven by the fact that while listeria does not cause many outbreaks and the morbidity is not the highest, mortality rates can reach up to 25%, especially in immunocompromised subjects (for reviews on listeria and listeriosis, see references 141 and 142). According to the CDC, there are 12 serotypes of *L. monocytogenes*, of which 1/2a, 1/2b, and 4b are most often isolated from food sources and reported in outbreaks. There are reports on bacteriophages with a broad range of activity against several serotypes of *L. monocytogenes* as well as reports on the particular resistance of some isolates of this pathogen to various bacteriophages. Strydom and Witthuhn reviewed the ability of bacteriophages to control *Listeria* in various food products (see Table 2 in reference 143). The critically reviewed studies indicate that, in general, a single treatment with a high number of bacteriophages usually delivers the best antimicrobial effect. However, in some studies, the pathogen started to regrow after an initial application of the bacteriophage formulation.

There are studies where repeated applications of bacteriophage treatment delivered good results. However, these cannot be called conclusive, as the results vary depending on the experimental scenario. For instance, Guenther and Loessner (144) reported on effective control of *L. monocytogenes* in several cheeses with the broad-host-range bacteriophage A511. When used at 3×10^8 PFU/cm^2, this bacteriophage caused a 2.5-log reduction in viable cell count over 21 days of ripening of Camembert cheese, and additional bacteriophage application did not deliver any further reduction in the numbers of listeria (144). The same authors reported that in a different experiment with red-smear cheese, the second application of bacteriophage delayed the outgrowth of *Listeria* but did not eliminate the pathogen. The bacteriophage treatment was effective when used at a high number (1×10^9 PFU/cm^2) and against the lowest initial number of *Listeria* cells (10^1 to 10^2 CFU/cm^2): this resulted in elimination of *Listeria* below the detection limit, compared to the 6-log growth of the pathogen in untreated cheese. Interestingly, Guenther and Loessner point at several promising studies where bacteriophages were used in combination with other, synergistically acting preservatives, such as nisin (mentioned above [Table 28.6]) and lauric arginate (144).

Table 28.7 Bacteriophages as an aid in infectious diseases and food safety: commonalities and differences in food and infection scenarios

Challenge	Infection	Food
Targeted microorganism	Often starts with a specific infectious agent; may lead to multimicrobial and sometimes secondary infections with different microorganisms	Usually specific microorganisms, whose possible presence is determined by the available nutrients and environmental conditions of the food system
Physical factors pH	Varying pH, mostly neutral or basic, but acidic in some healthy organs (e.g., stomach, vaginal environment)	Mostly below pH 7.0
Temp	Normal temp is approx 37°C; elevated temperature may occur in the case of infection	Ambient temperature is appropriate for certain products. Refrigeration (4°C) or freezing (approx. –10 to –20°C) temperature is required for food products as indicated on the label. Temperature-abused storage (often reported in the range of 10–14°C) is documented in numerous cases of spoilage and in outbreaks due to foodborne pathogens.
Environment Physiological and biochemical parameters	Stable in healthy subjects, with normal biochemical and physiological processes; changing in infected organisms	Stable in microbiologically unchallenged products; changing with outgrowth of spoilage microorganisms and/or foodborne pathogens
Microbiology	Healthy microorganisms are challenged and often suppressed or even replaced by infectious bacteria	Presence of food-related microorganisms is determined by the type of food product. There are products where microorganisms should be suppressed to provide the desired shelf life. No live bacteria should be present in canned foods.
Treatment Goal	Eradicate pathogens, if possible, with little to no damage to the host and the healthy microbiota (e.g., lysis of pathogens can "assist" with release of various toxins)	Eradicate foodborne pathogens before the food product is manufactured and prevent outgrowth of pathogens and spoilage bacteria during the product's transit and storage up until the point of consumption by the consumer.
Challenges	Effective therapy requires a threshold population (10^5 to 10^6 CFU) of actively growing bacteria. Bacteria can "disguise" themselves (e.g., by hiding in macrophages), and the environment can be challenging and cause nonspecific interactions that may prevent bacteriophages from reaching their intended target.	Not likely to be applicable as the only agent for control of "zero tolerance" pathogens. The environment can be challenging, causing nonspecific interactions that may prevent bacteriophages from reaching their intended target. Foodborne pathogens in low numbers can escape the bacteriophages' "radar." Stressed, viable but nonculturable pathogens may allow the absorption of the bacteriophage but may not necessarily result in killing of the intended target.
Overcoming challenges	Using cocktails of bacteriophages targeted at different serotypes and combinations with synergistically acting stressors	Using cocktails of bacteriophages targeted at different serotypes and combination with synergistically acting stressors

On the regulatory side, the FDA has affirmed GRAS status for a P100 bacteriophage preparation against *L. monocytogenes*. The P100 preparation was approved for use on meat and poultry products (FDA GRAS notice GRN no. 218; https://www.accessdata.fda.gov/scripts/fdcc/index.cfm?set=GRASNotices&id=218&sort=GRN_No&order=DESC&startrow=1&type=basic&search=218) as well as in normally aged and ripened cheeses (FDA GRAS notice GRN no. 198; https://www.accessdata.fda.gov/scripts/fdcc/index.cfm?set=GRASNotices&id=198&sort=GRN_No&order=DESC&startrow=1&type=basic&search=198). It has shown promising results in reducing *Listeria* in cooked turkey and roast beef, especially when combined with chemical preservatives such as potassium lactate and sodium diacetate (145). The authors evaluated the bacteriophage preparation against *Listeria*-challenged products stored at refrigeration temperature (4°C) and at abused-storage temperature (10°C). Interestingly, the bacteriophage performed the best in the abused-storage scenario, delivering a 7.5-log/cm^2 reduction of *Listeria* in cooked turkey and a 7.2-log/cm^2 reduction in roast beef.

Several formulations of multiple bacteriophages active against foodborne pathogens have been designed, have received approval from the regulatory agencies, and are currently marketed for various applications in food processing and preservation (for a review, see reference 146). Of particular interest are those active against *Shigella* (ShigaShield; FDA GRAS notice 672; https://www.accessdata.fda.gov/scripts/fdcc/?set=GRASNotices&id=672&sort=GRN_No&order=DESC&startrow=1&type=basic&search=672) and *Salmonella* (SalmoFresh; FDA GRAS notice 435; https://www.accessdata.fda.gov/scripts/fdcc/index.cfm?set=GRASNotices&id=435&sort=GRN_No&order=DESC&startrow=1&type=basic&search=Salmonella).

CONCLUSION

Meaningful fundamental study and exploration of possible food applications for natural/biological preservatives are still in their infancy, as it has been less than a century since their initiation. Unlike chemical preservatives, biopreservatives require sophisticated novel approaches in their formulations, controlled delivery, and combinations with synergistically acting stressors—all aimed at achieving the desired effectiveness and reproducibility in real food systems. An understanding of the role of health-promoting microorganisms in food and in human microbiota naturally includes an understanding of the need for more selective action of food preservatives, aimed specifically at spoilage and pathogenic microorganisms. The rapidly growing breadth of experimentally generated evidence indicates that this goal may be achieved with an increasing number of biopreservatives such as those discussed in this chapter (147).

Bacteriophages for Biological Control of Foodborne Pathogens

NEED FOR BIOLOGICAL CONTROL OF FOODBORNE PATHOGENS

Food safety is challenged by globalization and international trade as well as changes in lifestyle and consumer demands for a more natural and preservative-free diet. The latter trend has sparked the development of minimally processed foods that are low in salt and sugar yet safe, appetizing, and with long shelf lives. However, when foods are produced with limited physical preservation technologies and few chemical preservatives, the bacterial counts may increase and the food environment may not prevent growth of pathogenic and spoilage bacteria. While food spoilage results in significant economic loss for food producers, food poisoning has an even wider societal influence due to its effects on human health, food export, and economy. In primary production, the prophylactic and therapeutic use of antibiotics selects for antibiotic-resistant bacteria and contributes to the emergence of multidrug-resistant bacteria, resulting in declining efficacy of antibiotics used to treat bacterial infections in humans. Thus, novel trends in consumer demands and the global threat of antibiotic-resistant bacteria have generated the need for natural preservation techniques, both to reduce the use of preservatives in food production and to provide alternatives to aid safe food production. Bacteriophages, the natural killers of bacteria, may provide alternative biological solutions for control of foodborne pathogens covering the entire food chain.

BENEFITS OF USING PHAGES FOR BIOLOGICAL CONTROL OF FOODBORNE PATHOGENS

Bacteriophages are obligate parasite viruses that are specific to bacteria, thus being harmless to humans, animals, and plants. Phages do not have a metabolism of their own; rather, they use the bacterial host machinery to propagate, a process that leads to the killing of the infected bacteria. Because phages are dependent on bacteria to propagate, they are mainly found in environments that encompass diverse and abundant bacterial communities. Recent research has demonstrated that both the human and animal guts not only contain a highly diverse bacterial microbiota but also hold a rich and diverse virome of phages and other viruses (1). Therefore, it is no surprise that phages are also abundant and ubiquitous in foods and can be isolated from raw products such as beef and chicken (2), processed foods (3), fermented products like cheese and yogurt (4), and seafood (3, 5). This suggests that we daily consume not only bacteria but also extensive amounts of their phages.

Since their discovery a century ago, phages have been used to prevent and treat bacterial infections. Early work on the therapeutic use of bacteriophages in animals and humans was performed by French scientist and codiscoverer of phages Félix d'Hérelle. In his first paper, he observed that phage presence correlated with disease clearance in patients with dysentery (6). Moreover, he performed a study using rabbits, showing that phages provided protection from *Shigella* infection. Later, d'Hérelle treated cholera and other enteric human diseases using phages.

As described in this chapter, phages have proven to be promising for biological control of foodborne pathogens. In general, phages are particularly beneficial for developing natural and specific food control agents as novel antimicrobials due to their inherent characteristics (Table 29.1). Importantly, phages are self-replicating and self-limiting; thus, at low dosages, phages will multiply as long as a bacterial host is present, thereby enhancing the overall antimicrobial activity. In addition, the action of phages does not have any considerable impact on the physical, chemical, and overall organoleptic properties of the food. Because phages are abundant in the environment, they are easy to isolate and

usually persist well in foods. Phages are highly specific and leave the remaining microbiota untouched, another property that favors phages over conventional methods that may affect the beneficial microbiota of the food. Furthermore, phages have low inherent toxicity and are already present in foods as well as the human and animal gut. Finally, phages can be used along the entire food chain, including phage therapy for reduction of pathogen colonization of animals in primary production and phage biocontrol during food production.

Table 29.1 Main advantages of using bacteriophages for food safety [a]

History of safe use Ubiquitous in nature, including food ecosystems Natural commensals of humans and animals Extensive clinical use in Eastern Europe	Highly active and specifc No adverse effects on the intestinal microbiota Innocuous to mammalian cells Autoreplicative	Versatile use along the food chain Phage therapy: use in preharvest processes such as primary production Phage biocontrol: use at harvest during slaughter and fresh produce Phage biopreservation: use in RTE products	Source of potent antimicrobials Endolysins and other peptidoglycan hydrolases Depolymerases and other carbohydratedegrading enzymes

[a] Modified from reference 120.

In this chapter, we explain the principles and mechanisms behind the use of phages for biological control of foodborne pathogens, as well as the rationale and outcome of using phages for therapy and biocontrol, including the challenges and limitations of such applications. In terms of future prospects, we discuss the technical and regulatory challenges of widespread industrial use of phages for biological control of foodborne pathogens.

NATURE OF BACTERIOPHAGES

Phage Diversity and Taxonomy

Phages are the most abundant microorganisms on earth, outnumbering bacteria by a factor of 10, with an estimated 10^{31} phages in the biosphere (7). Most phages identified (approximately 96%) belong to the order *Caudovirales* and harbor double-stranded DNA genomes inside a polyhedral capsid attached to a tail. Both capsid and tail structures commonly consist of proteins forming the highly ordered and complex architecture of the phage particle. The tailed phages of *Caudovirales* encompass three major families (*Siphoviridae*, *Myoviridae*, and *Podoviridae*) displaying different tail morphologies. Phages of the family *Podoviridae* have short, noncontractile tails, while *Siphoviridae* phages carry long, flexible but noncontractile tails, and contractile tails are the unique characteristic of *Myoviridae* phages. Thus, phages belonging to the same family are morphologically related, yet they may not show any similarity at the DNA level. With the recent advances in DNA sequencing technologies, the number of phage genome sequences in the databases has increased tremendously, yet often without any morphological information. This has prompted a new classification scheme based on genome sequence and proteome analyses to classify phages (8). Fortunately, genome- and proteome-based classifications are in accordance with the morphology-based classification and allowed further classification of phages into species, genera, and subfamilies by comparative analyses (9). Importantly, the enormous abundance and diversity of phages in the biosphere provide an almost unlimited source of diverse phages for applicative purposes, including controlling foodborne pathogenic bacteria.

Phage Life Cycles

Being obligatory parasites, phages rely on their host bacteria for propagation. While strictly virulent phages cause cell lysis when new phage particles are released from the infected bacteria (lytic life cycle), temperate phages also have the ability to maintain their genomes in the bacteria in a dormant

form without causing cell death (lysogenic life cycle) (Fig. 29.1). Temperate phages can either integrate their genetic material into the bacterial chromosome and become prophages or maintain the genome as a plasmid in the cytoplasm. In both situations, the phage genome replicates and is passed on to the daughter cells during growth of the bacteria. However, unfavorable conditions for the bacteria may trigger dormant temperate phage to enter the lytic life cycle, thus propagating and releasing progeny phages by cell lysis. Temperate phages need specific genes for commencing and maintaining the lysogenic life cycle, such as integrases and repressors. By comparative bioinformatics analyses of phage genomes, genes involved in the lysogenic cycle of phages can be identified, thus allowing phages to be classified as temperate. In phage applications, it is important to avoid temperate phages due to their ability to perform specialized transduction by packaging host DNA flanking the site of integration. Furthermore, temperate phages may carry genes that can phenotypically alter the host bacterium.

Importantly, virulent phages with a strictly lytic life cycle always resulting in bacterial death are promising natural agents for biological control. In the lytic life cycle, the phage binds specifically to a bacterial surface receptor, injects its genome into the cytoplasm of the bacterial host, and converts the bacteria into a phage-producing cell. This includes directing bacterial resources to phage genome replication and synthesis of structural phage proteins, which then allow packaging of the phage genome into the assembled head followed by assembly of newly completed phage particles. Last, phage-encoded lytic enzymes rupture the cells from inside and promote bacterial lysis and release of progeny phages.

Even though the major steps of the phage life cycles have been known for decades, the understanding of the specific interactions and mechanisms that allow phages to hijack the bacterial metabolism is limited. For a long time, it was assumed that phages primarily control their hosts by eliminating host transcription and degrading host mRNA, based on the example of phage T4 (10). However, recent work has demonstrated large variations in the mechanisms by which phages interact with the infected bacteria. For example, phages infecting *Pseudomonas* spp. have been shown to influence host cell transcription, RNA degradation, cellular motility, and metabolism (11–13). In addition, some phages degrade the genomes and plasmids of their hosts to recycle the nucleotides for replication of the phage genome, whereas others leave the host DNA untouched. Recently, a feature important for phage applications was described, involving the propagation of two virulent phages that do not degrade host plasmid DNA, thus leading to release of the plasmid upon host lysis, which then can cause horizontal gene transfer by transformation (14). Additionally, certain virulent phages may promote generalized transduction by packaging parts of the host's bacterial genome (15). Due to the vast diversity of phages, it is expected that each phage may utilize a unique mechanism of host takeover.

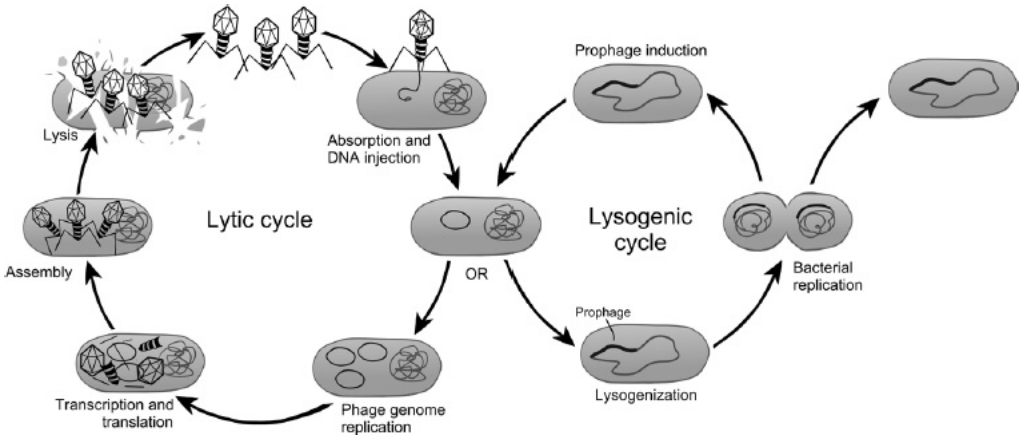

Figure 29.1 Life cycles of phages.

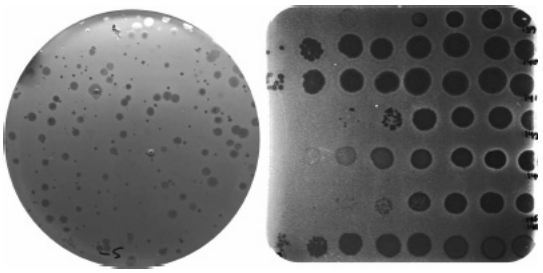

Figure 29.2 Plaque morphologies. (Left) Dilution of a wastewater sample that harbors phages showing different plaque morphologies. (Right) Ten-fold dilutions of purified phage stocks showing consistent plaque morphologies (right).

The killing of bacteria through lytic infections can be observed in different ways in the laboratory: by lysis of liquid cultures containing phages, by reduction of the number of CFU of the target bacteria in food models, or by phages forming zones of clearance (plaques) on bacterial lawns (Fig. 29.2). While plaque formation is useful for isolating and counting phages, reduction of the number of CFU in food models allows determination of the phage's killing efficiency in food biocontrol applications.

Phage Receptors and Host Range

The vast diversity in bacterial cell surface structures allows phages to recognize and adsorb to their particular host by binding to a specific surface component. Such receptors can be any surface component of the bacteria, including carbohydrate moieties, comprising lipopolysaccharides (LPSs), capsular polysaccharides, teichoic acids, and outer membrane proteins, as well as protruding protein structures, such as flagella and pili (16, 17). For some phages, adsorption is a two-step process in which a phage reversibly interacts with a primary receptor and then irreversibly binds to a second receptor to inject its genome. Phage adsorption may also be influenced by the accessibility and spatial distribution of the receptor on the cell surface, as well as environmental conditions such as availability of divalent cations or tryptophan for activation of adsorption. Examples of receptors of selected phages infecting foodborne pathogens are listed in Table 29.2. In some Gram-negative bacteria, such as *Salmonella*, numerous phage receptors have been identified and include flagellar proteins and outer membrane transporters, whereas core carbohydrates and the variable O antigen of the LPS have been shown to influence the initial phage binding serving as the primary adsorption (for a review, see reference 18). Thus, the large diversity of receptors reflects the enormous diversity of phages. For Gram-positive bacteria, the majority of identified receptors are associated with either peptidoglycan or teichoic acid structures of the cell wall. For example, phages infecting *Listeria monocytogenes* bind to the peptidoglycan, the glucosaminyl and rhamnosyl components of ribitol teichoic acid, or the glucosaminyl of ribitol teichoic acid (19). Finally, some phages may use more than one receptor, as exemplified by *Escherichia coli* phage T4, which can use both outer membrane porins (OmpC and OmpF) and the terminal glucose of the *E. coli* B-type LPS (20).

For tailed phages belonging to *Caudovirales*, the initial adsorption is mediated by receptor-binding proteins (RBPs) located at the distal part of the phage tail. These RBPs form long fibers or stubby spike-like structures that bind specifically to the bacterial receptor. Due to the specific interactions of the binding domains, amino acid substitutions in RBPs may drastically change the affi nity. In phage genomes, genes encoding RBPs are prone to diversification through mutations, duplications, and intra- and interspecies recombinations, leading to mosaic RBPs with new binding affi nities reflected by changes in the host ranges (17, 21). One study even showed that accumulation of mutations in RBP genes over the course of several phage replication cycles changed the RBP binding specificity from a protein to a carbohydrate moiety (22). RBP binding to the bacterial receptor typically triggers a conformational change at the distal tail that is transmitted along the tail, allowing the release of the phage genome from the capsid into the bacterial cytoplasm. Thus, the specificity of the phage binding to its receptor ensures that the phage injects genetic material only into a bacterium that has the potential to support propagation.

The host range of a phage defines the breadth of bacteria that a phage is able to infect and kill during propagation. Only when the phage is able to complete the lytic life cycle and produce new phage particles can the infected bacterium be regarded as a host (23). As only limited bacterial hosts support phage propagation, phages are usually specific to certain bacterial strains, species, or more rarely genus. While this specificity allows directed killing of pathogenic bacteria using phages, it also defines the coverage of the phage solution. Thus, detailed knowledge of the host range is a prerequisite for designing phage solutions to target specific bacteria. Recently, bioinformatics tools able to predict bacterial hosts at the genus level have been developed (24, 25). Still, biological data defining the host range are required for application purposes, as these programs do not take the natural diversity of bacterial strains of the same genus and species into account. Experimental host range data can be generated by determining the ability of a phage to form single plaques on bacterial lawns encompassing diverse strains of bacterial collections.

Table 29.2 Examples of phage receptors of selected phages infecting foodborne pathogens

Bacterium and phage	Receptor	Reference
S. enterica SPN2T	Flagellar proteins FliC and FljB	121

A500	Glucosaminyl residues in teichoic acid	19

Phage Resistance

For phage applications, it is important to consider both intrinsic phage resistance mechanisms already found in the natural bacterial populations and the selection or emergence of resistant subpopulations when phage solutions are applied. During exposure to high phage titers, bacteria most commonly develop phage resistance by modulating the availability of receptors or preventing phage access. These first-line defenses include receptor mutations, loss of receptors, or even synthesis of components that physically mask receptor access, thus preventing phage adsorption and infection. One example is *Campylobacter jejuni* phage F336, where the host gains resistance by preventing adsorption, either by losing the receptor or by introducing certain modifications to the capsule that indirectly prevent access to the receptor (26–28). This strategy of developing resistance also influences susceptibility to other different phages (29). However, such receptor changes become dominant in the bacterial population only if the environment allows bacterial growth. In a food environment that does not support growth of the pathogenic bacteria, phage-resistant variants cannot be selected for and will not become the dominant population. On the other hand, the application of phages targeting enteric bacteria residing in the animal gut may favor selection of phage-resistant receptor mutant populations.

In most applied studies, the underlying mechanisms of phage resistance development were not investigated in detail, and therefore, most of our understanding of phage resistance development is based on studies of well-characterized phage-bacterium model systems. From these studies it is clear that, depending on the receptors, mutations arising from phage exposure and resulting in phage resistance may influence the biology and pathogenicity of the bacteria. *Salmonella enterica* serotype Typhimurium may become resistant to several phages, but at the expense of reducing its virulence (30). It was shown that phase variation of the *opvAB* operon generates two subpopulations with different LPS O-antigen lengths. When exposed to phage, the virulent phage-sensitive subpopulation with long O antigens diminishes, while the avirulent phage-resistant subpopulation with short O antigens survives. Thus, while acquisition of phage resistance results in reduced virulence, phase variation permits recovery of virulent subpopulation when phage challenge ceases (30). However, phages may also counteract receptor changes and regain or acquire the ability to adsorb to novel receptors, thereby maintaining or even changing or expanding their host range. It has been proposed that phage genes involved in host recognition are among the fastest-evolving phage genes due to selection pressure during phage-bacterium coevolution (31). For example, phage T7 can evolve to infect *E. coli* cells with different LPSs upon successive propagations on *E. coli* strains expressing such LPS structures. The resulting T7 phage derivatives were found to carry mutations in the gene encoding the tail fiber protein responsible for interaction with LPS (32). Such experiments demonstrate the possibility to evolve and select for phages that recognize different receptor variants by mutations in the RBPs.

When phages are used for biological control of foodborne pathogenic bacteria, phage resistance development can be minimized by using phage cocktails. Phage cocktails consist of two or more phages, ideally targeting different receptors. The use of such cocktails decreases the likelihood of the development of resistance, as bacteria attacked by multiple phages will be killed before acquisition of resistance. Therefore, knowledge of phage receptors can aid in the design of efficient phage solutions that avoid phage resistance development.

Due to the coevolution and coexistence of bacteria and phages in all ecological niches, it is plausible to expect that bacteria have evolved many different and so far-unidentified ways to counteract the killing effect of phages but also that phages have developed responses to such mechanisms. Internal phage resistance mechanisms may include the ability to degrade the phage genome using host-encoded nucleases. Such restriction-modification defense systems modify the bacterial DNA to ensure self-discrimination and degrade only the invading nonmodified phage genomes to prevent the phage takeover during infection. However, there are examples of phages adapting to restriction-modification systems by modifying their own DNA, thus protecting the phage genome from degradation by host restriction enzymes (33).

Another internal phage defense mechanism is the CRISPR-Cas (clustered regularly interspaced short palindromic repeats [CRISPR] and CRISPR-associated proteins), which functions as an adaptive bacterial immunity system targeting foreign nucleic acids (34). The CRISPRCas loci are generally composed of an array of direct repeats interspaced by nonrepetitive diverse spacers and flanked by a varying number of different *cas* genes. In short, invading phage DNA is digested by a Cas nuclease in a sequence-specific manner. This requires the phage genome to contain a DNA sequence (protospacer) that matches one of the diverse spacers of the CRISPR array in the bacterial genome. The bacteria may evolve the CRISPR array by acquiring novel spacers upon initial phage infection, thus gaining resistance to future infections of the phages carrying the same protospacer sequence, working as an adaptive immunity (35). Still, phages have also developed countermeasures to CRISPR-Cas-mediated phage resistance mechanisms. Mutations in the protospacer sequences allow them to avoid spacer-mediated recognition of their genomes. More recently, phage anti-CRISPR proteins were discovered and shown to prevent the action of the CRISPR-Cas in different ways (36).

Bacteria may also encode abortive infection mechanisms in which an infected cell dies before phage replication for the benefit of the remaining sister cells in the population (31). Bioinformatics analyses have revealed clusters of defense islands abundantly found in many different bacteria, suggesting the presence of numerous novel phage resistance mechanisms that may shape phage-host interactions

(37). A number of these internal phage resistance mechanisms have been experimentally shown to affect phage replication (38–40). For phage application development, it is important to recognize that bacterial populations found in food and farm animals may be highly diverse, with differences in phage sensitivity. To ensure the isolation of phages able to infect a majority of a natural microbial population, a panel of defined highly resistant mutants can be employed as isolation hosts. In practice, this has not yet been done systematically, and to date, molecular studies of overcoming bacterial resistance have been generated from single-phage–single-host combinations, with an understanding of their broader presence in microbial systems gained through comparative bioinformatics.

CONSIDERATIONS PRIOR TO PHAGE APPLICATION FOR FOOD SAFETY

Bacterial Densities, Volume, and Environmental Conditions Affect Outcomes

When the concentration of phages to be used for a given application is being determined, it is important to consider the level of bacterial contamination, the volume, and the environmental conditions (41). Phages must first be physically able to collide with the bacteria in order to infect. Because phages are not able to move actively and are dependent on diffusion to find their hosts, microstructures of the inert surfaces may affect or even prevent diffusion. Also, the available fluid will impact the volume the phages must diffuse through to encounter the target bacteria. On the other hand, if limited fluid is available, phage diffusion may be hampered. Moreover, the target bacteria must be physically accessible in the food matrix, and the higher the reduction of bacteria aimed at, the more phages might be needed. Finally, using standard assumptions of mass-action interactions and moderate phage adsorption constants, Hagens and Loessner calculated that it takes around 1,000 years for one phage and one bacterium to meet within 1 ml of fluid (41). Thus, not only are the numbers of phages and bacteria important, but also, the overall volume will also influence the outcome of the phage application. In practice, phage applications are tested under the relevant conditions at different multiplicities of infection (MOIs; defined as the number of phage particles per bacterial cell) in order to determine the actual dose needed to obtain the desired efficiency of the phage application. However, at very high MOIs (>100), cells may lyse without phage propagation due to the changes in the membrane potential caused by excessive yet unspecific interaction of phages with the cell surface. This phenomenon is known as nonspecific killing, or “lysis from without,” and is usually associated with cell wall-degrading enzymes located at the tail tip of many bacteriophages (42).

In primary production, farm animals used for food production may be colonized with zoonotic bacteria at very high numbers, thus increasing the likelihood of phage-bacterium encounters when phages are applied therapeutically. In addition, phage treatment may lead to significant phage propagation in the gut, allowing progeny phages to infect new target cells and contribute to reductions in the bacterial counts. When a phage application to be used during slaughter is being designed, the distribution and number of target bacteria should be carefully considered, as this may vary between animals and different technologies of the slaughter process. In food matrices, the environment can be very diverse and very specific depending on the food product. Moreover, high-quality production of the raw material as well as good hygienic practices throughout the production chain often leads to low levels of contamination by the pathogenic bacteria. Thus, to target a low number of bacteria on a solid surface requires high numbers of phages, simply to ensure that phages will encounter a bacterial host. It is also important to consider whether the bacteria are able to grow in the food environment. In addition, application on solid food matrices limits the phage diffusion, and thus, high numbers of phages will be required to achieve infections and significant reductions in the bacterial counts. Finally, environmental factors may influence the success of different stages of the lytic life cycle, and these must be considered when phages are used to control foodborne pathogens.

Bacteriophages Are Safe for Humans and Animals

Since phages are abundant in the environment, humans and animals consume phages on a daily basis from food and water. As phages are specific to bacteria, they do not actively interact with human and animal cells, but nonetheless they may be perceived as foreign particles and stimulate the human and animal immune systems. However, this does not affect the safety but rather the efficiency of the phage application, and to date, there is no evidence that phages exert harmful or allergenic effects on humans or animals. On the contrary, the use of phage therapy to treat infections over the past century has provided a large body of evidence showing that phages are harmless for humans and animals. However, applying phage to kill bacterial cells within the human body may cause adverse effects, not because of the phages themselves, but as a side effect from the release of large amounts of cellular material, such as LPS, during lysis. This has been observed in only a few clinical applications with high bacterial loads and therefore cannot be directly compared to the effects of most other food safety applications. Oral toxicity studies have shown that high doses of *L. monocytogenes* phages fed to albino rats had no measurable impact on rodent behavior or physical appearance (43). Also, a study using oral administration of *E. coli* phages to mice and human volunteers showed no adverse effects on the test subjects (44, 45). In summary, phages as entities are well tolerated by humans and animals and are part of their own natural microbiota, and they are therefore considered safe.

Historically, phage preparations used for therapy in humans were made from crude phage extracts, which often contained immunogenic and pyrogenic materials from the lysed bacterial cells. Modern methods of large-scale phage production require the removal of such cell debris, LPS, or endotoxins originating from the host bacteria used for production. This may be achieved by downstream purification of the phage preparation to remove cell debris and toxin contamination from the propagating bacterial host. In addition, it has been suggested that nonpathogenic surrogate host bacteria can be used for large-scale production to eliminate the hazards associated with large culture volumes of pathogenic bacteria. This may also require less stringent downstream purification procedures if the surrogate host does not produce the soluble toxins which may be associated with a pathogenic strain.

For safety reasons, temperate phages should be avoided in biological control of foodborne pathogens, as they may alter the phenotype of the bacterium by expressing genes during the prophage state. It is known that prophages may carry and express moron genes that are not involved in phage propagation but provide beneficial traits to their host by encoding virulence or antimicrobial resistance factors. Moreover, following induction, temperate phages may transfer fragments of host DNA by specialized transduction into nontargeted bacteria (possibly to other related species) by packing bacterial DNA flanking the prophage integration site into the progeny phage capsids. Phage genome sequencing and bioinformatics analyses can reveal unwanted genes or genes associated with a lysogenic lifestyle. Virulent phages that perform generalized transduction should be avoided to prevent the spread of genes encoding toxins, antibiotic resistance factors, or virulence factors. These phenomena can be tested in the laboratory by conducting transduction experiments (46).

There is a particular concern that extensive use of phages may also select for bacterial strains with altered phenotypes, as has been observed with extensive use of antibiotics. In practice, by investigating the phage-resistant strains and determining the mechanisms and frequencies of phage resistance, it is possible to evaluate the consequences of phage resistance for colonization and virulence of pathogenic bacteria. In addition, using predefined phage cocktails globally and continuously in a manner similar to antibiotics may select for bacterial populations that become permanently resistant to such specific phage cocktails. However, comprehensive studies of phage infection patterns suggest that new infectious phages will nevertheless be available (47). Compared to antibiotics, the diversity and numbers of phages are immense, suggesting that phage resistance may not be a concern at all, even in the long run (48).

Designing Phage Applications for Biological Control

When novel biological applications for the control of foodborne pathogens using phages are being designed, both safety and efficacy should be considered, and any phage that is used must meet several criteria. For biological control of pathogenic bacteria, only virulent phages should be used, as

temperate phages can lysogenize and not kill the host or might cause horizontal gene transfer between susceptible strains. Ideally, these virulent phages should be produced using a nonpathogenic host, and they should show no signs of being able to perform transduction. The complete genome of the phage should be available and devoid of any lysogeny-, pathogenicity or antibiotic resistance-associated genes as well as proteins associated with allergic reactions. In addition, oral feeding studies should demonstrate no adverse effects. Ideally, these phages should degrade the host DNA during infection to minimize the risk of transfer of host genes following the lysis of the target bacteria (14).

While these criteria are important for human and environmental safety, the following considerations are necessary to ensure the efficiency of the phage solution. Phages should have as broad a host range as possible in order to cover the potential diversity of strains of the target bacterium. In reality, covering the strain diversity of even one target bacterial species is challenging and remains a major obstacle for phage application efficiency. Phage cocktails consisting of multiple phages can be designed to tackle this limitation and increase the coverage of the application. Importantly, such phage cocktails can delay the emergence of phage-resistant populations. Phages in the cocktails should be dependent on different receptors for infection, since accumulating mutations to counteract phage infection for several receptors will be cumbersome for the target bacteria. Finally, for phage solutions to be commercially feasible, phages must be able to be produced on a large scale and be sufficiently stable over the storage and application period.

BIOCONTROL OF FOODBORNE PATHOGENS IN PRIMARY PRODUCTION

Rationale for Applying Phages in Primary Production

The habitats of zoonotic foodborne microbial pathogens include animals used for food production, but many of these bacteria do not result in clinical symptoms in livestock, thus allowing undetected contamination of foods. Furthermore, intensive animal breeding practices, global animal transportation, and the introduction of new animals to production facilities facilitate spread between individual animals within herds or flocks, consequently increasing the risk of food contamination throughout the farm-to-fork chain. Therefore, the elimination or reduction of zoonotic foodborne bacterial pathogens, early in the farm-to-fork chain, is regarded as a cost-effective approach with a high potential to reduce the risk of human infections. A study assessing the efficiency of controlling *Campylobacter* in broiler meats estimated that applying phage therapy to *Campylobacter*-positive flocks throughout the Netherlands could result in a 63% reduction in the risk of human campylobacteriosis (49). Moreover, control of foodborne pathogens in production animals can reduce the shedding and incidence of new infections in herds or flocks, thus contributing to good production practices in livestock. In addition, management of both pathogens and zoonotic bacteria in primary production and aquaculture is dependent on the use of antimicrobials, contributing to the current trend of increasing prevalence of antibiotic-resistant bacteria. Collectively, these issues drive the search for novel approaches to the management of zoonotic foodborne bacteria during primary production, including application of phages.

Administration of phages to production animals for prophylaxis or therapeutic purposes is not a novel concept and was quickly initiated after the discovery of phages. A number of works have compiled therapeutic uses of phages for diseases of livestock (50–52) as well as of aquatic animals (53–58), but here, we focus on the accumulating studies demonstrating that phage therapy in production animals is an effective measure against several foodborne pathogens belonging to different genera.

Outcome of Applying Phages in Primary Production

Several works have investigated phage therapy in ruminants, swine, and poultry, with the primary focus being on *E. coli* O157:H7, *Salmonella enterica* subsp. *enterica* serotypes, or both *Salmonella* and *Campylobacter*. A summary of studies of these approaches and their outcomes is listed in Table 29.3. In most of these studies, the use of phages for reduction of specific pathogens was promising.

However, the outcome of phage therapy is dependent on the successful encounters between phage particles and the target bacteria in the animal, as well as their individual success in killing the target bacteria. When administered orally via feed or drinking water, phages should be able to tolerate the acidic conditions of the digestive tract and maintain their viability in the presence of digestive enzymes and other digestive compounds (e.g., bile) before reaching the intestinal tract. Hence, the stability of phages in feed material or drinking water, adequate dosage, number of doses (single doses versus continuous administration), and the route of administration are important factors affecting the success of encounters between phages and their target pathogen.

Administration of Phages in Primary Production

In order to allow phages to bypass the deteriorative environment of the stomach without rapid loss of viability, a number of different approaches have been used. In some work, researchers coadministered antacid buffers (e.g., calcium carbonate or sodium bicarbonate) along with phage cocktails to neutralize stomach acid (59–62). Although this approach was useful for experimental studies, its application in livestock production with thousands of animals would be challenging. In chickens, a comparison of phage administration via drinking water and aerosol spray was performed (63). Borie and colleagues showed that a prophylactic single-dose coarse spray treatment of chickens 24 h prior to bacterial challenge can also lead to significant reductions in *Salmonella* Enteritidis loads (63). In sheep and cattle, rectal phage administrations were tried as an alternative, due to the fact that the lymphoid follicle-rich recto-anal junction (RAJ) mucosa is a significant colonization site for *E. coli* O157:H7 (64). To reduce the colonization levels in experimentally inoculated Holstein steers, phages SH1 and KH1 were coadministered directly to the RAJ mucosa, while the phages were also continuously administered via drinking water throughout the experiment (65). Although they observed significant reductions in all five treated steers, a total clearance was seen in only a single calf. Later, it was found that oral treatment with a cocktail of four phages resulted in lower O157:H7 counts than RAJ mucosa application, although the differences were not significant (66). Researchers concluded that RAJ application alone might not be sufficient to ensure encounters of phages with *E. coli* O157:H7, since the bacterium can also be found at the proximal regions of the intestines, such as cecum, colon, and rarely duodenum (67).

In aquaculture, phage therapy is currently not feasible in settings such as grow-out ponds or sea cages due to the large volume of water. However, it remains an attractive alternative particularly for hatcheries that can establish high phage titers in hatching and larval growth tanks (68). In addition, pretreatment of live feed with phages, targeted and controlled phage-releasing feed adjuvants, injection of phage preparations, and immersion of fishes in phage solutions offer an array of different administration approaches that can be considered according to their practicality and the particular aquaculture practice (56).

Microencapsulation-based delivery techniques are another method to protect phages from adverse acidic conditions. In this approach, phages are packaged into miniature capsules (300 nm to 1 mm) to protect against acids and can be liberated at controlled rates under specific conditions (e.g., in the intestine). Ma and colleagues encapsulated the broad-host-range *Salmonella* phage Felix O1 in the natural polysaccharides alginate and chitosan and evaluated the phage stability *in vitro* in simulated gastric fluid of pig (69). They found that the encapsulated phages survived significantly better than free particles under low-pH conditions and in the presence of pepsin or bile salts and were almost completely released from the microcapsules in simulated intestinal fluid with a pH of 6.8. Later, others encapsulated four different *E. coli* O157:H7 phages in methacrylate polymer and fed them to steers either orally in gelatin capsules or in feed (70). Although fecal samples yielded active phages in acceptable levels, the shedding of the bacterium was not significantly reduced. In another work, Wall and colleagues investigated whether oral administration of a microencapsulated phage cocktail could effectively reduce *Salmonella* counts in market-weight pigs (71). The pigs were kept in contaminated holding pens and allowed to comingle with *Salmonella*-negative mock-treated pigs in order to imitate the preslaughter transport- and lairage-associated *Salmonella* colonization of the pigs. Although significant reductions in cecal colonization were observed in *Salmonella*-positive animals, colonization

of *Salmonella*-negative and mock-treated control pigs was not prevented. Colom and colleagues encapsulated three *Salmonella* phages in cationic liposomes to improve protection in the gizzard and retention time in the intestines of chickens (72). They found that liposome-encapsulated phages were markedly more stable to acid and retained in the intestine significantly better than nonencapsulated phages. Consequently, the oral administration of a liposome-encapsulated phage cocktail significantly reduced *Salmonella* colonization of chickens, with activity persisting more than 15 days postadministration. Additionally, their approach of encapsulating phages into liposomes allowed storage of the preparation for at least 3 months without a significant loss of activity and increased protection of phages against lyophilization. Thus, microencapsulation is a very promising approach to protect phages to be administered to live animals; however, other technologies may be developed.

Table 29.3 Outcomes of phage therapy against foodborne pathogens in the primary production

Pathogen and animal	Bacterial inoculum (CFU)	Phage	Phage dosage (PFU)	Application method	Application time[a]	Reduction
E. coli O157:H7						
Lamb	10^8	DC22	10^{13}	Oral	Day 2 p.i.	Undetectable[b]
Ewe	10^{10}	CEV1	10^{11}	Oral	Day 3 p.i.	2–3 log
Ewe	10^{10}	KH1	10^{11}	Oral	Day 0	9–10 log
Steer	10^6	Cocktail (KH1 and SH1)	10^{10}	Rectal	Days 0, 1, 2, and 4 p.i.	1–4.6 log
Sheep	10^{10}	8-phage cocktail	10^9	Oral	Day 2 p.i.	4 log
Steer	10^9	Cocktail (wV8, rV5, wV7, and wV11)	10^{11}	Oral	Days—2, 0, 2, 6, and 9 p.i.	3.5–5 log
Steer	10^{10}	Cocktail (wV8, rV5, wV7, and wV11)	10^{11}	Oral, rectal, and oral and rectal	Days—2, 0, 2, 6, and 9 p.i.	5–7 log
Cattle	10^{10}	Cocktail (e11/2 and e4/1c)	10^{11}	Oral	Days 1, 2, and 3 p.i.	Undetectable
Steer	10^{11}	Encapsulated cocktail (wV8, rV5, wV7, and wV11)	10^9	Oral	Days—1, 1, 3, 6, and 8 p.i.	4–5 log
Ewe	10^{10}	Cocktail (CEV1 and CEV2)	10^{11}	Oral	Day 3 p.i.	3–4 log
Cattle hide	10^5–10^6	Cocktail (e11/2 and e4/1c)	10^9–10^{10}	Spraying on Hide	1 h p.i.	1.5 log
Cattle	Natural Load	Cocktail (Finalyse)	10^{10}	Spraying on Hide	Upon animal Arrival	From 57.6 to 51.8% in Prevalence
Salmonella enterica subsp. *enterica* serotypes						
2-day-old chickens	10^8	ϕAB2	10^5	Oral	Day 0	2 log (by 13th day)
Newly hatched chicks	10^4	Various: single and cocktails	Various	Oral, feed or Water	Various	0.3–1.3 orders of magnitude
3-week-old pigs	10^8	Felix O1	10^{10}	Oral and Intramuscular	3 h p.i.	1–3 log
1-day-old broilers	10^8	Cocktail (CNPSA1, CNPSA3 and CNPSA4)	10^{11}	Oral	Day 7 p.i.	3.5 orders of magnitude
3-day-old chicks	10^5	Cocktail (S2a, S9 and S11)	10^6	Oral	Days 0, 1, 2, 5, 6, and 7 p.i.	6-fold in cecum
36-day-old chickens	10^8	ϕ10, ϕ25 or ϕ151	10^9 or 10^{11}	Oral	Day 2 p.i.	2.2–4.2 log

Pathogen and animal	Bacterial inoculum (CFU)	Phage	Phage dosage (PFU)	Application method	Application time[a]	Reduction
1-day-old chicks	10^3	Cocktails (CB4Ø and WT45Ø)	10^8	Oral	1 h p.i.	30–55% in recovery rate
10-day-old chickens	10^6	Cocktail (BP1 to -3)	10^8	Coarse spray or drinking water	24 h prior to Inoculum	1.5 log
3- to 4-week-old pigs or market-weight pigs	10^8 or 10^9	Microencapsulated cocktail of 15 phages with Felix O1	10^9	Oral	Day 0 and every 2 h p.i. for 6 h	2–3 log or 1.5 log
Pigs	10^9	Microencapsulated cocktail of 14 phages	10^{11}	Feed or oral	For 5 days p.i. or day 5 p.i.	1 or 2 log
Pigs	10^5, 2 days	Cocktail (F3-8)	10^3, 10^5, 10^7, and 10^9	Oral	Day 1 p.i.	1–1.5 log
Campylobacter spp. 10- or 32-day-old chickens	10^5	Phage NCTC12669 or NCTC12671 singly or consecutively	10^9–10^{10}	Oral	Days—3 to 6 p.i. or days 5 to 10 p.i.	2 to 1 log or 3 to 1 log
Broiler chickens	10^3 to 10^8	CP8 and CP34	10^5, 10^7, and 10^9	Oral	Day 5 or 7 p.i.	0.5 to 5 log
Broiler chickens	10^8	CP220	10^5, 10^7, and 10^9	Oral	Day 5 p.i.	2 log
31-day-old chickens	~10^5, 10^6, and 10^7	Cocktail (ϕCcoIBB35, ϕCcoIBB37 and ϕCcoIBB12)	10^6 or 10^7 in Feed	Oral or feed		2 log
6-day-old chicks	10^4	Single (NCTC12673) or cocktail (NCTC12673, NCTC12674, NCTC12678 and NCTC12672)	10^7	Oral	Day 3 p.i.	Max, 2.8 log
Field flocks	Various	Cocktail (NCTC12673, NCTC12674, NCTC12678 and NCTC12672)	~10^6–10^8	Drinking water	Various	Up to 3.2 log

Pathogen and animal	Bacterial inoculum (CFU)	Phage	Phage dosage (PFU)	Application method	Application time[a]	Reduction
Various-age chickens	10^7–10^9	Single (CP14) and cocktail (CP14 with CP81 or CP68) consecutively	10^8–10^{10}	Oral	Day 5 or 7 p.i.	Up to 3.5 log
Vibrio parahaemolyticus Brine shrimp	Various	Vpms1	Various	Tank water	Various	~10% decrease in mortality
Vibrio harveyi Shrimp	10^5	Single or cocktail (VHM1, VHM2, and VHS1)	10^9	Tank water	Day 0	3–5 log

[a] p.i., postinoculation.

[b] Undetectable, to undetectable levels.

Emergence of Phage-Resistant Mutants in Livestock

A concern regarding phage therapy in livestock is selection for phage-resistant mutants of the target bacteria, which may dominate the population after phage exposure, as the target bacteria are metabolically active under *in vivo* conditions. As mentioned previously, phages and their hosts continuously coevolve in a variety of ecological niches, a concept termed “arms race evolution.” In this situation, both phage-resistant mutants and phages are excreted with the feces, continuously circulating in the farm environment, and may potentially affect the activity of the phage preparation used against the target pathogen at primary production. At the same time, phage-resistant bacteria may lose fitness in colonization or virulence and might be outcompeted by their sensitive-phenotype counterparts (59, 73, 74), although this might not always be the case (27, 75, 76). Therefore, determining the molecular basis of the phage resistance posttherapy, as well as its persistence and consequences for the fitness (both in colonization of the animals and pathogenicity in humans) of the target bacteria must be further researched.

Researchers have compared the frequency of phageresistant mutants of three *Salmonella* serotypes in chickens (60). In brief, they observed that the number of phage-resistant colonies posttreatment was at least doubled in comparison to those in control groups and that higher phage concentration selected for greater proportions of resistant mutants. However, upon consecutive subculturing *in vitro*, these resistant mutants reverted back to being phage sensitive. Moreover, when obtained resistant mutants were readministered to the birds, neither colonization levels nor the percentage of the emerging resistant mutants differed noticeably from those in the control group (60).

As mentioned above, in addition to expanding the host range, phage cocktails that are composed of individual phages using different receptors offer a promising strategy to control emergence of phage-resistant mutants. Fischer and colleagues demonstrated that the application of a phage cocktail against *C. jejuni* in commercial broilers can both moderate (from 43% to 24%) and delay the emergence of phage resistance in comparison to application of a single phage (62). On the other hand, the use of phage cocktails might have unintended consequences, as phages in a cocktail may exchange genomic material, possibly through superinfection of the same host, resulting in the emergence of novel hybrid phages (77). However, this phenomenon was observed in continuous cultures in the laboratory and not in the gut of the animals. Another approach to increase the efficacy of phage therapy in primary production includes the rotation of different phage cocktails composed of different phages. This approach allows targeting of phage-resistant mutants that have emerged from the use of the previous

phage cocktails and are currently applied in aquaculture practices (56, 78). Proving such efficacy in large livestock farms would be challenging due to large numbers of animals; however, in aquaculture practices, tracing the efficacy can be feasible, and thus, cocktail rotation appears to be an applicable strategy (56, 78).

Collectively, phage therapy in primary production appears to be a promising approach, yet current data indicate that single-phage or phage cocktail administration will not be enough to ensure production of pathogen-free animals. Instead, phage therapy can currently be considered as an additional mitigation strategy for management of foodborne pathogens. However, there are currently no phage preparations approved for therapeutic use in livestock. The challenges facing regulatory acceptance are discussed later in this chapter. Moreover, in the real-life setting, ensuring administration of standard dosages to all animals remains a major challenge, particularly in intensive animal breeding and aquaculture. Finally, the application of phages at an epidemiological end point, such as on foods, would prevent phages and phage resistant mutants from circulating in the farm environment, and such applications have attracted considerable interest, as described below.

BIOCONTROL OF FOODBORNE PATHOGENS AT SLAUGHTER

Rationale for Applying Phages at Slaughter

As explained above, studies on phage therapy in live animals vary considerably depending on the animal, administration route, and dosage, as well as the phage(s) used, resulting in different efficiencies of the phage application. The efficacies of phage-based applications after primary production are expected to be superior to those of phage therapy in live animals, as certain untraceable dynamics, such as the immune response of the animal and the ever-changing microenvironment of phages in the gut or farm environment, can be avoided. Cattle hides and chicken feathers have long been known to play a role in contaminating carcasses during the slaughtering processes. Hence, phage preparations applied on hides or feathers prior to slaughter may reduce the pathogen loads preslaughter.

Outcome of Applying Phages at Slaughter

An early work demonstrated that the application of phages to cattle hides was a promising approach to reduce pathogen numbers. One hour after application of the phage preparation to hides, Coffey and colleagues observed a significant reduction of 1.5 log CFU/cm^2 in *E. coli* O157:H7 counts (79). The first regulatory approval for the use of phages on live animals via hide or feather spray/mist application was issued by the U.S. Department of Agriculture (USDA) in 2007. Since then, there have been several commercial *E. coli* O157:H7 and *Salmonella* phage preparations on the market for use on cattle hides and poultry feathers prior to slaughter. One recent study evaluated the efficiency of a phage preparation in reducing the contamination levels of *E. coli* O157:H7 on cattle hides and carcasses (80). After applying phage spray at the lairage area of two different commercial beef processing plants, Arthur and colleagues observed ~6% and 0.5% reductions in the prevalence of *E. coli* O157:H7 on hides and carcasses, respectively. As the reduction was not significant, researchers concluded that the application of phages to cattle hides before going through the lairage environment may not improve food safety (80).

As with many phage-based biocontrol approaches, the outcome of phage application on hides and feathers is also dependent on ensuring successful encounter of the phages with target bacteria. In the lairage environment, however, increasing amounts of organic matter accumulate on the hides of the animals. Perhaps due to this fact, the application of phages to hides upon arrival of the animals at the slaughterhouse remains insufficient, and their application at the exit of lairage, just before slaughtering, could increase the efficiency. So far no reports have evaluated preslaughter efficacy of phage application on feathers of poultry mimicking real-life application. However, due to the factors mentioned above, the outcome of such applications might not be favorable. Collectively, preslaughter application of phages on animal hides and feathers has a limited degree of success.

BIOCONTROL OF FOODBORNE PATHOGENS IN FOODS

Rationale of Applying Phages in Foods

The contamination of food materials with foodborne pathogens can occur in primary production, throughout transportation, and during or after processing of foods. Therefore, application of phages for biocontrol of specific foodborne bacteria should be considered according to how the food item is contaminated with the pathogen (i.e., surface contamination or in deeper fractions) and take the food processing steps into account. The application of phages at an epidemiological end point, such as in food processing plants or slaughterhouses, is advantageous for limiting the circulation of phages and avoiding a constant selection of phage-resistant strains.

However, applying phages to control foodborne microbial pathogens in foods is a complex and challenging task. The design and efficiency of phage solutions for food safety are highly influenced by the food environment during processing and storage. The microenvironment of food is primarily characterized by intrinsic factors, such as available free water and pH, as well as extrinsic factors, such as temperature, oxygen level, and the relative humidity of the environment. Moreover, these conditions might change throughout the processing of foods. While these factors are known to influence the growth of bacteria, they may also affect the activity of the phages and the efficiency of the phage application. There seem to be no general rules as to under which conditions a phage will be most efficient, since this may be dependent on the phage and influenced by a multitude of environmental variables. Thus, it is necessary to evaluate phages for their killing efficiency and stability under relevant conditions encountered during food processing. The environmental variables of the food processing cannot be mimicked by *in vitro* experiments in laboratory media, and thus, such experiments do not always reflect the efficiency of phage biocontrol on the foods. Therefore, determining the efficiency of phage killing on an actual food model with relevant processing conditions is required.

Nonetheless, experiments in laboratory media can be used to compare different phages with respect to their biology and stability. Since phage infection and killing are usually most efficient when the bacteria are at a metabolically active state, the ability of the target pathogen to grow in the food might also influence the outcome of phage biocontrol. Therefore, it is important to understand how the food environment influences the growth of the target pathogen as well. Even though phages are robust, some conditions such as high temperature or low pH may inactivate phages, and foods that go through or harbor such deteriorative environments may not be suitable for phage application.

For identifying phage application sites in the food processing plant, the process design and the processing technology of the food item must be considered. The application of phages should be considered at a processing step that allows optimal phage distribution and survival. Furthermore, the relevant mode of application should be considered to ensure phage-host encounters in or on the food matrix and according to the nature of food contamination. Since many food products, including fresh produce and meat, are surface contaminated, spraying of food products or dipping them into phage solutions may be an effective mode of application, whereas in other foods, phages may be directly added to the raw material (e.g., milk, brine, or fruit juice). As mentioned before, foods are often contaminated with pathogens at low levels, and the application technology as well as the concentration of applied phages should be carefully considered to increase the likelihood of phage-bacterium encounters.

For all these reasons, literature on the efficiency of phage biocontrol covers a broad variety of food items inoculated with relevant foodborne pathogens and kept under various conditions after exposure to different modes of phage applications. Table 29.4 displays a summary of these studies and outcomes of phage biocontrol. Due to the large variance of the enlisted biocontrol studies with regard to the food item, phage or phage cocktail investigated, experimental conditions, and mode of applications, it is hard to draw general conclusions. However, there are strong tendencies towards better phage biocontrol efficiencies when initial bacterial counts are higher, phages are applied in higher numbers (i.e., a high MOI is used), and the environmental temperature is above refrigeration temperature

(Table 29.4). In the following paragraphs, we summarize and discuss the outcome of phage use for biocontrol of pathogens in meat and processed meat products, in milk and dairy products, and in fresh produce.

Outcome of Phage Biocontrol of Pathogens in Meat and Meat Products

In fresh meat from production animals, poultry, and fish, the pH, water content, and rich nutrients support growth of a variety of bacteria. The slaughtering, cooling, storage, cutting, and packaging practices may vary between different slaughterhouses according to needs and regulatory frameworks. Nonetheless, the safety of raw meats is primarily dependent on hygienic production, as well as the chilling of the carcasses to refrigeration temperatures (4 to 8°C) both to delay microbial spoilage and to suppress the growth of pathogenic bacteria. In addition, modified atmosphere packaging of raw meat is known to delay spoilage, yet it does not have a major influence on growth of most of the foodborne pathogenic bacteria relevant for fresh meat.

Contamination of raw meat with enteric zoonotic pathogens such as *Salmonella*, *Campylobacter*, and pathogenic *E. coli* begins at the abattoir upon removal of the inedible parts (e.g., hides and feathers) and offal. Moreover, meats can also get cross-contaminated with ubiquitous pathogens, such as *L. monocytogenes*, due to their contact with conveyors, personnel, abattoir utensils, or other inert surfaces. Since contamination is at the surface of the meat, phages offer a pathogen-specific approach that has the potential for biocontrol without influencing the overall sensory qualities of the meat. Upon slaughter, efficient chilling of the carcasses is important for food safety, and consequently, the activity of phages that are applied immediately on the surface of the carcasses or at the final fresh meat product will be challenged by rapid drops in temperature and surface humidity. Hence, several scientific works have evaluated the application of phage solutions on meat surfaces under a variety of storage conditions (4 to 37°C) that mimic meat production, refrigeration, or abused-refrigeration temperatures associated with cooling and transportation of fresh meats and products thereof (Table 29.4).

O'Flynn and colleagues showed that seven of nine steak pieces challenged with 2 log CFU of *E. coli* O157:H7 underwent total elimination of the pathogen 1 h after phage cocktail treatment (81). Significant pathogen reduction was observed during storage at 37°C, a temperature that allowed active host metabolism but is not relevant for storage of fresh meat. On the other hand, Carter and colleagues evaluated the effect of phage-bacterium contact time on the surface of meat at 4°C, over 24 h of incubation (82). They showed significant reductions in the bacterial counts 5 min after phage cocktail application. While 5 min at 4°C is not an optimum period for successful completion of any known lytic phage cycle, this finding indicates that phages do encounter and infect their hosts on the meat surface, regardless of the temperature, and perhaps the phage life cycle is completed later, when conditions allow host metabolism to proceed (i.e., on plating media).

Table 29.4 Outcomes of phage biocontrol against foodborne pathogens on foods

Food	Bacterial inoculum (CFU)	Phage	MOI	Application method	Condition(s)	Reduction
E. coli O157:H7						
Steak meat	2 log	Cocktail (e4/1c, e11/2, pp01)	10^6	Spotting	37°C	4–5 log
Broccoli, tomato, spinach, ground meat	2.5–4 log	ECP-100 cocktail (ECML-4, ECML-117, ECML-134)	10^4–10^6	Spray	10°C	94–100%
Iceberg lettuce Cantaloupe	3.7 log 4.5 log	ECP-100 cocktail (ECML-4, ECML-117, ECML-134)	10^2–10^4	Spray Spotting	4°C, 20°C	~2–3 log
Spinach, romaine lettuce	4–6 log	BEC8 cocktail (38, 39, 41, CEV2, AR1, 42, ECA1, ECB7)	1, 10, 10^2	Spotting	4°C, 8°C, 23°C, 37°C	1–3 log
Beef steak, ground beef, romaine lettuce	3 log	EcoShield cocktail (ECML-4, ECML-117, ECML-134)	10^2, 10^3, 10^4	Spray	4°C	94–98%
Beef	~3–5 log	Single DT6 or cocktail (DT1, DT6)	10^2–10^5	Spotting	5°C, 24°C	0.3–2.6 log
Spinach, lettuce	4.5 log	EcoShield cocktail (ECML-4, ECML-117, ECML-134)	10^2	Spray	4°C, 10°C, modified atmosphere	1.2–4.3 log
Raw beef	Various (2–4 log)	FAHEc1	10–10^4	Spotting	37°C	0.5–2.6 log
Raw and cooked beef	0.6–4 log	FAHEc1	10–10^4	Spotting	5°C, 24°C	0.2–4.6 log
Iceberg lettuce	2–3 log	EcoShield cocktail (ECML-4, ECML-117, ECML-134)	10^2–10^5	Immersion with different durations, spray	4°C	1 log to undetectabl [a]
Ground beef, spinach, cheese	5–7 log	Cocktail (FFH1, FFH2, FFH3)	1	Spotting	4°C, 24°C, 46°C, 63°C	0.1–3.3 log

Food	Bacterial inoculum (CFU)	Phage	MOI	Application method	Condition(s)	Reduction
Milk	3 log	PhaxI	10^3	Addition to milk	37°C	Undetectab
RTE raw meatball	0.5–1.8 log	M8AEC16	2.4–5.6 log	During manufacturing	4°C, 22°C	0.7–2.1 log
Edible cabbage	3 log	HY01	10^5, 10^6	Spotting	37°C	~2.5 log
Green bell peppers, spinach	6.6 log	OSY-SP	~10^2	Immersion	4°C, 25°C	0.9–3.5 log
Beef, pork, chicken meat	5 log	BPECO19	10^3, 10^4, 10^5	Spotting	4°C, 37°C	0.5 log to Undetectab
Beef	3 log	Chitosan coating film embedded with liposome-encapsulated phage	Not Applicable	Wrapping with chitosan coating film	25°C	4.8 log
Salmonella enterica subsp. *enterica* serotypes						
Melon and apple Slices	~4 log	SCPLX-1 cocktail (4 phages)	5, 10, 20	Spotting	5°C, 10°C, 20°C	2.5–3.5 log
Cheddar cheese (whey or curd)	4 log	SJ2	10^4	Addition to milk	Various	3–4.4 log
Chicken frankfurter	2 log	Felix O1 or its Variant	10^4	Spotting	22°C	1.8–2.1 log
Chicken skin	2–3 log	P22 or 29C	1–10^7	Spotting or Spray	4°C	2 log to Undetectab
Sprout seeds, Mustard	2–3 log	Cocktail (A, B)	10^4	Soaking	25°C	1.5 log
Chicken carcass	0–3 log	PHL4 or cocktail (72 phages)	Various (1 to 10^{10})	Spray; immersion	37°C	2 log
Chicken carcass	0–2 log	WHR	10^7–10^8	Spray	37°C	2 log to Undetectab
Raw and cooked Beef	2–4 log	P7	10, 10^4	Spotting	5°C, 24°C	2.8–5.9 log
Alfalfa sprout seeds	7 log	Single or cocktail (SSP5, SSP6)	70	Immersion	25°C	~1 log
Tomato rhizospheres	6 log	Cocktail (F01, P01, P102, P700, P800)	10^{-3}, 1	Extending to the stem base	15°C	0.8 log

Food	Bacterial inoculum (CFU)	Phage	MOI	Application method	Condition(s)	Reduction
Sprouting mung bean and alfalfa seeds	6 log	Cocktail (F01, P01, P102, P700, P800, FL41)	10^{-1}, 10^{2}	Immersion	20°C, 25°C, 30°C	3.4 log
Pig skin	3, 4, 6 log	PC1 cocktail (ϕSH17, ϕSH18, ϕSH19, Felix O1)	10^{-2}–10^{4}	Spotting	4°C	2 log to Undetectab
Hot dogs, cooked/sliced turkey breast, seafood, chocolate milk, egg yolk	3 log	Felix O1, FO1-E2	10^{5}	Various	8°C, 15°C	5 log to Undetectab
Chicken skin	3–4 log	wksl3	10^{3}–10^{4}	Spray	8°C	2.4 log

[a] Undetectable, to undetectable levels.

Although this is an important finding, there are also examples in which storage at refrigeration temperature influenced the outcome of phage biocontrol. When Big-wood and colleagues applied phage P7 or CJ6 on 2-cm² raw beef samples inoculated with *Salmonella* or *Campylobacter* at low densities (<100 CFU/cm²), significant reductions were observed only when the samples were stored at 24°C, not at 5°C (83). The adverse effect of low storage temperature on overall pathogen reduction by phage biocontrol on meat has been observed in several other studies of different phage-pathogen combinations (Table 29.4). However, this phenomenon should not be considered to reflect a general rule, as the outcome of phage application will still be influenced by densities of bacteria and phage and

their successful encounters in the food matrix. When Tomat and colleagues applied a cocktail of phages (DT1 and DT6) at an MOI of ~10^5 on beef samples inoculated with *E. coli* O157:H7, they observed a significant reduction (~1.4 log CFU) in 3 h only when samples were stored at 24°C, not at 5°C (84). On the other hand, when a single phage (DT6) was used at a much lower MOI (~10^2), storage at 5°C rather than 24°C led to significant pathogen reduction (~0.4 log CFU) in 3 h, demonstrating the multifactorial nature of the phage biocontrol outcome. Moreover, the mode of host recognition can also be influential in the outcome of phage biocontrol. Zampara and coworkers showed that the ability of phages to reduce *Campylobacter* on refrigerated chicken skin was dependent on the receptor used by the phages (85).

When variables such as storage temperature or bacterial inoculum density are kept constant, higher phage concentrations (i.e., higher MOIs) often lead to higher efficiency in phage biocontrol. Such phage concentration-dependent results have been observed in several reports that have evaluated the effect of phage MOI when other variables remain unchanged. For example, Hooton and colleagues reported the biocontrol efficiency of phage cocktail PC1 against *Salmonella* on pig skin samples at 4°C with three different concentrations of phage and bacterial inocula, establishing an MOI matrix between 0.01 and 10.000 (86). They found that the use of phage concentrations above an MOI of 10 were necessary for obtaining significant reductions, whereas an MOI of 1 or below led to little or no reduction. Such correlations between higher phage concentrations and more efficient pathogen reductions have also been observed on chicken skin with *C. jejuni* (87), on ready-to-eat (RTE) beef, chicken, and salmon with *Shigella sonnei* (88), and on RTE sausages, sliced turkey breasts, and smoked salmon with *L. monocytogenes* (89, 90).

Meats can be ground or processed further to a variety of meat products. In particular, ground meat and ground-meat products are challenging food items for phage biocontrol due to their increased surface area and their potential to harbor pathogens within deeper fractions, preventing phage access. Nonetheless, several works have shown significant reductions in *E. coli* O157:H7, *Salmonella*, and *Yersinia enterocolitica* counts in ground meats with phage application (91–94). Of note, Carter and colleagues found that following the initial reduction of *E. coli* O157:H7 on the meat surface, when meats were ground and recontaminated with the pathogen, residual phages that remained from the earlier surface application did not show any effect, despite being actively present at approximately identical initial numbers in the ground meat. While this finding emphasizes the adverse effect of substantial surface area changes in the food matrix on phage-host encounters, it also demonstrates that residual active phages do not always exert a continuous effect under these circumstances (82). However, the addition of phages in the liquid fraction during manufacturing of a ground-meat-based RTE food achieved significant reductions in *E. coli* O157:H7 counts, presumably due to the homogeneous access of the phages to deeper fractions of the food item prior to artificial contamination (95).

Meat can also be subjected to a number of traditional preservation techniques, such as heat treatment, smoking, curing, fermentation, and drying, as part of food production (see chapter 6 of this volume for more details). These products are produced with different additives that are beneficial for achieving distinct characteristics of the food item, such as color, texture, flavor, and shelf life. As a result, the microorganisms present in meat products are different from those in fresh meat. Pathogenic bacteria in such meat products may originate from either the raw material or cross-contamination during production. Since these products are often marketed as RTE food items and consumed without additional steps to alleviate the risk of foodborne infections (e.g., heat treatment), phages offer promising potential in the management of contaminating pathogens. Guenther and colleagues evaluated the biocontrol activity of phage FO1-E2 on samples of RTE hot dogs, cold turkey breast cuts, and mixed seafood (shrimp, shellfish, and squid) artificially contaminated with ~3 log CFU/g *Salmonella* (96). After 2 days of storage at 15°C, a reduction of more than 2 log was observed in hot dog and turkey samples, whereas in seafood, the reduction was not as pronounced. However, in the following days, the surviving *Salmonella* continued to grow, yet counts remained 1 to 4 log lower than those in the phage-negative control groups. When a similar experiment was conducted in seafood at 8°C, *Salmonella* was not totally eliminated, yet the reduction was 3 log in the first day without the

regrowth of the bacterium over the 6 days of the experiment (96). In another work, Soffer and colleagues demonstrated the biocontrol potential of a commercial phage cocktail on several different food items previously implicated in foodborne shigellosis (88). The five-phage cocktail had a comprehensive host range, lysing 97% of *Shigella flexneri*, *S. dysenteriae*, *S. sonnei*, and *S. boydii* strains tested. When applied at 10^5, 10^6, and 10^7 log PFU/g on RTE deli corned beef slices, chicken breast strips, and smoked salmon samples that were spiked with 10^3 CFU/g of the test bacterium, the phage cocktail yielded significant yet dose-dependent reductions ranging between 31 and 98% regardless of the technology used in production of the food item (88).

An important food safety problem associated with RTE meat products is *L. monocytogenes* contamination. The ubiquitous nature of the bacterium results in cross-contamination of RTE meat products postproduction, while the ability of *L. monocytogenes* to grow at refrigeration temperatures increases the associated risk, in particular for RTE food items that are approaching their expiration date. Therefore, achieving either total elimination or a significant reduction in CFU counts by phage biocontrol has been the aim in several works (Table 29.4). As observed in numerous other studies, when Guenther and colleagues applied different concentrations of phage A511 on RTE hot dogs, cold turkey breast cuts, smoked salmon, and mixed seafood that were spiked with 103 CFU/g of two different test strains, they observed higher efficiency in biocontrol with the higher concentration (108 PFU/g) of the applied phage (89). In the first day of the 6-day incubation at 6°C, A511 reduced *L. monocytogenes* counts in samples of RTE hot dogs, turkey cuts, smoked salmon, and mixed seafood by approximately 3, 1, 1, and 1.5 log CFU/g, respectively. The results were found to be strain dependent, often leading to regrowth at lower levels than in negative controls. All surviving isolates tested were still phage sensitive, and the authors concluded that the observed regrowth stemmed from cells that escaped contact with phage particles due to either the complexity of the food matrices (i.e., uneven surface) or the ability of the food item to adsorb liquid, both of which incapacitate phage diffusion (89). Overall, scientific studies have demonstrated that the application of phages for biocontrol can reduce pathogenic bacteria on meat surfaces, even under refrigeration, yet testing of specific phages and phage cocktails under conditions that are specific for the food is essential for designing efficient phage biocontrol.

Outcome of Phage Biocontrol in Milk and Dairy Products

Due to its rich lactose content and approximately neutral pH (6.6 to 6.8), milk can support the growth of a broad range of bacteria. Moreover, milk is a very complex medium consisting of proteins such as casein, lacto-globulins, immunoglobulins, and bovine serum albumin, as well as large lipid globules, minerals, vitamins, and various acids. Hygienic milk production begins at the dairy farms upon milking of healthy udders and cooling of the raw milk to refrigeration temperature to minimize bacterial growth. Thereafter, heat treatment ensures microbiological safety. Heat treatment includes various pasteurization techniques (e.g., high temperature for a short time or low temperature for a long time, or equivalent combinations). Regular pasteurization usually achieves an approximately 90% reduction in viable bacterial counts, eliminating the pathogenic bacteria, while ultra-high-temperature (UHT) treatment sterilizes milk from all viable bacteria and spores. In practice, heat processing of milk can show variability depending on how the milk is going to be marketed, according to the technological requirements of the downstream dairy product, the regulations in force in different countries, and cultural consumer preferences.

Raw milk contamination with bacterial foodborne pathogens such as pathogenic *E. coli*, *Salmonella* spp., *Shigella* spp., *Staphylococcus aureus*, *L. monocytogenes*, and *Cronobacter* (formerly *Enterobacter*) *sakazakii* can originate from the udders, farm environment, or the milking, storage, or transportation equipment. This could particularly pose a problem if milk is to be used for production of artisan or traditional cheeses, a process which requires raw milk. Moreover, inert surfaces in dairy plants and inadequate personal hygiene are associated with contaminations of milk and milk products. Bacterial pathogens may also be present due to pasteurization errors or cross-contamination from the production environment. In addition, throughout the further processing of raw or heat-treated milk to dairy products such as cheese and yogurt, slow or inadequate acidification of the curd may also lead to

growth of pathogenic bacteria. Numerous works have evaluated phage biocontrol in both raw and heat-treated whole or skim milk, as well as various cheeses and other dairy products (Table 29.4).

Garcia and colleagues evaluated the biocontrol activity of a phage cocktail (ϕH5 and ϕA72) against a mastitic *S. aureus* strain in pasteurized whole-fat milk and raw semiskimmed and raw whole-fat milks (97). Interestingly, by the end of incubation (8 to 10 h) at 37°C, the reduction observed in pasteurized milk was higher (3.6 log CFU) than that observed in raw milk samples (2.2 log and 1 log CFU, respectively). Although allof the observed reductions were statistically significant, the lower activity observed in raw whole-fat milk coupled with the decrease in the phage titer led the authors to conclude that the fat globules and the milk proteins might weaken phage activity (97). Indeed, a similar inhibitory effect of raw milk on staphylococcal phage K was observed by O'Flaherty and colleagues (98). Their results indicate that a combinatory effect of both milk fat and milk proteins and, in particular, heat-labile soluble immunoglobulins is responsible for inactivation of phages. When heat-treated milk was used by other researchers for evaluating phage biocontrol against *Salmonella*, *L. monocytogenes*, and *Y. enterocolitica*, promising results were consistently observed (89, 91, 94, 99). In addition, in heat-treated milk, phages may be valuable for the management of bacterial pathogen growth resulting from cold chain failures, a high-risk condition for dairy plants. In their work, Garcia and colleagues mimicked such a breakdown of a cold chain by shifting the incubation temperature of whole-fat UHT-treated milk samples spiked with *S. aureus* and phage cocktail from refrigeration to 22°C (97). Upon the shift after 18 h of refrigeration at 4°C, phages started to propagate, leading to a bacterial reduction of approximately 4.5 log CFU. Such a delayed yet beneficial activity may be favorable especially when heat-treated milk is cross-contaminated or is to be processed into curd for producing various dairy products that may not suppress the growth of bacterial pathogens.

Enzymatic- or acidic-curd production from milk is a widely used technology for many dairy products. In cheese production, the addition of calf rennin (chymosin) to milk cleaves casein, which then can form bonds with Ca^{2+} ions to produce the enzymatic curd. Acidiccurd formation relies on acidification of milk by the production of lactic acid, which then decreases the pH, leading to aggregation of casein molecules. Yogurt and fresh-cheese technologies are primarily based on acidiccurd formation, whereas in hard-type cheese technology, following (or in parallel with) formation of enzymatic curd, acidification of whey is often necessary for achieving the distinct sensory qualities of the cheese product. For acidification purposes, starter cultures are often used, although in certain products the natural flora of raw milk may also be of benefit. Nonetheless, the temperature used during different production technologies and slow or inadequate acidification may allow growth of contaminating bacterial pathogens. Therefore, Garcia and colleagues evaluated the ability of two phage cocktails in biocontrol of *S. aureus* throughout production of both curd types from pasteurized milk (100). Tested phages did not tolerate acidic curd as the pH dropped below 6, but nevertheless, they drastically reduced the *S. aureus* counts to undetectable levels in less than 1 h and 4 h of enzymatic and acidic curdling, respectively.

In another work, the addition of the same phage cocktail to the milk in production of fresh and hard-type cheeses demonstrated promising biocontrol activities (101). In just 6 h after curdling of fresh cheese, *S. aureus* counts became and remained undetectable, whereas at the end of 30 days of ripening of hard-type cheese, the *S. aureus* count dropped from 6 to 1.2 log CFU/g, while the count in the control group increased to ~7.5 log CFU/g (101). Similarly, *Salmonella* Enteritidis counts could be reduced in Cheddar cheese after the addition of phages to either raw or pasteurized milk before curdling, although the activity was superior in the latter, most likely due to heat-labile phage inhibitors (102).

While the above results strongly indicate that phages could be beneficial during production of dairy products against pathogens already present in the milk, several other works have evaluated the biocontrol efficiency of phages during later stages in dairy production, when pathogens contaminate the surface of cheeses. Due to its ubiquitous nature, ability to grow in cold storage, and implication in numerous foodborne outbreaks, *L. monocytogenes* was the focus of these studies. In one work, a surface contamination of 4 log CFU/g of *L. monocytogenes* on pasteurized hard-type cheese was significantly reduced 0.7 log 5 min after treatment with a phage cocktail of 10^8 PFU/g (90). In another

work that simulated the commercial production of surface-ripened Munster-type soft cheeses, a single application of phage P100 at a high concentration (~10^9 PFU/ml) in the washing/smearing solution led to total elimination of the initial 20-CFU/cm^2 surface contamination of *L. monocytogenes*, while in control groups, counts increased up to ~7 log CFU/cm^2 over 21 days of maturation (43). In another type of cheese (queso fresco), which is dependent on acidic curdling, the initial concentration of 3.5 log CFU/cm^2 *L. monocytogenes* was reduced to undetectable levels (<5 CFU/cm^2) after 1 day of storage at 4°C after application of P100, although total elimination was not achieved (103). In addition to the encouraging results observed for the application of phages to the surface of cheeses for biocontrol of *L. monocytogenes*, phages also have a high potential to totally eliminate the bacterium in cheeses that are marketed in brine (e.g., mozzarella) (89).

Finally, *C. sakazakii* is an emerging ubiquitous pathogen that contaminates milk postpasteurization and survives spray-drying production of powdered infant formulas. Due to its high resistance to desiccation and osmotic stress, its wide range of growth temperatures, its thermotolerance, and its ability to form biofilms, powdered infant formulas were primarily implicated in its transmission. Therefore, several research groups evaluated the biocontrol activity of phages against this pathogen, which causes severe clinical infections in immunocompromised individuals and high mortality in infants (Table 29.4). In their pioneering work, Kim and colleagues tested the outcome in two separate phage-host combinations in reconstituted infant formula at 37, 24, and 12°C over 10, 14, and 60 h of incubation, respectively (104). In both phage-host combinations, they demonstrated significant reductions to nondetectable levels after 2 h, with dose-dependent efficiencies. Interestingly, the biocontrol results differed between the two phage-host combinations for different conditions, emphasizing that phage biocontrol outcomes can be influenced by strain-phage combination and their respective intrinsic biology. In a similar setup, Endersen and colleagues evaluated the biocontrol efficiency of a three-phage cocktail in four commercial brands of powdered infant formulas that were spiked with 4 log CFU/ml of *C. sakazakii* and incubated at 37°C (105). They demonstrated total elimination of the test strain in less than 5 h regardless of powdered infant formula brands. Considering that *C. sakazakii* contamination levels are generally much lower (<1 to 100 CFU/100 g) in powdered infant formulas than what was experimentally tested, these studies strongly suggest that phages have high potential for biocontrol of this particular public health concern, although implementation in practice remains a challenge.

Outcome of Phage Biocontrol in Fresh Produce

Fresh produce is a large and very diverse group of foods representing different food environments and food safety problems. In general, microorganisms grow more rapidly in cut vegetables and fruits than in whole products, due to access to the nutrients after the outer barrier of the product has been broken. Vegetables and fresh fruits may be contaminated by pathogens from soil, fertilizers such as manure, and water. In addition, precut RTE vegetables and fruits undergo washing steps in the production facilities, allowing recontamination and cross-contamination of the final product. Shiga-toxin producing *E. coli* strains (including O157:H7), *L. monocytogenes*, *Shigella* spp., and *Salmonella* spp. are frequently implicated in foodborne-illness outbreaks following consumption of contaminated fresh produce. Therefore, these foodborne pathogens have been the main target for phage biocontrol in such food products. However, to implement phage biocontrol in fresh produce in industrial settings, the application of phages must be adjusted for the production line and washing steps, as well as possible inactivation by organic compounds. To date, most food model studies use either spraying, spotting, or soaking of the fresh produce for different durations for application of phages.

Several studies have determined the efficiency of phage biocontrol against *E. coli* O157:H7 on a variety of fresh fruits, vegetables, and sprouts (Table 29.4). Most of these studies were performed using phage cocktails, including commercial products such as ECP-100 or EcoShield, and showed 0.3- to 4.3-log reductions depending on the food and temperature of incubation. For example, the phage cocktail ECP-100 (total 10^8 PFU/cm^2) reduced the number of viable *E. coli* O157:H7 organisms on contaminated (7×10^3 CFU/cm^2) fresh-cut iceberg lettuce by 2 log after 2 days at 4°C (106). Interestingly, the use of same

phage cocktail to reduce *E. coli* O157:H7 on fresh-cut cantaloupe wedges resulted in a larger reduction at 4°C than at 20°C, suggesting that the phage cocktail was more effective at a lower temperature. However, the application method varied, as the phages were sprayed on lettuce and spotted on the melon wedges (106). The application of the EcoShield phage cocktail to leafy greens lowered *E. coli* O157:H7 counts and was more effective when the leafy greens were packaged under modified atmosphere. However, the reduction in *E. coli* O157:H7 counts in modified atmosphere was not significantly different from that observed in atmospheric-air storage (107).

Phages infecting *Salmonella* were used for biocontrol on the surface of fresh produce, such as fruits, lettuce, cucumber, and sprouts, and demonstrated significant reductions in bacterial counts. A cocktail composed of three phages (UAB_Phi20, UAB_Phi78, and UAB_Phi87) significantly reduced *Salmonella* Typhimurium and Enteritidis counts in packaged lettuce by 3.9 and 2.2 log CFU/g, respectively (108). The lettuce was experimentally contaminated by *Salmonella* by immersion in a suspension of the bacterial inoculum (10^5 CFU/ml) for 5 min and subsequently exposed to the phage cocktail at an MOI of 10^4 by immersion for 5 minutes and then incubated at 60 minutes at room temperature, resulting in significant reductions (108). In another work, whole fresh cucumbers were spiked with *Salmonella* Newport (10^5 CFU per cucumber) and sprayed with 10^{10} PFU/ml of a six-phage cocktail, which led to a significant reduction after incubation at both 10 and 22°C (109). Other studies have shown significant reductions of *Salmonella* in sprouts using a single phage or a cocktail of six phages, leading to 2.5-log reduction at 22°C and a 3.4-log reduction at temperatures ranging from 20 to 30°C, respectively (110, 111). Phages have also been used to target *L. monocytogenes* present on the surface of lettuce by spraying the phage cocktail ListShield, resulting in 1.1-log reductions (90). Finally, phages have been used to target *L. monocytogenes* by spraying a cocktail of 12 or 6 phages on fresh-cut apple and melon. On apples, the reduction was below 0.4 log, whereas on melon, phages were able to reduce *Listeria* by 2.2 to 4.6 log, suggesting that the acidity of the apples may have prevented the efficient reductions of the pathogen (112). These experiments demonstrate that food conditions, such as acidity, have a large impact on the outcome of phage biocontrol in fresh produce.

CHALLENGES AND OUTLOOK FOR INDUSTRIAL USE OF PHAGES

Phages are increasingly used for biocontrol of pathogenic bacteria in the food chain, yet many challenges remain for their successful widespread implementation, including adjustment of existing regulatory frameworks and the efficiency of phage products. Moreover, public understanding of the drivers for novel solutions in foodborne pathogen control and acceptance of phage applications in food biocontrol play key roles in making phage biocontrol widely applicable. Hence, education of consumers and food producers on the safety, efficacy, biology, and ubiquity of bacteriophages is important. Many more activities, including communication of the science behind the use of phages, the potential applications, and general knowledge of phages, are already being promoted largely on social media, websites, and in the press. Some of these activities are driven by independent scientists and scientific communities, but the increasing number of phage companies and food consultants also plays an important role in communicating the pros and cons of phage applications.

In this section, our main focus is on the technical and regulatory challenges of widespread industrial use of phages for biocontrol of foodborne pathogens in foods to discuss the future of a broader implementation of such solutions. The major technical challenges of phage biocontrol are primarily associated with their efficiency, which is influenced by a number of biological and technical parameters described throughout this chapter and reviewed by Moye and colleagues (113). In summary, the efficiency of phage biocontrol is dependent on (i) the specific host range of the phage as well as the diversity of the target bacterium; (ii) the probability that the phage will come into contact with the target bacteria in the food or animal gut; (iii) the killing activity of the phage within the food matrix or animal gut; (iv) the mode of application or administration of phage on the food or in the animal; and (v) the emergence of phage-resistant bacterial populations. As explained previously, there are ways to overcome the specificity and activity challenges by designing and testing phage cocktails in settings relevant for the application. Furthermore, application procedures should ensure successful delivery of

the phage to relevant area of the food where the target bacterium is more likely to be found. While isolation of novel phages may be important for developing efficient phage cocktails consisting of mutually complementary phages, the concept of phage training in the laboratory to select for phages that are able to overcome phage-resistant populations or have expanded host ranges may also be used as a tool to improve the phage solutions for the food industry (114). It is also important to develop innovative ways to administer phages to animals.

Widespread applicability of phage biocontrol requires documentation of efficacy and reproducibility, especially in industrial settings using naturally contaminated food items. However, this poses a challenge, in particular for pathogens that are present in low numbers or at a low prevalence, consequently making it difficult to provide such documentation due to the enormous number of samples needed to demonstrate statistically significant reductions. However, such work is in progress for some pathogens and is expected to complement the necessary documentation for supporting efficient implementation of phage solutions that targets low-number and low-prevalence foodborne pathogens as well. Finally, even though phages do not usually entirely eliminate the pathogenic bacteria, they may still render the food safer for consumption by reducing the pathogen numbers by > 1 to 2 log, thus providing significant improvements in food safety and public health due to decreased risk of exposure.

Several commercialized phage preparations have obtained permissions from regulatory bodies in the European Union and United States. In the United States, these phage products are approved as food additives, and the FDA had issued no-objection letters consolidating certain phage biocontrol products on the GRAS (generally recognized as safe) list. To date, the application of GRAS seems to be the general route of approval for phage products intended for biocontrol of foodborne pathogens in foods in the United States. The GRAS designation applies to lytic phages that are not genetically modified, as phages are already inherently present in food. Moreover, USDA guidelines for safe and suitable ingredients for production of meat, poultry, and egg products include the application of phages to animals prior to slaughter using *E. coli* O157:H7 phages on cattle hides, *Salmonella* phages on poultry feathers, and phage preparations targeting *Salmonella* in meat. Even though these guidelines refer to specific phage products, it is anticipated that other phage products meeting the criteria in the directive may be considered compatible. In the European Union, the European Commission issues approvals of phage products for use on foods based on expert evaluations made by the European Food Safety Authorities (EFSA). Similar to the U.S. FDA, the EFSA evaluated the safety and efficacy of a phage product targeting *L. monocytogenes* and stated that “[T]he material should not present human toxicological problems because the bacteriophage P100, used as active principle, is not regarded as harmful to consumers nor to organisms other than *Listeria* spp., and because the fabrication parameters do not include anything obvious that might compromise safety” (115). Thus, regulatory bodies acknowledge the safety of specific phage products, and it is anticipated that documentation of safety of similar phage products will promote the approval of other phage products for use in the food industry.

For phages to be used to their full potential, regulatory pathways must include defined phage cocktails as well as permission to update the cocktails according to the need. Such constant evolution of phage solutions appears to be the key in providing effective phage products when emerging phage resistance is considered. A similar approach has been implemented in both Georgian and Polish phage therapy centers that maintain extensive therapeutic phage collections which are regularly supplemented with new phages. Importantly, this will ensure the expansion of the total host range of the collection and allow phage cocktail adjustments in response to changing bacterial populations. The current legislation does not allow such adjustments, but the urgent need for alternative antimicrobials may promote the needed changes. Recently, an expert opinion proposed that phage therapy should have its own regulatory platform, allowing more flexible approaches for composition and adaptation of phage products (58) that promote phage training as a means to overcome phage-resistant variants.

Over the past decade, several phage companies with product portfolios targeting pathogenic bacteria relevant for the food industry have emerged (113), suggesting that several phage solution options will soon be more broadly available to food manufacturers. Importantly, phages have much more to offer

other than just killing bacteria. Phages also encode antimicrobial enzymes that may be applied and optimized for killing of pathogenic bacteria in the food chain. To date, these enzymes have mainly been developed for clinical use in human medicine, but as manufacturing prices fall, enzymes may also become applicable for biocontrol in the food industry. Even though such enzymes have mainly been developed to kill Grampositive bacteria, current research also focuses on modifying the enzymes to target Gram-negative bacteria (116, 117). Furthermore, synthetic biology and phage engineering are being used to develop phages targeting specific bacteria or genetic elements, such as phages used for targeted delivery of antibacterial genes, such as those encoding RNA-guided nucleases that specifically degrade the DNA of antibiotic-resistant bacteria (118, 119). Thus, the development of novel phage solutions, including phage enzymes and designer phages, will most likely follow a more widespread use of phages for biological control of foodborne pathogens in the future.

We sincerely thank our colleague Stephen J. Ahern for critically reading the manuscript. We are grateful to Marie Balzer Brøndsted for creating artwork presented in Fig. 29.1.

30
Starter Cultures

The production of fermented foods and beverages is one of the oldest biotechnological practices, dating back 7,000 years or more (1). For the vast majority of the intervening time, the biological nature of such fermentations was unknown—the production of these foods was an art or craft based on a series of operations which yielded products that were not only better preserved than the original raw material but also organoleptically pleasing. Throughout human history, many different substrates of animal or plant origin have been fermented, including milk, meat, fish, various vegetables, and soybeans.

The manufacture of fermented foods, although rooted in practices developed over many thousands of years, is today a major biotechnological activity which is valued at many billions of dollars. Fermented foods are generally viewed as being healthful in addition to possessing many organoleptic attributes that are attractive to the consumer. Consequently, the market for these products, particularly dairy products, has been experiencing significant growth, and more recently, new markets have been developed in Asia and Africa for Western-type fermented products. Of course, the converse is also true; many fermented oriental products are gaining increasing acceptance in the Western world.

It is remarkable that the success of such a large and diverse activity is critically dependent on the activity of microorganisms, particularly yeasts and the lactic acid bacteria (LAB). The yeasts are primarily involved in the production of alcohol and in raising dough

and are not the subject of discussion in this chapter; here, we focus exclusively on the LAB, which are central to the production of a wide range of fermented milk, meat, vegetable, soy, and other products. These are the microbes for which the term “starter culture” was specifically coined, as they are added deliberately to a substrate to start a given fermentation process.

This chapter provides a detailed examination of the LAB, outlining their key functional properties, particularly those relevant to their role in fermentation. The historical development of starter cultures, their composition, the formats in which they are commercially available, and the particular issues pertaining to the use of starters in a modern, high-throughput industrial setting are also discussed.

In many regards, the impact of bacteriophages (phages) on the starter culture applications in industrial practice represents an unusual ecological scenario. Bacteriophage infection of starters can impede or destroy starter activity, and controlling them has been a constant theme of starter application since the issue was first highlighted in the mid-1930s (2). Recent advances in the analysis of phage-host interactions, employing molecular and genomics approaches, have provided several knowledge-based strategies for dealing with this problem. These are also reviewed in this chapter. Finally, the grand challenges relating to the use of starters in the production of fermented foods are examined, particularly as they relate to strain diversity and the generation of new products with modified flavor, texture, and health attributes.

DEVELOPMENT OF STARTER CULTURES

The start of the golden age of microbiology, coinciding with the work of Pasteur, Koch, and many others, represented the beginning of our understanding of the processes involved in food and beverage fermentation. Early investigations led to the isolation and identification of bacteria that were typically linked with fermented foods, particularly fermented milk products. Initial efforts to

characterize these bacteria demonstrated their ability to produce lactic acid, and it became clear that the number of different bacteria associated with such products was quite limited. The first of these lactic acid-producing bacteria was characterized by Lister in the 1870s, and he named it *Bacterium lactis* (with subsequent redesignation as *Streptococcus lactis* and *Lactococcus lactis* [the name currently in use] as taxonomic methods improved through the ensuing decades).

Subsequently, additional members of the LAB were identified in a range of fermented milks and other foods. This burst of information regarding the association between fermented foodstuffs and a distinct group (from a functional rather than taxonomic perspective) of bacteria coincided with the rapid transition in the manufacture of some fermented products, especially cheeses, from a small-scale local activity to a full-scale industrial process. It is generally accepted that the first Cheddar cheese-manufacturing factory, using milk from multiple suppliers, was founded by Jesse Williams in Rome in upstate New York in the United States in 1851 (3). By 1880 there were many hundreds of such factories. It quickly became clear that such large-scale operations could not reliably depend on the indigenous LAB, or "backslopping," whereby a sample derived from a previous batch of product (this could be whey in the case of cheese) is added to assist in the fermentation process. The fortuitous coincidence of the discovery of LAB with the need to develop processes for cheese manufacture that could cope with the demands of continuous production on an industrial scale led to the development of starter cultures. Initially, these were simply liquid cultures that were subject to serial transfer and scaling up so that sufficient inocula could be developed to start the fermentation. The use of such cultures provided the manufacturer with a far higher degree of reliability and consistency of performance, and consequently a better-quality product. This process also enhanced product safety.

Later, methods were developed to oven-dry milk cultures or to produce frozen preparations in a manner which allowed survival of

the bacteria. These had the advantage of providing material that was suitable for shipping to geographically distant customers. A further major development was the application of lyophilization to the commercial production of LAB; depending on the concentration of the cells in the preparation, this could mean that there was no need to propagate the starter culture in the manufacturing plant. These technologies are now almost universally employed for the preparation of starter cultures, and a relatively small number of commercial enterprises supply the majority of the world's demand. Considerable research has been devoted to developing these technologies to ensure minimal impairment of the activity of the starters when they are subsequently inoculated into a bulk starter tank or the cheese vats in the factory.

As is evident throughout this chapter, continuous research has been devoted to developing high-performing starter cultures, and this progress has been most evident in the cheese starters, and probably most obviously with those used in Cheddar manufacture. The revolution that was enabled by the application of molecular genetics to the LAB since the 1980s provided an approach to understanding functionality of starter cultures at the level of the gene, a process that has been accelerated considerably in the more recent era of "-omics" technologies. This has been particularly true in the key areas of metabolism, flavor production, environmental sensing, stress responses, and bacteriophage-host interactions. The improved understanding that has been gained over recent decades has allowed a knowledge-based approach, rather than the empirical screening and selection approach, to be applied to improving the quality and reliability of starters (notwithstanding the limitations imposed by regulatory barriers, which in different jurisdictions can be more or less of an impediment to the final application of modified strains).

These developments and their impact, which are described below, may in fact not be universally beneficial in that selection based on genomics-derived information could lead to an ever-narrowing selection funnel, yielding a small group of "ideal" strains, which may result in loss of culture diversity and, consequently, product

diversity. Other advances relating to growth, harvesting, tolerance to drying and freezing, and resuscitation have resulted in starter formats that are more suited to the needs of the manufacturer and more reliable in the high-throughput megafactories that are becoming increasingly common. These developments are also discussed.

LACTIC ACID BACTERIA AND FOOD FERMENTATIONS

The LAB are a diverse group of Gram-positive, obligately fermentative microorganisms that produce lactic acid as the main product of sugar metabolism. This group of bacteria is currently classified in the order *Lactobacillales* and comprises species of the genera *Lactococcus*, *Lactobacillus*, *Streptococcus*, *Leuconostoc*, *Oenococcus*, and *Pediococcus*, among others. In general, LAB have complex nutritional requirements and therefore are usually associated with nutrient-rich environments, occupying a diverse range of ecological niches that includes plants and fermenting plant material, milk, and the gastrointestinal and genitourinary tracts of animals and humans. For millennia, these organisms have been employed in various fermentation processes for the production of fermented foods and beverages, such as cheese, yogurt, wine, and sourdough bread. In more recent times, some members have been shown to have health-promoting effects and are used as probiotics, i.e., live microorganisms used as food supplements in order to benefit health (4, 5). The food-related LAB are afforded GRAS (generally recognized as safe) status, as a result of their long history of use in food fermentations.

Members of the LAB group play an essential role in the food processing industry, where they are used as starter or adjunct cultures for the production of fermented dairy, meat, and plant-derived foods. The technological properties associated with the

different species are central to their selection as starters tailored to meeting particular product requirements (Table 30.1).

Various *Lactobacillus* species are employed as starters in the manufacture of fermented meats. These include *Lactobacillus plantarum*, *Lb. pentosus*, *Lb. sakei*, and *Lb. curvatus*. *Pediococcus* species, including *Pediococcus acidilactici* and *P. pentosaceus*, may also be used in meat fermentations. LAB such as *Leuconostoc* and *Lactobacillus* are responsible for the fermentation of cabbage to produce sauerkraut. Starters employed in the production of sourdough often include *Lactobacillus sanfranciscensis*. Finally, *Oenococcus oeni* is a wine-associated LAB responsible for wine malolactic fermentation, in which malic acid is converted to the softer-tasting lactic acid.

Table 30.1. List of major LAB and their primary applications in food fermentations

LAB	Primary application(s)
Lactococcus lactis	Starter culture used in the production of fermented milk products, e.g., cheese, sour cream, lactic butter, and buttermilk
Streptococcus thermophilus	Starter culture used in the production of fermented milk products, e.g., cheese and yogurt
Lactobacillus spp.	Starter and adjunct cultures used in the production of fermented dairy, meat, and plant products, e.g., cheese, yogurt, sauerkraut, kimchi, and fermented sausage
Weissella spp.	Present in "wild" fermentations, e.g., kimchi and sauerkraut production. Not deliberately added as a starter culture due to link to biogenic amine production.
Oenococcus oeni	Malolactic fermentations in wine production
Pediococcus spp.	Meat and plant fermentations
Leuconostoc spp.	Meat and milk fermentations

KEY FUNCTIONAL ACTIVITIES OF LACTIC ACID BACTERIA

The LAB display a number of key functional activities that are particularly relevant to their role as starter cultures in dairy and food fermentations. These include specific metabolic capabilities, such as the ability to ferment the uniquely milk-associated sugar lactose, as well as other traits, such as bacteriophage resistance, which can be essential in ensuring a successful fermentation.

Sugar Metabolism

LAB metabolize sugars or other carbohydrates through a fermentative process whereby energy is derived from the partial oxidation of an organic compound using organic intermediates as electron donors and electron acceptors (6). ATP is produced by substrate-level phosphorylation, without the requirement for a membrane or electron transport system.

From a biochemical perspective, the LAB include both homofermentative and heterofermentative organisms (Fig. 30.1).

1. Homofermentative LAB produce lactic acid as the primary end product of their fermentations and include *Lactococcus*, *Streptococcus thermophilus*, *Pediococcus*, *Enterococcus*, and certain species of *Lactobacillus*, e.g., *Lactobacillus casei*, *Lb. plantarum*, and *Lb. curvatus*.
2. Heterofermentative LAB produce a number of fermentation products in addition to lactic acid, such as carbon dioxide, ethanol, acetic acid, and formic acid, and include *Leuconostoc*, *Oenococcus*, and certain *Lactobacillus* species, e.g., *Lactobacillus brevis*, *Lb. fermentum*, and *Lb. reuteri*.

The first step in the metabolism of sugars is their transport across the cytoplasmic membrane. Many different transporters exist in LAB, which are generally sugar specific and can be categorized as follows:

1. Phosphoenolpyruvate-phosphotransferase systems (PEP-PTS) that couple sugar transport to its phosphorylation
2. Ion-linked sugar exchange mechanisms, which are secondary transport systems where the sugar uptake is driven by an ion gradient
3. Sugar ATPases, primary transport systems that couple ATP hydrolysis with translocation

Sugars then enter either the Embden-Meyerhof-Parnas (EMP) pathway, in the case of homofermentative LAB, or the phosphoketolase pathway, in the case of heterofermentative species.

Due to the economic relevance of lactose fermentation, the metabolism of this disaccharide has been studied extensively in LAB. In *L. lactis*, the lactose metabolism process starts with translocation of the sugar either via a lactose-specific PEP-PTS to yield lactose 6-phosphate or by a permease. Phosphorylation of lactose by PEP occurs as it is transported into the cell via the membrane-bound lactose-specific PTS. Lactose-6-phosphate is hydrolyzed by phospho-β-galactosidase (encoded by *lacG*) into glucose and galactose-6-phosphate (Gal-6-P). Glucose is phosphorylated by glucokinase, when it then enters glycolysis via the EMP pathway and is metabolized to pyruvate, which is converted to l-(+)-lactic acid by lactate dehydrogenase (Fig. 30.1). Two ATP molecules are generated for each glucose molecule processed. Simultaneously, Gal-6-P is further metabolized by enzymes of the tagatose pathway to the glycolytic intermediates glyceraldehyde-3-phosphate and dihydroxyacetone-phosphate.

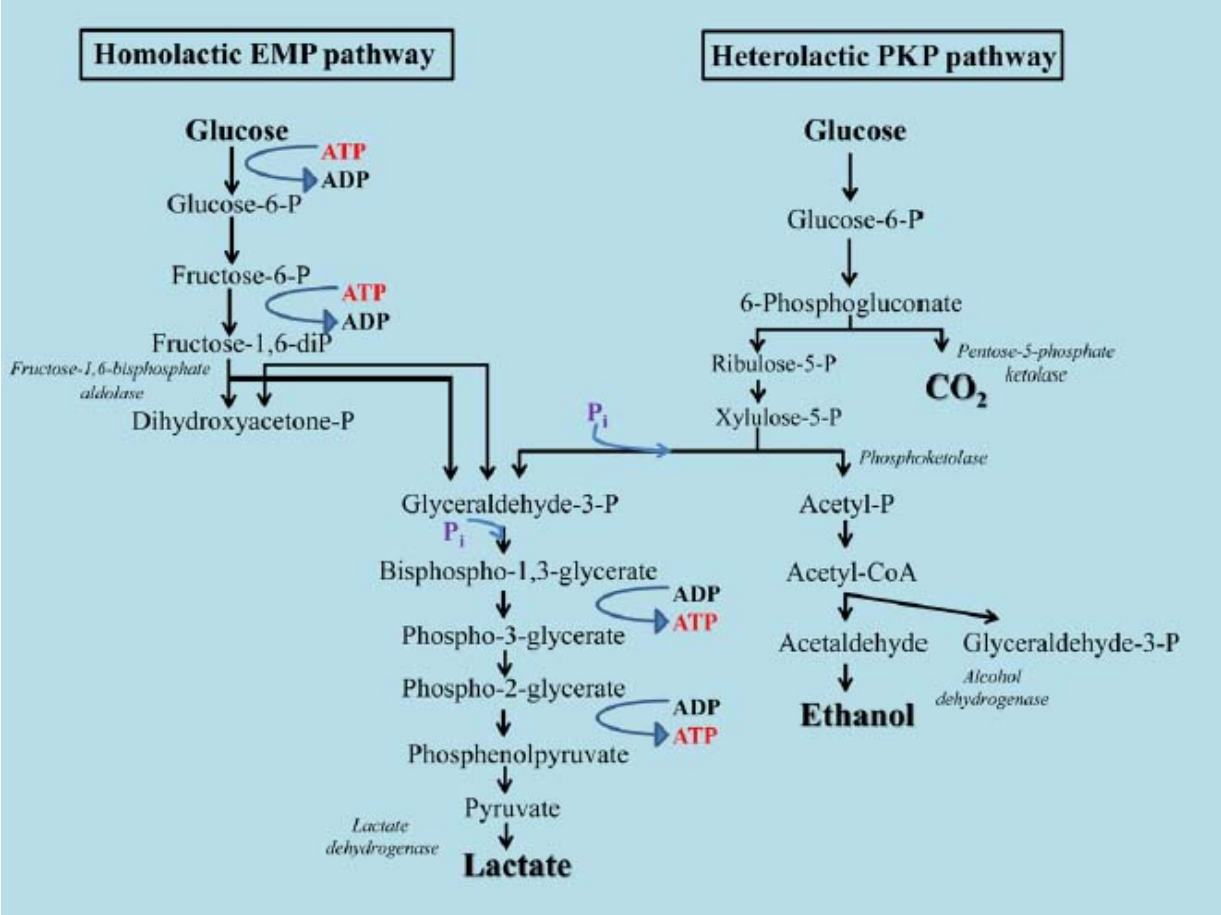

Figure 30.1. Homolactic and heterolactic fermentation pathways for glucose employed by different LAB.

The enzymes for lactose metabolism are generally plasmid-encoded in *L. lactis*. Some lactococci employ a chromosomally encoded lactose permease–β-galactosidase system, depending on *lacZ*, which encodes β-galactosidase. In this case, lactose uptake by a permease is followed by hydrolysis via β-galactosidase, yielding glucose and galactose. Galactose is further metabolized via the Leloir pathway to glucose-1-phosphate, which can, after isomerization to glucose-6-phosphate via a phosphoglucomutase, enter the glycolytic pathway.

With the exception of *L. lactis* and *Lb. casei*, homofermentative LAB do not possess a lactose PTS, and instead, they use a lactose permease system (*lacS*) and an intracellular β-galactosidase (*lacZ*) for metabolism of lactose. Lactose metabolism in the *L. lactis* species also differs from lactose metabolism by other

homofermentative LAB, as in the former, simultaneous catabolism of glucose and galactose occurs. In the majority of other cases, such as in *S. thermophilus* strains, only the glucose moiety is further processed via the EMP pathway, while the galactose moiety is excreted into the growth medium.

In heterofermentative LAB, including some species of *Lactobacillus* and *Leuconostoc*, the phosphoketolase pathway is the major route of glucose metabolism (Fig. 30.1). These bacteria typically produce equimolar amounts of CO_2 plus lactate and ethanol or acetate from the catabolism of glucose. The efficiency of this pathway in terms of ATP generation is about half that of the EMP pathway, as only one ATP is produced per molecule of glucose. Many heterofermentative species also ferment glucose and galactose simultaneously, with galactose being metabolized via the Leloir pathway.

Proteolysis

Members of the LAB are nutritionally fastidious organisms that require an exogenous source of many of the amino acids and peptides necessary for growth (5). For milk-based LAB, the degradation of the main milk protein, casein, through the proteolytic cascade provides the cells with the essential amino acids they require. The first step in the process is initiated by a single cell envelope proteinase (designated CEP or PrtP) which partially degrades the casein into a large number of oligopeptides (Fig. 30.2). CEP enzymes are serine proteases belonging to the subtilisin family and are divided into two main classes based on specificity. Enzymes of the PI class primarily target β-caseins and to a lesser extent κ-casein, while the PIII type are also able to degrade αs1-casein. In general, LAB species possess only one CEP; however, the presence of two enzymes has been described for some lactobacilli. LAB cannot grow in milk in the absence of a functional CEP. However, species that do not exhibit this activity can often grow in milk in the presence of a CEP-positive strain.

In the second step of the process, oligopeptides generated as a result of CEP action are taken into the cell via specific peptide transporters. The main peptide transport system functional in LAB is the oligopeptide permease (Opp) system (Fig. 30.2), identified in *L. lactis*, *Lactobacillus bulgaricus*, *Lb. helveticus*, *Lb. plantarum*, *Lb. sanfranciscensis*, and *Leuconostoc mesenteroides*. The Opp proteins belong to a superfamily of highly conserved ATP-binding cassette transporters that mediate the uptake of casein-derived peptides. This system has been studied extensively in *L. lactis*, where it has been shown to transport peptides up to 18 residues in length. Other active transport systems include a proton motive forcedriven DtpT, which transports di-, tri-, and tetrapeptides containing relatively hydrophobic branched-chain amino acids and which has been identified in *Lb. helveticus*, *Lb. sanfranciscensis*, and *S. thermophilus*. An ATP-driven Dpp (previously referred to as DtpP), with an affinity for more hydrophilic and charged di- and tripeptides, has also been reported in LAB (Fig. 30.2).

After uptake into the cell, the next step in the proteolytic cascade involves degradation of the casein-derived peptides to free amino acids through the combined action of a series of peptidases. These are intracellular enzymes with differing but overlapping specificities that cleave internal peptide bonds of casein-derived peptides. Peptidases can be divided into two types: endopeptidases, which hydrolyze internal peptide bonds, and exopeptidases, which remove amino acids from the end of a peptide chain.

In LAB, the majority of the exopeptidases are aminopeptidases, and their specificity depends on the peptide length and the nature of the N-terminal (or penultimate) amino acid residue. The first peptidases to act are the broad-specificity metallopeptidase PepN, the cysteine peptidase PepC, and the X-prolyl dipeptidyl aminopeptidase PepX (Fig. 30.2). These have been identified in *Lactococcus*, *Lactobacillus*, and *S. thermophilus*. The products generated by these enzymes are then subjected to further cleavage by the tripeptidase PepT and the dipeptidases PepV and PepD. Other enzymes with more targeted substrate specificities are also present.

Examples include PepA, an aminopeptidase acting on acidic residues found in *L. lactis*, *S. thermophilus*, and *Lactobacillus gasseri*; PepS, specific for aromatic residues and found in *P. pentosaceus*, *S. thermophilus*, *Leuconostoc mesenteroides*, *Lb. casei*, and *Lb. sakei*; and PepL, identified only in *Lactobacillus delbrueckii* and displaying high specificity for Leu and Ala residues. The genes encoding the peptide transport systems and the peptidases are typically chromosomally linked, while those encoding the proteases are exclusively plasmid associated.

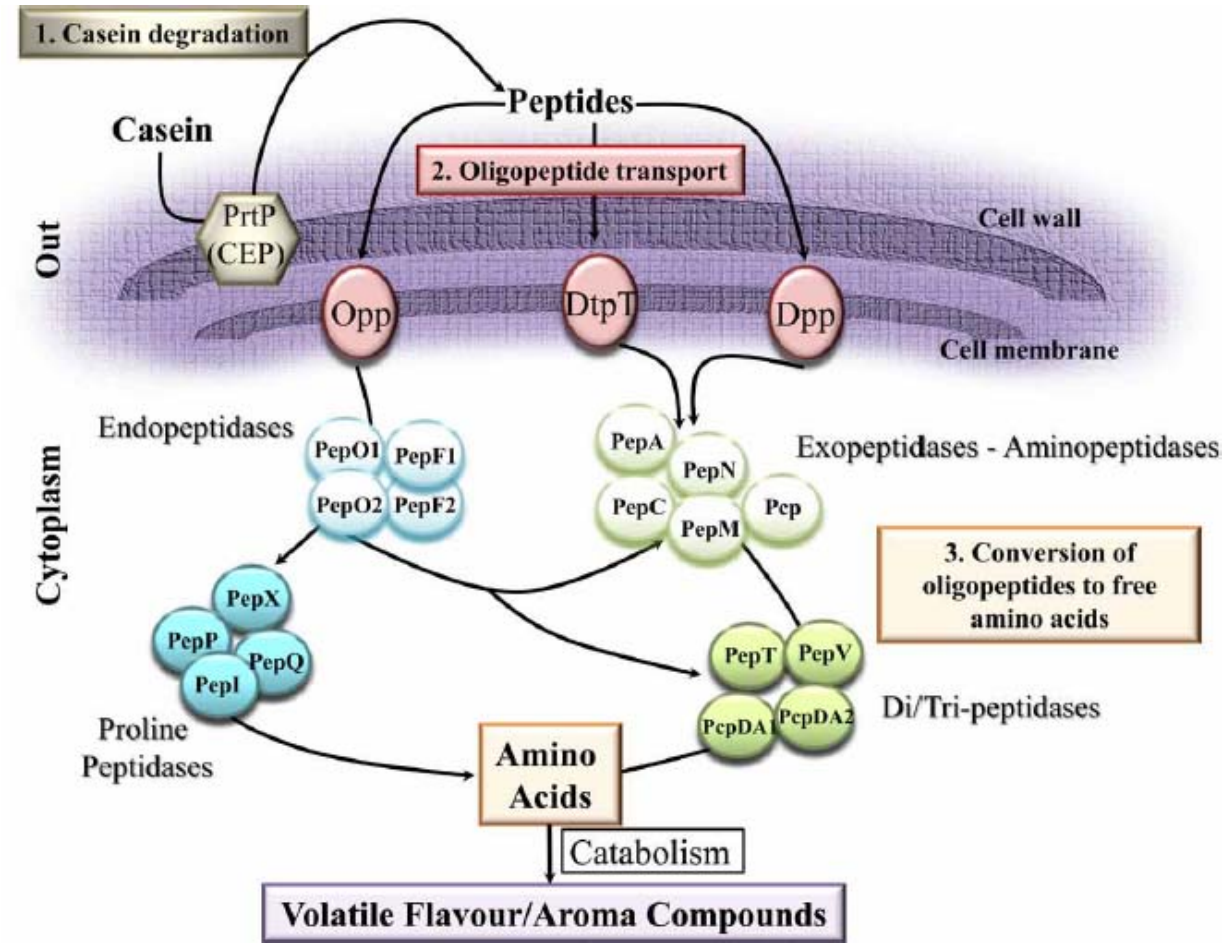

Figure 30.2. Schematic representation of the proteolytic system of *Lactococcus* showing the cell membrane-anchored proteinase PrtP, the membrane-located transport systems (Opp, DtpT, and Dpp), and the array of intracellular peptidases, including endopeptidases, aminopeptidases, di- and tripeptidases, and proline peptidases, that are involved in protein/peptide catabolism and the ensuing release of compounds associated with flavor and aroma.

The subsequent metabolism of free amino acids is an important resource for LAB, and they are used for a number of physiological purposes, such as intracellular pH control, generation of metabolic energy or redox power, and resistance to stress. It is also an industrially important trait, as the end products of amino acid catabolism, such as acids, aldehydes, alcohols, and esters, contribute greatly to defining the flavor and aroma of fermented dairy products. The catabolism of amino acids also has implications with

regard to the safety of fermented foods, as the synthesis of biogenic amines could possibly be a consequence of their activity. In general, the ability of LAB to metabolize amino acids varies greatly among species and is tightly regulated.

Amino Acid Metabolism and Flavor Formation

Flavor development in dairy fermentations is the result of a series of chemical and biochemical processes which occur during the fermentation and ripening of a product (7). Flavor compounds are formed by various biochemical pathways:

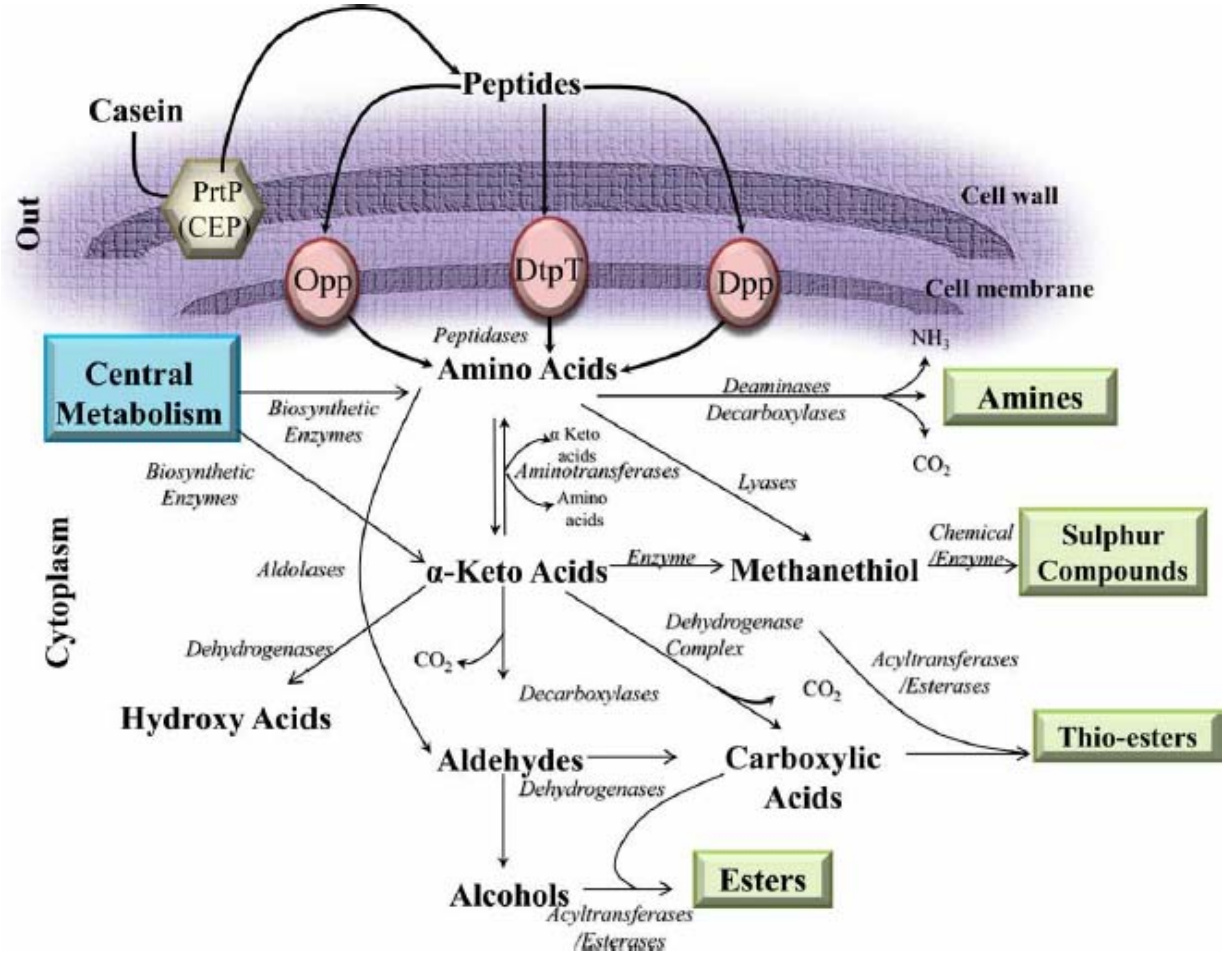

Figure 30.3. Pathways observed in *Lactococcus* through which amino acids are converted to compounds which are significant in the development of flavor in ripened cheeses.

1. Glycolysis, where the conversion of lactose via its intermediate pyruvate to various flavor compounds (diacetyl, acetoin, acetaldehyde, and acetic acid) contributes to typical yogurt or buttery flavors
2. Proteolysis, with free amino acids forming the precursors for many volatile flavor-forming compounds
3. Lipolysis, with the formation of free fatty acids as precursors of flavor compounds such as methyl ketones, alcohols, lactones, and esters
4. Citrate metabolism by certain LAB species, resulting in the production of diacetyl

However, it is proteolysis, and more specifically the catabolism of free amino acids to various alcohols, aldehydes, acids, esters, and sulfur compounds, that is undoubtedly the most important biochemical process for flavor formation in many dairy products but particularly in hard ripened cheeses, such as Cheddar and Dutch types (Fig. 30.3). Certain amino acid groups are the major precursors of volatile compounds, which confer flavor and aroma in fermented dairy products, and the pathways associated with the production of the flavor compounds are highlighted in Fig. 30.3. The amino acid groups involved in volatile compound formation include (i) the branchedchain amino acids valine, isoleucine, and leucine, which are precursors of aroma compounds such as isobutyrate, isovalerate, 3-methylbutanal, 2-methylbutanal, and 2-methylpropanal, found in various cheese types; (ii) the aromatic amino acids tyrosine, tryptophan, and phenylalanine, the products of which are involved in the development of off flavors in certain products; and (iii) the sulfur-containing amino acids (methionine and cysteine), which are linked to the production of potent volatile compounds, including methanethiol, dimethyl sulfide, and dimethyl trisulfide, that are considered essential flavor components in many cheese varieties.

Lipid Metabolism

Lipolysis by LAB is thought to play some, perhaps small, role in the flavor development of certain dairy products, such as Cheddar cheese (8). Free fatty acids (FFA) can contribute to flavor and can be further converted into methyl ketones, lactones, or thioesters, which can also influence the final flavor profile. Starter LAB and the nonstarter microbiota are believed to represent the main sources of lipolytic agents in pasteurized Cheddar cheese. In order to hydrolyze milk fat, starters need to possess active lipolytic and esterolytic enzymes, capable of hydrolyzing FFA and other fat-based substrates. However, it is generally accepted that LAB are weakly lipolytic, and to date, the lipolytic and esterolytic systems of dairy LAB remain poorly characterized. Despite this, the extended presence of LAB starters and adjuncts in Cheddar cheese over the ripening time is thought to play a significant role in the generation of FFAs. Members of the LAB which exhibit lipolytic activity include *L. lactis*, *Lb. casei*, *Lb. fermentum*, *S. thermophilus*, and *Lb. plantarum*.

EPS Production

Many LAB produce extracellular polysaccharides, or exopolysaccharides (EPS), with various chemical compositions and properties (9). Production of EPS by starter cultures can alter the rheological properties of fermented products, leading to typically viscous and “ropy” characteristics. Starter production of EPS can have a significant impact on the properties of certain fermented dairy products, such as yogurt, cheese, milkbased desserts, and sourdough bread. For example, the use of the EPS-producing starters *S. thermophilus* and *Lb. delbrueckii* subsp. *bulgaricus* in yogurt production leads to improved consistency, texture, and mouthfeel of the product, whereas in sourdough production, EPS produced by *Lb. sanfranciscensis* facilitates water absorption, softening the gluten content of the dough.

EPSs generally exist in one of two forms: cell-bound EPSs, which closely adhere to the bacterial surface as capsular material, and free

EPSs, which are released into the surrounding medium.

EPSs produced by LAB are often distinguished as either ropy or non-ropy. These long-chain molecules consist of branched, repeating units of sugars or sugar derivatives, are synthesized by highly specific glycosyltransferase enzymes, and can be classified into two groups. Homopolysaccharides consist of one type of monosaccharide (e.g., □-d-glucans, β-d-glucans, or fructans) and are produced by *Leuconostoc* species, some *Streptococcus* species (but not *S. thermophilus*), and certain *Lactobacillus* species (e.g., *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. reuteri*). The majority of EPSs produced by LAB are heteropolysaccharides, composed of different types of monosaccharides, mainly d-glucose, d-galactose, l-rhamnose, and their derivatives. EPSs produced by *L. lactis*, *S. thermophilus*, and many food-related *Lactobacillus* species are of this type.

The genetic determinants for EPS production are typically plasmid encoded in the case of mesophilic starters, while for *S. thermophilus* and thermophilic species of *Lactobacillus*, they are chromosomally encoded functions, and their production is typically more stable. EPS biosynthesis is a complex process, with many enzymes and regulatory proteins involved. It typically begins with sugar transport into the cytoplasm, followed by the synthesis of sugar-1-phosphates, polymerization of the repeating units, and finally export of the EPS. Each of these steps is crucial and can be manipulated to modify the amount and composition of the EPS.

Bacteriophage Resistance

Phage contamination is a significant risk to any industry that relies on fermentation for product manufacture, as it can lead to delays in production, lower product quality, or, in the worst cases, total loss of production. Careful selection of LAB starter cultures known to harbor natural resistance mechanisms that prevent or limit infection by common phages is one control method that can be adopted to minimize the risk. A diverse range of phage resistance

systems have been identified in various LAB species (10), and this is discussed in detail below (see “Bacteriophages”). Furthermore, progress in research on bacteriophages of LAB and their interactions with their hosts and how this knowledge can be utilized to develop more robust starter strains is also discussed in more detail below.

Bacteriocin Production

Bacteriocins are ribosomally synthesized antimicrobial compounds produced by a variety of bacteria that kill closely related bacteria. Bacteriocins have been classified into a number of categories.

1. Class I, the best known of which are the lantibiotics, is defined as small membrane-active peptides (<5 kDa) containing modified amino acids such as lanthionine or β-methyl lanthionine and other dehydrated residues.
2. Class II is the small heat-stable unmodified or minimally modified peptides.
3. Bacteriolysins, formerly referred to as class III bacteriocins, are large heat-labile proteins often with enzymatic activity.

The best-studied LAB bacteriocin is nisin, a lantibiotic produced by *L. lactis* and widely used as a biopreservative in a diverse range of foods (11). It exhibits activity against a broad spectrum of Gram-positive bacteria and is particularly effective against endospores. It acts by disrupting the integrity of the bacterial cell membrane by forming pores. This leads to the dissipation of the membrane potential and the efflux of small metabolites and other cytoplasmic solutes, resulting in the termination of allbiosynthetic processes, leading to cell death. The genetic determinants of nisin production make up an 11-gene cluster, *nisABTCIPRKFEG*, which is typically chromosomal.

Other well-characterized LAB bacteriocins include the two-component class I lantibiotic lacticin 3147, produced by *L. lactis*; the

class II bacteriocins pediocin PA-1 and enterocin A, produced by *P. acidilactici* and *Enterococcus faecalis*, respectively; and the bacteriolysin helveticin J from *Lb. helveticus*. While the production of bacteriocins can be problematic, as it may limit the growth of other useful starter cultures in some fermentations (e.g., in cheese production), bacteriocin-producing strains are routinely incorporated into certain starter culture blends (e.g., those involved in meat fermentations) to limit the proliferation of pathogenic organisms such as *Listeria* (12).

Autolysis

Autolysis can be defined as the spontaneous disintegration of the bacterial cell through the action of the cell's own intracellular peptidoglycan (PG) hydrolases. These enzymes are often referred to as autolysins. Autolysis of cells is the result of the uncontrolled action of PG hydrolases when cell wall assembly and/or repair is inhibited. This action is potentially lethal, and so the activity must be tightly regulated. The enzymes play an important role in cell division, cell wall synthesis, and cell wall turnover. During cheese ripening, these enzymes are crucial, since they allow the cheese microbiota to release their enzyme-rich cytoplasmic content into the cheese matrix during the maturation process, which results in the development of characteristic organoleptic properties. The rate of autolysis is strain dependent and is also influenced by the environment and the cheese-making process.

Autolysins have been characterized in some LAB species. The glycan chains of PG can be cleaved by *N*-acetylglucosaminidases or *N*-acetylmuramidases. *N*-Acetylmuramoyl-l-alanine amidases hydrolyze the bond between the glycan chain and the pentapeptide side chain, while carboxypeptidases and endopeptidases can cleave the different bonds of the peptide side chain. *L. lactis* has four *N*-acetylglucosaminidases, namely AcmA, AcmB, AcmC, and AcmD. AcmA is required for cell separation and is the major autolysin that is responsible for lysis during the stationary phase of growth of *L. lactis*.

Besides the genome-encoded PG hydrolases, phageencoded endolysins can also contribute to autolysis of lactococcal cells (13). Endolysins are generally coexpressed with holins that form pores in the cytoplasmic membrane of the host, thereby abolishing membrane potential and allowing translocation of the endolysin over the membrane. Natural expression of phage lysins can lead to an increase in the release of intracellular peptidases needed for enhanced cheese ripening.

STARTER CULTURE TYPES FOR DIFFERENT PRODUCTS

Starter cultures can be categorized in a number of different ways, often reflecting their composition or specific functional attributes. Some of these classification systems are used by industry practitioners in particular and are more readily applicable to cheese starters. Cultures are generally characterized as either mesophilic cultures, which have an optimum growth temperature in the range of 27 to 33°C and can be non-gas producing or gas producing, or thermophilic cultures, which have an optimum growth temperature in the range of 37 to 50°C. Both types are discussed further below (14).

Mesophilic starters are used in cheeses where the curd cooking or scalding temperature does not exceed approximately 40°C during the early stages of acid production. Such conditions apply to Cheddar, Edam, Camembert, and Gouda cheeses. *L. lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris* are the dominant non-gas-producing mesophiles, are typically strong acidifiers, and are used as starter cultures in the manufacture of cheeses such as Cheddar, feta, and cottage cheese. Gas (CO_2)-producing mesophilic cultures include *L. lactis* subsp. *lactis* biovar *diacetylactis* and *Leuconostoc mesenteroides* subsp. *cremoris*. Both species are capable of catabolizing citrate to CO_2 and diacetyl and are used in the

production of Edam, Gouda, and soft mould-ripened cheeses such as Camembert and Brie.

Thermophilic starters are those utilized in the manufacture of cheeses where a higher scalding temperature (>37°C and in some instances 48 to 55°C) is employed during manufacture. This is particularly relevant to Swiss (Emmental and Gruyère) and Italian (Mozzarella, Grana, and Pecorino) cheeses, with the species in question being *S. thermophilus* alone or in combination with thermophilic lactobacilli (*Lb. delbrueckii* subsp. *lactis* and *Lb. helveticus*). *S. thermophilus* is the only *Streptococcus* species employed as starter cultures. This organism is widely exploited in the manufacture of yogurt and Mozzarella cheese, and since the mid-1990s, it has also been used (along with the standard lactococci) in the manufacture of Cheddar cheese. Thermophilic lactobacilli are used as starters in the manufacture of yogurt and Mozzarella cheese (*Lb. delbrueckii* subsp. *bulgaricus*) and are also incorporated as starter adjuncts to promote faster ripening of Cheddar and similar cheeses (e.g., *Lb. casei*), to reduce the incidence of bitterness (e.g., *Lb. helveticus*), and as probiotics in yogurt-type products (*Lb. acidophilus, Lb. rhamnosus*, and *Lb. gasseri*, among others). It should be noted, however, that the distinction between cheeses produced by mesophilic versus thermophilic starters is not as clear as it has been in the past, and an increasing number of cheeses contain both types of starters.

O, D, L, and DL Cultures

Typically, mesophilic cultures used in Cheddar cheese manufacture, where the requirement of the *L. lactis* starter is to produce lactic acid and not to generate gas, are referred to as O cultures. Those that are required to generate the flavor compound diacetyl along with CO_2 gas from the utilization of citrate in the milk, while still utilizing *L. lactis* as the primary producer of lactic acid, are referred to as either D cultures (where the citrate utilizer is *L. lactis* subsp. *lactis* var. diacetylactis), L cultures (where the citrate utilizer is a

Leuconostoc species), or DL cultures (where both are present as flavor and CO_2 producers). The latter starters are used in Dutch cheese manufacture and in the production of sour cream and lactic butter.

Starters may also be subclassified on the basis of the isomer of lactate that is produced as an end product of glycolysis, which is dependent on the type of lactose dehydrogenase (D- or L-lactose dehydrogenase) that is present in the cell or the ability of cells to racemize L-lactate. The isomer D-lactate (e.g., *Lb. delbrueckii* subsp. *bulgaricus*), L-lactate (e.g., *Lactococcus* and *S. thermophilus*), or DL-lactate (e.g., *Lb. helveticus*) will be generated depending on the nature of the lactose dehydrogenase enzyme.

Mixed-Strain and Defined-Strain Starters

The designation of a starter as either a mixed-strain starter (MSS) or a defined-strain starter (DSS) depends on its composition. MSSs are of an undefined composition and are ultimately derived from the original starters that were first developed by commercial starter companies over 100 years ago. Thus, while they frequently made excellent-quality products, they consist of an unknown number of strains (which in the case of Cheddar cheese, for example, would have largely, but not exclusively, been strains of *L. lactis*). As the industrialization and intensification of cheese making increased throughout the 20th century, these MSSs came under increasing pressure and often failed to perform adequately. Issues such as gas production (which in Cheddar is undesirable) and bacteriophage sensitivity prompted New Zealanders, as early as the 1930s, to first move away from such systems. The undefined nature of MSSs made it very difficult to troubleshoot problems, and even when one MSS preparation was replaced with another, one could never know with any degree of assurance that the replacement was in fact significantly or wholly different from the MSS that it was replacing. In other countries, MSSs were employed much later into the 20th century, but in most cases, especially where Cheddar cheese is

manufactured on a large scale, they have largely been replaced by DSSs.

DSSs contain a specified number of well-characterized, scientifically studied strains (usually in combinations of two to six individual strains). For starters such as those used in Cheddar manufacture, the DSS may be as simple as two strains of *L. lactis* whose properties have been thoroughly characterized and whose suitability for cheese making has been demonstrated. Thus, in order to be included in a DSS, individual strains are tested exhaustively to ensure that they grow and acidify the milk at a rate commensurate with the cheese-making process, that they do not produce mutually inhibitory compounds (such as bacteriocins), that they generate the appropriate flavor profile (and this may be, to a greater or lesser degree, a reflection of their propensity for autolysis), that they will not be killed by the scald temperatures used in the cheese-making process, and that they exhibit the appropriate degree of salt tolerance. However, it is in the area of bacteriophage sensitivity that the most rigorous and challenging tests are applied in the selection process. Since phages are virtually impossible to fully eliminate from cheese plants and because severe phage infection of the starter can be devastating to the manufacturing process (and this, after all, was the principal reason why there was a need to move away from the MSS system), it is essential that strains included in DSS systems exhibit a high degree of phage resistance. Thus, a rigorous selection process must be applied. This usually involves collecting phage samples from industrial cheese plants (phages will be present in whey) and using cocktails of factory whey as a selective screen to identify isolates that exhibit resistance.

While there may have been a naive assumption that strains exhibiting total resistance to such phage challenges could be readily isolated, this was proved erroneous once these strains were deployed in cheese plants. Nevertheless, it was apparent that some strains did exhibit a significant degree of robustness (while still not totally resistant), and these could actually operate on a reliable basis in real-world situations. However, it was essential to constantly

monitor the whey drawn from the cheese vats for phage levels. Typically, it is found that phagerobust cultures can tolerate levels of about 10^3 to 10^4 PFU/ml of whey, but any increase above this level is a signal of impending problems and a warning that it would be prudent to replace the phage-sensitive component of the DSS with another well-characterized and phage-unrelated strain. This is the strength of the DSS system—the known composition of the starter culture allows individual strains to be constantly tested for sensitivity to factory phage, and if they start to fail, the offending strain can be removed from the starter and replaced with another strain. Indeed, in order to protect the DSS starters further, factories often rotate two different DSSs in a single day's manufacture so as to reduce the pressure on individual DSS systems. Approaches such as these have been adopted on an almost worldwide basis for Cheddar cheese starters, and similar strategies are also used for many other cheese types that are produced on an industrial basis.

A notable exception is Dutch cheese manufacture, where undefined MSSs are still used almost exclusively. While attempts have been made to develop a defined-strain system for the Dutch cheese industry, allefforts have failed to reproduce the flavor and other quality attributes imparted by the mixed strains. Microbiological analysis of these strains has shown that they are highly complex and that their stability, even in the face of intensification of manufacturing schedules and the consequent increased risk of phage interference is, in part at least, attributable to the dynamic ecological balance that exists between phagesensitive and phage-resistant components—a state of equilibrium that may be maintained by the presence of phage in the actual starter preparations.

Generally, in other cheese fermentations, such as those utilizing thermophilic starters (Italian and Swiss) as well as yogurt fermentation, the industry has moved to defined systems except in more traditional settings, where backslopping (i.e., the use of whey from a previous fermentation as the starter for the next fermentation) is practiced in the traditional manner.

In general, it can be concluded that DSSs have met the demands of modern, large-scale industrial fermentations. They are relatively robust in terms of phage resistance, they are reliable, which ensures predictable manufacturing schedules, and the fact that they can be used over relatively long periods of time ensures product of consistent quality. A limitation may be that the rigorous process of strain selection can result in a limited number of distinctly different strains (especially in terms of flavor development capacity), which can result in a sameness in cheese flavor, irrespective of who the manufacturer is. This issue is being addressed, in part at least, through the increasing use of adjunct starters, which is the topic of the next section.

Secondary and Adjunct Starters

While the starter cultures described above are primarily responsible for acid production in food fermentations, other additional strains, which do not contribute significantly to acid development, are used to perform functions which are essential to the characteristics of the product (secondary strains) or confer additional benefits that that primary starter alone cannot deliver (adjunct starters) (15). Examples of secondary starters include *Propionibacterium shermanii*, which contributes significantly to flavor development in Swiss cheese manufacture (propionic acid derived from lactate) and is also responsible for the formation of eye holes due to CO_2 production. Other examples of secondary starters include the inoculation of molds of the *Penicillium* species (*Penicillium camemberti* in surface-ripened Camembert and Brie cheeses and *Penicillium roqueforti* in various blue cheeses) or even the coating of the surfaces of very heavily ripened cheeses, such as Munster and Limburger, with bacteria to create a smear. In allof these cases, the primary starter is responsible for acid production during manufacture, but the flavor is developed to a complete or significant extent by the secondary starter, and their presence is essential to the formation of the product's final characteristics.

Adjunct starters are not essential to the formation of the product's final properties but instead contribute some additional functionality which enhances the product. Adjunct cultures are being met with increasing favor by cheese makers, in particular to enhance flavor or to promote accelerated flavor development. The use of adjuncts in Cheddar cheese involves the addition of usually, but not exclusively, particular *Lactobacillus* species (*Lb. helveticus*, *Lb. casei, Lb. paracasei*, *Lb. rhamnosus*, and *Lb. johnsonii*) along with the primary starter. The adjunct is added in high cell numbers but is not the agent of acid production. However, these *Lactobacillus* strains are chosen for their high levels of proteinase and peptidolytic activities, which contribute significantly to the development of flavor during ripening. In particular, such strains can compensate for what has been described as a certain degree of blandness in cheeses manufactured using the highly specialized DSS systems. The numbers and range of adjunct starters available from the culture supply companies are expanding, but they are relatively expensive, adding significantly to the overall starter costs incurred by cheese companies.

Another relatively new development is the use of *S. thermophilus* adjunct starters along with the primary cultures in the manufacture of Cheddar and Cheddartype cheeses as added protection should the *Lactococcus* DSS become infected with phage. The underlying motivation is that *S. thermophilus*, being entirely phageunrelated to the *Lactococcus* strains, can take over acid production in the event that the activity of the latter is compromised by phage.

Many of the adjunct starters used to intensify flavor or accelerate the maturation process are actually isolated from a group of microorganisms called nonstarter lactic acid bacteria (NSLAB). NSLAB were originally regarded as adventitious contaminants which can grow to relatively significant levels of 10^6 to 10^7/g of cheese during ripening and are considered to influence flavor development. Specific strains which are deemed to confer positive attributes to the cheese have been isolated and developed into adjunct strains and are now added to some starter blends to harness

these traits in a controlled manner. Screening to select such strains needs to be carried out with care, as some NSLAB may possess undesirable traits, such as the production of biogenic amines (16), or harbor antibiotic resistance genes. Desirable and undesirable traits were traditionally screened for using phenotype-based culture techniques, but the advent of the "-omics" era has largely replaced these methods with genome-based assessments to detect the presence of the genetic determinants of such attributes, with phenotypic confirmations being performed only where such genetic determinants are identified. This significantly reduces the labor-intensive screening processes that were traditionally employed and increases the throughput of screening that may be performed by starter culture manufacturers.

PRODUCTION OF STARTER CULTURES BY CULTURE MANUFACTURERS

When a strain of LAB is considered for commercial application, starter culture producers assess each newly acquired isolate for production and performance attributes. For example, the culture should not display resistance to antibiotics that are used in human therapies. Furthermore, it should be capable of acidifying milk to produce the desired fermentate within a technologically appropriate time frame and at specific temperatures depending on the desired application. For certain applications or fermentations, additional specific properties are desirable, including the production of volatile compounds which are associated with aroma development, the production and potential extracellular release of flavor-associated enzymes, and resistance to infection by bacteriophages. These attributes are assessed using a range of techniques, including culture identification using microbiological tests (growth temperature profiling, sodium chloride tolerance, ability to metabolize compounds such as citrate, and sensitivity to antibiotics) and genetic techniques, which usually include DNA sequencing of either the whole genome or so-called housekeeping genes, such as

the 16S rRNA gene. The production of volatile organic compounds is also assessed using gas chromatography-based tests, and enzymatic capabilities may be identified through PCR-based assays, while microbiological assays can also be used to confirm these activities. Figure 30.4 outlines some of the attributes and methods employed in culture assessment. If the culture is deemed technologically appropriate, it is included in the culture collection and either is produced as necessary as a single culture or is applied as part of a culture blend. Starter culture production for application in the dairy fermentation industry follows these basic steps: determination of the optimum composition and preparation of medium, optimization of growth parameters, harvesting, and preservation. These steps are covered in more detail below.

Medium Preparation and Growth

The majority of commercially produced dairy starter cultures are grown in sterile milk-based media whose composition may be modified based on the specific requirements of a given species or even strain. These media are generally subjected to a thermal sterilization treatment. The starting material needs to be of premium quality in order to ensure the highest level of starter activity; thus, medium selection and preparation are critical steps in the starter culture production process. For example, milk derived from mastitis-infected animals, in most instances, will not support optimal growth of lactic starter cultures, as it often contains lower concentrations of lactose and exhibits a higher pH than normal milk. Heat treatment of the milk generally renders it more suitable for fermentation due to the generation of lowmolecular-weight nitrogen compounds, highlighting the importance of thermal processing of the starting material.

As discussed above, the LAB, including *L. lactis* and *S. thermophilus*, which are the most widely exploited LAB, produce lactic acid as the primary by-product of hexose fermentation. In the absence of buffering, the hydrogen ion concentration becomes limiting near pH 5.0, which restricts further biomass production.

pH control of the starter culture fermentation during its preparation is usually applied to ensure that values remain between 5.4 and 6.3, usually by the addition of gaseous ammonia or concentrated alkali (sodium or more usually ammonium hydroxide). This serves to reduce production times, increase biomass, and increase the reliability of cultures and is employed in the vast majority of commercial operations.

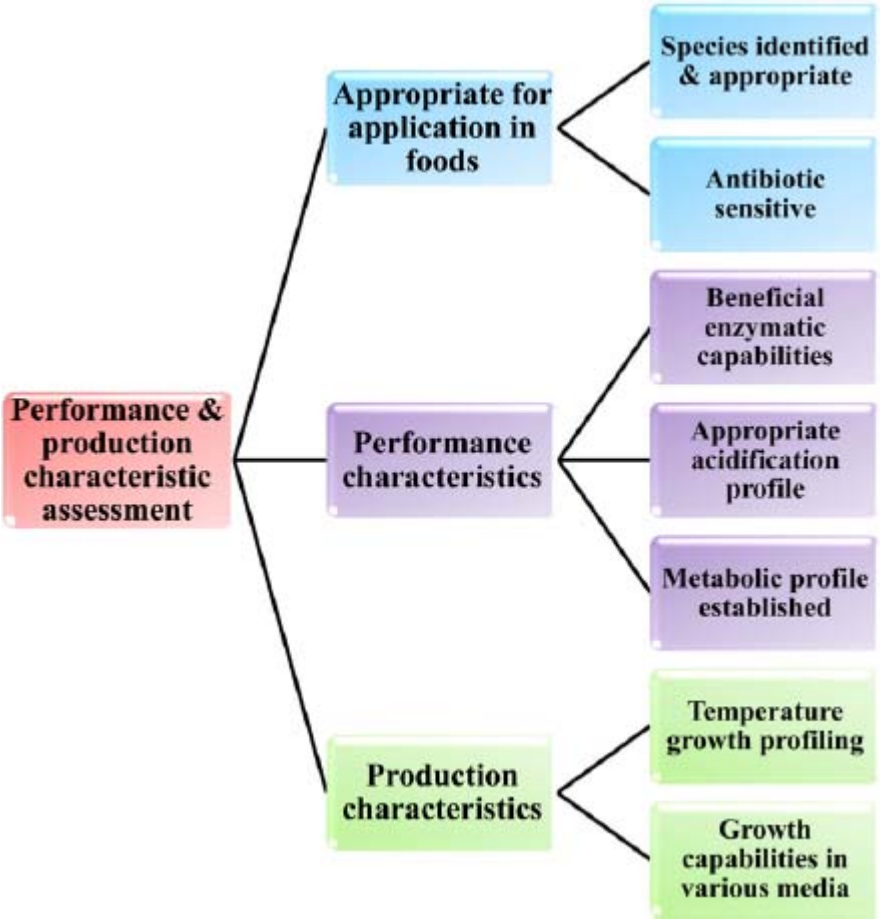

Figure 30.4. Key attributes assessed to determine the technological appropriateness of starter or adjunct cultures by starter culture manufacturers. These attributes include safety for use in foods and performance and production characteristics.

Harvesting and Preparation for Storage

Upon reaching the desired pH and biomass, cells may be harvested using a range of methods. These may include direct aliquoting of

the fermentate into appropriate sterile containers, but more frequently, it is necessary to separate the bacterial cells from the growth medium by either centrifugation or (ultra) filtration. The cells are then standardized to a specified activity and mixed with a cryoprotectant. The concentrated cells may then be packaged for subsequent use or storage. Frozen concentrated cultures typically contain 10^{10} to 10^{11} CFU/g.

The preservation of starter cultures is achieved through freezing or freeze-drying. Frozen concentrated cultures are prepared by rapidly freezing the cell suspension either in liquid nitrogen (–196°C) or in a dry ice-ethanol mixture and are subsequently stored in a freezer. These cultures are immediately active upon thawing.

Alternatively, the concentrated cultures may be freezedried by first suspending the cells in a suitable medium such as milk or a solution of sugar (such as lactose, trehalose, glycerol, or sucrose) and aliquoting in the final storage containers prior to rapid freezing using a cooling mixture or evaporation by cooling under vacuum. The package may contain a single strain or a blend of strains that have been individually propagated, concentrated, and freeze-dried. When the desired moisture content has been achieved (<3%), the cells are blended to achieve a specified activity. These are commercially available in aluminum pouches under nitrogen. The freezedried cultures can be stored at refrigeration temperatures for a period of up to a year without loss of activity. The disadvantage of freeze-dried cultures is that they undergo a longer lag time in the cheese vat than frozen concentrated cultures, with an additional 30 to 60 minutes required to ferment the milk. In addition, while the majority of LAB may be freeze-dried without significant loss of viability or activity, some LAB, such as *Lb. helveticus* and *Lb. delbrueckii* subsp. *bulgaricus*, are not amenable to this form of preservation.

STARTER CULTURE FORMATS EMPLOYED IN COMMERCIAL PRACTICE

The selection of starter culture type by a dairy company is a multifactorial decision which balances economic factors with the production system in use (traditional versus modern practices). In addition, the dairy company must consider the possibility of a specific need for a particular culture, the cost-effectiveness of employing different culture formats, the convenience level required, and the reliability of a culture. This is performed on a case-by-case basis by each dairy company depending on their specific processes and needs.

In-House Preparation and Backslopping

In dairy fermentations, the traditional practice of propagating the starter culture by serial subculturing in the factory (Fig. 30.5) is rarely practiced nowadays. This is highly labor-intensive, and there is considerable risk of exposure to contaminants in the factory environment, particularly to bacteriophages.

The production of some traditional and regionally protected fermented dairy products involves the application of a process known as backslopping (described above). Other traditional methods incorporate the use of wooden vats, for example, and rely on the autochthonous microbiota to initiate the fermentation process. While these fermentations are dependent on either material from previous successful batches or the native microbiota of the vats and equipment to drive the process, there may be inconsistencies in the organoleptic properties of the final product, as the starter mix is undefined and may vary from batch to batch. However, failure of such processes is quite rare, since the diversity of bacteria in any given fermentation will generally be sufficient to successfully acidify the milk. Additionally, traditional fermentations often employ raw cow, goat, or ewe milk, each bringing its own innate microbiota, which may further contribute to the fermentation process and the highly valued flavors associated with traditional rawmilk cheeses.

Bulk Set Cultures

The majority of modern large-scale fermentation facilities employ ready-made starter strain blends that are prepared by starter culture providers based on the specific needs of the processor. These cultures are designed to produce acid at a rate that is reliable and consistent with the requirements of the process and also to generate products with certain desired flavor and texture characteristics. Such cultures are generally provided in the form of deep-frozen or freeze-dried concentrated or highly concentrated (superconcentrated) formats (17). The level of concentration of these starter culture preparations as provided by the starter supplier allows the cheese manufacturer to determine the extent of in-factory propagation that they wish to perform.

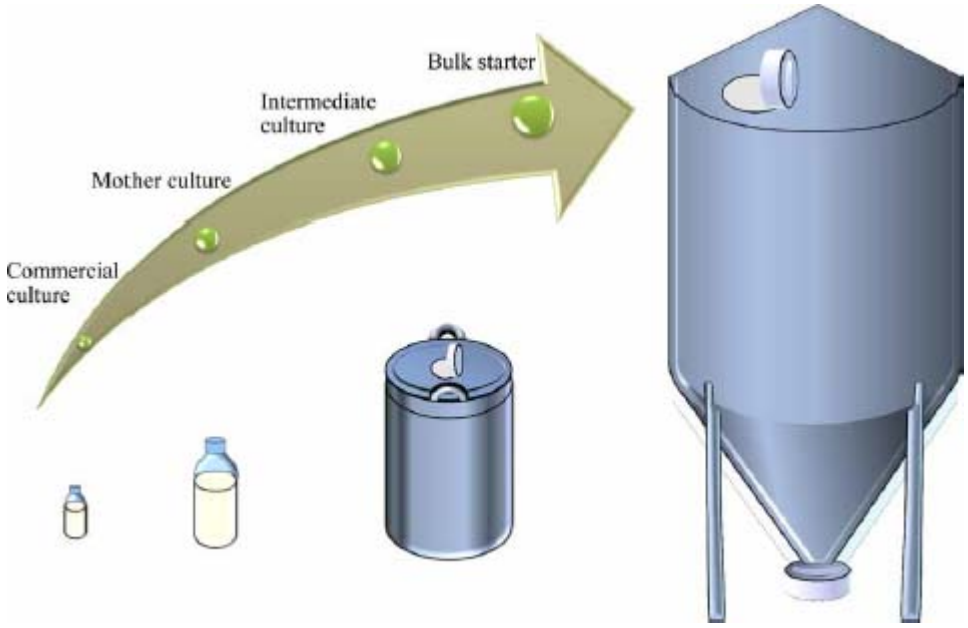

Figure 30.5. Stages in the production of a bulk starter, where intermediate propagation steps are incorporated to scale up the production of the desired starter culture.

Concentrated cultures are usually appropriate for processors using a bulk starter system in the factory. In this case, the frozen or freeze-dried preparations, at concentrations of approximately 10^{10}/g, are slowly thawed or reconstituted and then inoculated into a bulk starter tank. In most cases, the growth medium for bulk cultures is antibiotic-free, skimmed-milk powder reconstituted in water to a 10

to 12% solids content, which is sometimes supplemented with growth stimulants such as tryptone. The process starts by the inoculation of milk that has been heated to 90 to 95°C for 30 to 60 minutes with a commercial culture to produce a bulk culture (Fig. 30.5). The progress of the bulk culture fermentation is assessed by measuring the titratable acidity or pH at regular intervals, and in some cases, neutralization is used to achieve a higher cell number by minimizing acid damage. When a titratable acidity of approximately 0.85 to 0.90% is reached, the fermentation is halted by agitating the cultures and chilling the fermentation vessel to 4 to 5°C.

The bulk culture approach to starter production reduces the cost associated with the in-factory, stepwise propagation of the starter from stock; however, it also incorporates a level of risk. For example, a dairy facility that regularly employs a particular starter may house bacteriophages capable of infecting the culture. The presence of such bacteriophages may slow the acidification process and cause downstream problems in the subsequent fermentation, as the bacteriophages will continue to propagate in the vats. The higher risk of bacteriophage infection associated with bulk starters necessitates increased microbiological testing of the culture, which requires suitably trained personnel, adding further to the costs. The preparation of bulk cultures also necessitates the use of highly engineered and expensive bulk tanks (essentially bioreactors), and the number of bulk tanks that the dairy company possesses will limit the number of different production batches that may proceed on a given day. Furthermore, the bulk starter rooms which house these tanks must be carefully and expensively designed so as to minimize the risk of phage infection and typically incorporate measures such as filtered air, positive air pressure, gowning areas, and sanitizer footbaths. They must also be designed and constructed to facilitate thorough cleaning and sanitization. Therefore, while the preparation of bulk cultures provides dairy companies with reduced direct starter costs and greater flexibility and control in terms of the long-term application of desired starter cultures, it must be accepted

that there is a greater risk of phage infection due to the need to undergo a subculturing step, despite all of the measures that are taken to mitigate this risk.

A routine quality assurance step to ensure that the bulk starter will be fully active when inoculated into the cheese milk is the so-called activity test, in which milk is inoculated with 2% of the bulk culture and incubated at the relevant temperature for mesophilic or thermophilic systems for 4 to 6 hours. The titratable acidity is then determined through titration with N/9 sodium hydroxide, and if the values achieved (measured as percent developed lactic acid) are not at the expected levels, it indicates that the starter is “slow” and may not produce acid in the fermentation at the appropriate rate. This is a simple and inexpensive test that provides same-day results, which is beneficial in the industrial context.

Superconcentrated Cultures: DVS Systems

An alternative approach for the cheese maker is to use superconcentrated cultures (up to 10^{12}/g), which are suitable for direct inoculation into the cheese milk. These are often referred to as direct vat set (DVS) or direct vat inoculation (DVI) cultures. Their use avoids the need for any in-factory propagation, thereby significantly reducing the risk of exposure to phages. They are also very convenient, and there are considerable labor savings compared with bulk starter preparations. Furthermore, in recent years, the number and types of starters that are available in DVS/DVI formats have increased significantly; these benefits have been sufficiently attractive to the cheese manufacturer to outweigh the disadvantages of higher purchase costs and some loss of activity immediately following inoculation into the cheese milk (due to the lag as the cells acclimatize from the frozen or dried state to the milk environment). The use of DVS/DVI starters may be a particularly attractive option in situations where new cheese plants are being commissioned; the capital costs of constructing bulk starter

facilities are considerable, and thus there is a significant savings to be made if this step can be avoided.

Long-term application of DVS/DVI cultures can be expensive for dairy companies, and a commitment to using such systems means that they are continually reliant on starter culture manufacturers to provide these cultures on demand. Furthermore, the supply of particular DVS/DVI cultures preferred by individual dairy companies may be discontinued, with obvious negative consequences for those relying on their continued availability. Dairy companies also need to have adequate storage (freezer) space and good temperature-monitoring systems to maintain the large volume of DVS/DVI cultures if they are purchased in the frozen state (which is usually preferred in the case of cheese starters).

While the culture systems described above are generally very effective in limiting production issues and product inconsistencies, allfermentations are additionally prone to external factors that may influence the acidification activity of starter cultures, as discussed below.

FACTORS AFFECTING STARTER CULTURE PERFORMANCE IN DAIRY FERMENTATIONS

The major components of milk are water, fat, protein, lactose, and minerals. Its exact composition is dependent on a number of factors, including the animal's diet, environmental factors, the breed of the animal, the stage of lactation, seasonal considerations, and the health status of the animal. The most variable component of milk is the fat, while lactose is the least variable constituent. The animal's diet may be designed or altered to manipulate the fat composition. The composition of milk may significantly impact the production regimens and the acidification rates by starter cultures. Therefore, the milk protein levels (and, indeed, the fat-to-protein ratio) are often standardized in cheese milk, as high levels of

protein are associated with a higher buffering capacity, thereby reducing the acidification rate of the culture.

Agglutinins are antibodies that may be present in the protein fraction of raw milk, but their concentration is significantly higher in early-lactation milk (colostrum) or in response to an infection, such as mastitis. Their presence can cause the agglutination of some dairy starters, including lactococci and *S. thermophilus*. Agglutination results in precipitation of the starter cells to the bottom of the fermentation vessel, with negative impacts on their acidification capabilities, which can be a particular problem in the production of cottage cheese and other soft cheeses (18). However, agglutinin-associated issues can be restricted by using agglutinin-insensitive starter cultures or by inactivating the agglutinins through homogenization or heat treatment of the milk or by simply avoiding the use of milk in which agglutinin levels would be expected to be high.

Antibiotics are used routinely in veterinary medicine to treat a range of infections, including mastitis, which is an inflammation of the udder caused by bacterial infections by *Streptococcus agalactiae, Streptococcus dysgalactiae*, and *Staphylococcus aureus*, among others, in the lactating animal (18). Six major groups of antibiotics are currently employed in veterinary medicine. These include the penicillins and cephalosporins, the aminoglycosides, the macrolides, the quinolones and fluoroquinfluoroquinolones, the tetracyclines, and the sulfonamides. Clearly, it is highly undesirable for antibiotic residues to be present in milk, as, apart from inhibiting starter cultures, they may also result in serious allergic reactions in sensitive individuals.

The milk of infected and antibiotic-treated cows is withheld for a period of time, typically six milkings (usually 3 days), to eliminate the possibility of contaminating the bulk milk. Many of the tests for the presence of antibiotics that are currently used were originally designed to detect penicillin, implying that other antibiotics may not be detected by such methods. Concentrations of 0.005 to 0.05 IU of

penicillin are sufficient to cause at least partial inhibition of starter cultures, with *S. thermophilus* being particularly sensitive to this family of antibiotics.

Sanitary practices on farms and in dairy fermentation facilities are continuously improving; often, economic sanctions and/or incentives are applied to farmers to promote the production of high-quality milk, while there is also increasing pressure on processors to conform to stringent modern quality control standards. Although scalding and rinsing of the equipment are part of most sanitization regimens, residual traces of disinfectant may remain in the absence of adequate draining or rinsing. Concentrations of 1 to 5 ppm of the majority of sanitizers employed in dairies are effective in inactivating lactic starter cultures.

In contrast to the short-lived or batch-specific issues associated with sanitizers and antibiotics, bacteriophages present a threat that is much more insidious and more difficult to control. Next, we review the developments in the rapidly advancing areas of research on phages and phage-host interactions and examine how this knowledge can be exploited to better manage cultures and to reduce the risk posed by phage infection.

BACTERIOPHAGES

Phages are bacterial viruses that specifically recognize and infect strains of a given bacterial genus or species. While disruption of fermentations by phages is rarely a significant problem in other food fermentations, it represents the most problematic and consistent issue facing the dairy fermentation sector today. The interplay between bacteriophages and their hosts has been the subject of intensive research over the past several decades. This is not surprising considering the devastating impact that phages can have on fermentation processes that are worth many billions of dollars on an annual basis. This research has recently made significant progress, aided considerably by advances in genomics

and structural analytical technologies. This section focuses on the sources of phages, their structure and classification, and the means by which they replicate. We discuss how phages interact with their hosts and how the host bacteria attempt to counter phage infections by incorporating antiphage strategies.

Sources of Phages in Dairy Production Facilities

There are a number of potential sources of phages in a dairy factory, ranging from the incoming raw materials, including the milk and other ingredients, to the air and the factory environment, where phages are known to survive for long periods of time. Equipment surfaces, personnel, and, more contentiously, the starter culture itself may also be sources; in the latter case, phages may be carried as “pseudolysogens” (incompletely replicated phages which are internalized in the cells and which may become active upon reintroduction to suitable growth conditions) or as low-level contaminants. To limit the proliferation of phages, the majority of modern dairy factories incorporate design features that curb their development and survival at each of the critical points of the fermentation process. For example (with the obvious exception of raw-milk cheeses), the incoming raw milk is pasteurized and homogenized in most dairy factories, which reduces the phage and microbial load; however, it is also known that many phages are not inactivated by pasteurization treatments of 72°C for 15 seconds. Second, positive air pressure is used to ensure that the air flow is unidirectional, and personnel are trained to move in a similar unidirectional manner to prevent contamination of culture preparation rooms with phages from the cheese production areas. Furthermore, strict sanitation regimens are seen as being essential in controlling phage numbers in the plant to manageable levels. This includes sanitization of the vats, piping, and valves to ensure that phages are inactivated and flushed out of the system to the degree possible. Such regimens typically involve routine application of chemical sanitizers such as peracetic acid, sodium hypochlorite, iodophors, and nitric acid, among others. Since phages, if present in

the plant environment, will be concentrated in the whey (in the case of cheese manufacture), it is essential that the management and removal of whey be done in such a manner as to reduce, as far as possible, the likelihood of contamination through dispersal of aerosols.

Many dairy fermentation plants also engage in the process of monitoring the levels of phage present in factory wheys. These tests measure the extent of acidification of the milk by the starter culture in the presence of aliquots of factory whey using time and temperature profiles that are typically applied in the actual fermentations and results are compared with acidification in the absence of whey. Reduction in the starter acidification activity may be attributed to phage inhibition. If the presence of phage is suspected, the actual levels can be determined by plaque assay on the sensitive host.

Phage Structure and Classification

All phages of LAB characterized thus far possess doublestranded DNA packaged in either an isometric or elongated (prolate) head which is connected to a tail structure (Fig. 30.6). The tails of LAB phages may be long and contractile (family *Myoviridae*), long and noncontractile (family *Siphoviridae*), or short (family *Podoviridae*). Lactococcal phages are classified into 10 taxonomic groups based on their morphology and genetic composition (19). Among these 10 groups, eight are classified as *Siphoviridae* phages and thus possess long noncontractile tails, while the remaining two groups are classified as *Podoviridae* and exhibit short tails. While members of all10 groups have been encountered in the dairy environment, three groups predominate irrespective of geographical location. These are named the 936, c2, and P335 phages (allpossess long noncontractile tails), and members of the former two follow a strictly virulent lifestyle, while the P335 phages include both virulent and temperate members (phage lifestyles are covered in more detail below). The 936 phages are the most abundant and frequently isolated lactococcal phages (20). They are highly conserved at the genomic

level, and this has facilitated the development of model systems to unravel the interactions between this lactococcal phage group and their hosts (21, 22).

In contrast to the genetic and morphological diversity of lactococcal phages, those infecting *S. thermophiles* are apparently less diverse. Until recently, only two groups were known to exist, but an additional two were identified more recently (23, 24). The latter groups are infrequently encountered and may in fact represent newly emerging types. All four groups of *S. thermophilus* phages exhibit long noncontractile tails and thus are members of the *Siphoviridae*.

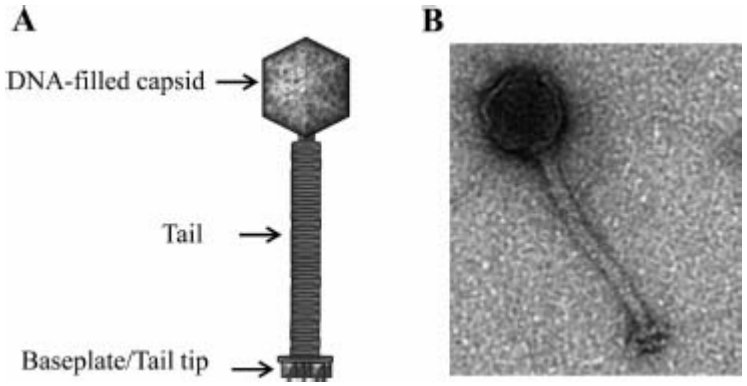

Figure 30.6. (A) Structure and general characteristics of a tailed phage highlighting the DNA-filled capsid, the tail, and tail tip appendages. Some phages possess large multicomponent structures at the distal ends of their tails, termed baseplates. (B) Representative electron micrograph of the lactococcal P335 phage Tuc2009, which exhibits the structures highlighted in the schematic in panel A.

Phage Replication: Lytic and Temperate Cycles

Phages may be largely classified into two groups depending on their lifestyle, i.e., whether they are virulent or temperate. Virulent phages are those that infect a specific bacterial host, replicate intracellularly, and thus cause the death and lysis of the host cell. This is the situation which causes failure of starters in commercial practice. In contrast, when temperate phages infect their bacterial

host, the injected phage genome becomes integrated within that of the host, where it replicates silently *in situ*. When conditions become favorable for lytic development of the phage, the genome is excised and enters the lytic cycle (Fig. 30.7). While at one time, it was thought to be a rare event, genomics studies have now made it clear that lysogeny is a common, and even usual, feature of many genera of LAB. For example, it is notable that the ever-increasing bank of genomic data relating to lactococcal strains demonstrates a very high incidence of integrated prophages (25), while lysogeny has been shown to be much less frequently observed among *S. thermophilus* genomes (26).

Both the lytic and lysogenic cycles involve an initial binding to the cognate receptor on the host cell surface, which may be a (poly) saccharide, protein, or teichoic acid component (this aspect is discussed in more detail below and is directly related to determination of host specificity and host range) and the injection of its DNA into the cytoplasm. A clear picture of the structure of phage genomes now exists, and we know that they are organized in functional modules, with specific genes or clusters of genes controlling functions such as lysogeny (in temperate phages only), replication, morphogenesis, DNA packaging, and lysis (Fig. 30.8).

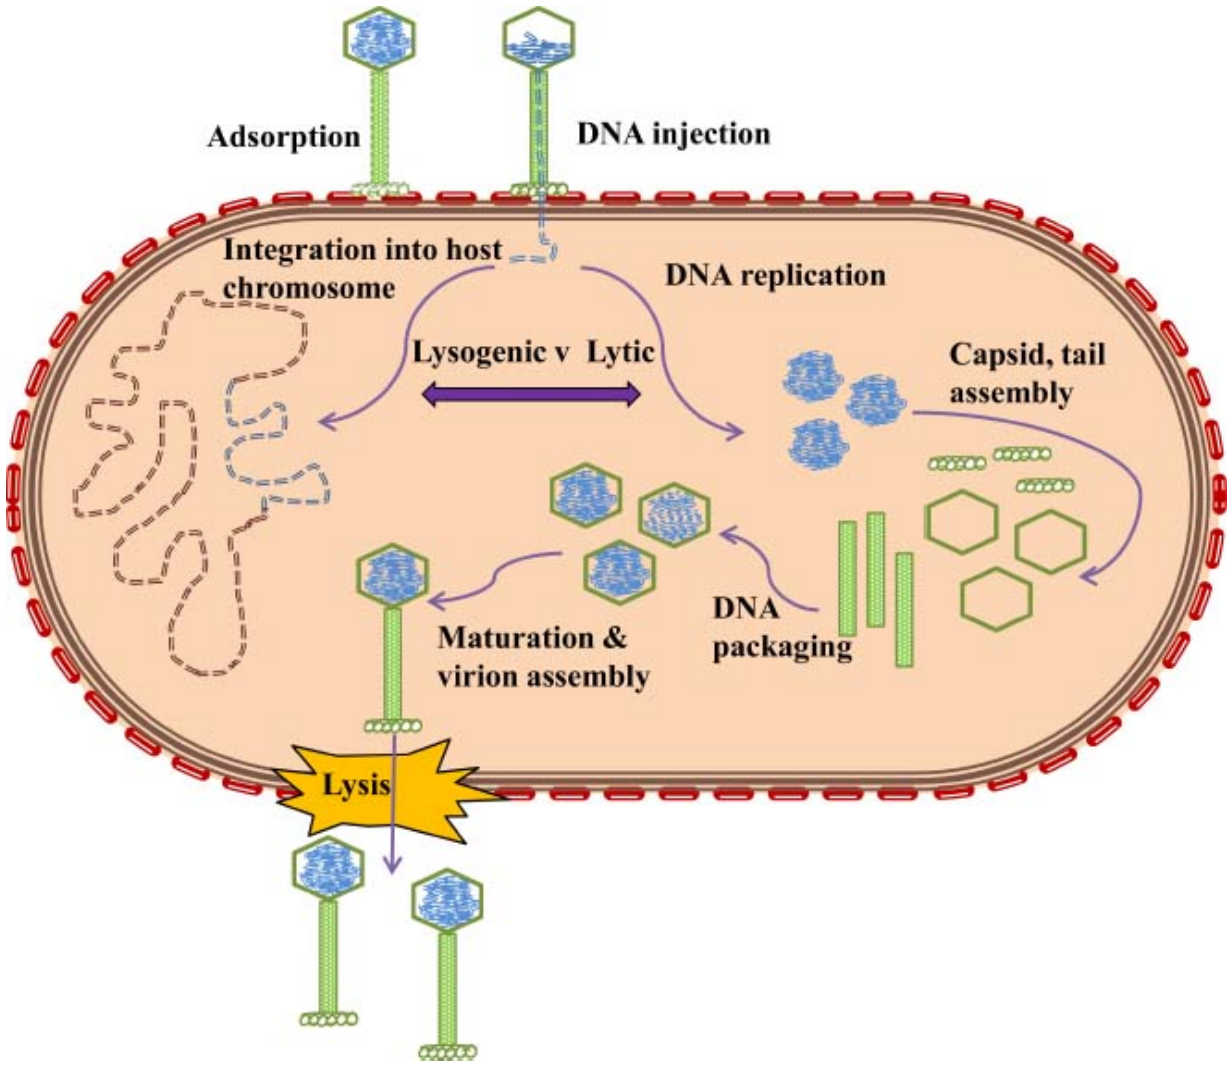

Figure 30.7. Schematic representing the lytic and lysogenic cycles that may be followed by phages.

Figure 30.8. Schematic representation of the genome organization of a typical lactococcal P335 phage highlighting the functional modules of gene clusters, including those associated with lysogeny, replication, and DNA packaging and head and tail morphogenesis functions.

The structural components comprising the head and tail (where relevant) of the phage are produced and are assembled separately.

Following assembly of the immature head (or procapsid), DNA is packaged inside this structure, allowing maturation of the head and attachment of the tail to form the final assembled and packaged phage particle (Fig. 30.7). The final step involves the activity of the components encoded within the lysis cassette, i.e., the holin and lysin. Holins are small proteins that localize at the cytoplasmic membrane, creating a pore through which the lysin gains access to the cell wall, which it then degrades, thereby facilitating the release of the progeny phage particles. A replication cycle can occur in as little as 40 minutes, and typically, each lysed cell can release 80 to 200 new phage particles, although these values can vary considerably and be strain and phage dependent.

While lytic phages are an obvious threat to fermentation practices, temperate phages also constitute a silent risk factor, as they may be induced into the lytic cycle (as mentioned above). Starter culture companies are becoming increasingly aware of this threat, and the identification of potentially inducible temperate phages in starter strains has become part of the standard practice used by many companies when screening new strains. However, it should also be noted that the presence of inducible temperate phages may sometimes be beneficial in fermentations. For example, if it is the case that the acidification rate is not impaired, the lysis of starter cultures through the phage induction process facilitates the release of intracellular flavor-associated enzymes, which can play a key role in the development of the characteristic organoleptic traits of certain fermented dairy products.

Since the first discovery of lactococcal phages by Whitehead and his group in New Zealand in the mid-1930s (2), much of the research linked to LAB has focused on phage-host interactions, with an ultimate expectation of being able to develop and employ starters with a higher degree of confidence in the factory setting. While this earlier research was very valuable, it was limited by the analytical and investigative technologies of the day. However, since the advent of the molecular biology and genomics era, the situation has changed dramatically, making possible findings that are of wider

biological significance, such as the initial discovery of CRISPR (clustered regularly interspaced short palindromic repeat)-Cas systems in *S. thermophilus* (27).

The section below focuses on the tremendous advances that have been achieved in the past decade in terms of understanding phage-host interactions in LAB, but especially the lactococci, where the most dramatic progress has been made, and highlights how this improved understanding has resulted in much more informed and knowledge-based approaches being taken to deal with the issue of bacteriophage infection in industrial settings.

Bacteriophage-Host Interactions

In order to establish effective control and/or preventive measures against phages, it is first essential to understand the intricate interactions and relationships between these predatory entities and their host bacteria. Of all the starter bacteria used in food fermentations, the lactococci are the most extensively studied and much of our understanding of the activities of the LAB in general has been founded on initial observations obtained from research on members of the genus *Lactococcus*. So it is also with the study of bacteriophage-host interactions, a topic that was further stimulated by the fact that Cheddar and related cheese fermentations were among the first to be developed into intensive, more or less continuous, industrialized processes. Under such circumstances (with the continuous presence of very high numbers of microbial cells in the factory environment), phage infection became a more likely possibility and also had more devastating consequences. Thus, it is still the case that we know more about lactococcal phages and their interactions with their lactococcal hosts than we do about other phage-host systems.

The initial step in the infection process involves adsorption of phage in a tail-first orientation to specific receptors on the cell surface. This is one of the best-characterized steps in the phage cycle and involves a phage-encoded adhesion device located at the tail tip that

"docks" the phage on the host cell and a host-encoded receptor moiety, which may be a surface-exposed protein, (poly) saccharide, or (lipo)teichoic acid structure. This critical step has been the subject of considerable research, particularly with respect to *L. lactis* (28), but also to a lesser extent with *S. thermophilus* and *Lactobacillus* spp. (24, 29). The three-dimensional structure of the adhesion device (located at the tail tip) of 936 and P335 group phages is defined as a multicomponent complex that is known to recognize a cell wall polysaccharide structure on the host cell surface.

The majority of phages infecting LAB, including *L. lactis* and *S. thermophilus*, typically display a very narrow host range; in other words, they infect a very small number of bacterial strains. For decades, the biological reason for this was unclear, but the biochemical diversity of particular regions of the polysaccharide structures on the lactococcal cell wall is now proposed to account for the remarkably high degree of specificity of phage-host interactions.

It is now believed that many *S. thermophilus* and *Lactobacillus* spp. phage receptors are likely to be carbohydrate or carbohydrate linked. Among the lactobacilli, carbohydrate moieties of teichoic acid and lipoteichoic acids as well as cell envelope carbohydrates are known to be involved in the initial interactions of tailed phages of *Lb. delbrueckii* subsp. *lactis*, *Lb. delbrueckii* subsp. *bulgaricus*, *Lb. plantarum*, and *Lb. casei*. As there is also now a growing availability of genome sequences for these LAB species (Table 30.2), it is possible to identify the host receptor-encoding genetic elements using comparative genomic analysis of phageresistant derivatives and the parent strain. While in this chapter we focus largely on lactococci, as they are the best-studied phage-host systems, similar principles and approaches could be applied to most members of the LAB which are employed as starter or adjunct cultures.

Table 30.2. Number of completely sequenced genomes of lactic acid bacterial species

LAB	No. of complete genomes published[a]
L. lactis subsp. *Lactis*	19
L. lactis subsp. *lactis* biovar Diacetylactis	1
L. lactis subsp. *Cremoris*	12
S. thermophiles	25
Lactobacillus spp.	193
Leuconostoc mesenteroides	9
Leuconostoc lactis	1
Weissella cibaria	5
Weissella ceti	3
Weissella koreensis	1
Oenococcus spp.	2

[a] A much higher number of incomplete/draft genome sequences are also available.

While the majority of lactococcal phages employ a carbohydrate receptor on the host cell surface, the c2 group of lactococcal phages recognize a membraneanchored protein, termed the phage infection protein (PIP) (30). This protein is highly conserved among lactococci and contains a number of transmembrane domains and a large ectodomain, which is exposed at the cell surface; it is to this that the c2 phages bind. In contrast to the highly host-specific 936 and P335 phages, which bind to carbohydrate receptors, the c2 phages are typified by a wide host range; they can infect multiple strains of *L. lactis*. The presence of PIP-encoding genes in allsequenced lactococcal genomes explains this observed broad host range.

In recent years, the number of reported incidences of c2 phages has declined significantly. It would appear that starter culture companies have selected spontaneous c2-resistant derivatives of lactococci by incubating the strain(s) with its infecting c2 phage(s) and selecting the survivors, which presumably have a mutated *pip* gene, and that these are now prevalent in starters employed successfully throughout the world.

The lactococcal c2 phages are the best-described group of protein-recognizing LAB phages, although others are known to exist. For example, a phage of *Lb. helveticus* recognizes surface S-layer proteins. While the majority of phages infecting Gram-positive bacteria are now presumed to employ a saccharidic component in the primary adsorption step, it is likely that many of these also interact with other cellular components, including proteins, as part of their infection pathway.

Starter Cultures Encode Antiphage Systems

Phages and their host bacteria have coevolved over millennia and continuously adapt to ensure their survival and continued existence. Phage-host coevolution is a well-described phenomenon among the majority of bacterial species; however, it is particularly well studied among LAB due to their commercial importance (31). Each stage of the phage infection process is matched by the presence and activity of host-encoded phage resistance systems (Fig. 30.9), as follows.

1. Adsorption inhibition, where the bacteria have evolved a range of barriers to prevent phage adsorption, including the blocking of phage receptors, the production of an extracellular matrix, or the production of competitive inhibitors (31)
2. Superinfection exclusion systems, where specific proteins block the entry of phage DNA into host cells (32–34)
3. Restriction/modification (R/M) systems, where incoming phage DNA is degraded by a restriction endonuclease (35)

4. Abortive-infection systems, where a range of heterologous proteins target a crucial step of phage multiplication, such as replication, transcription, or translation (36)
5. CRISPR-Cas systems (37), where an immunity system targets foreign nucleic acids, including phage genomes and plasmids. Short segments of DNA of the infecting phage are incorporated into the CRISPR spacer array, thereby preventing subsequent infection by the same phage

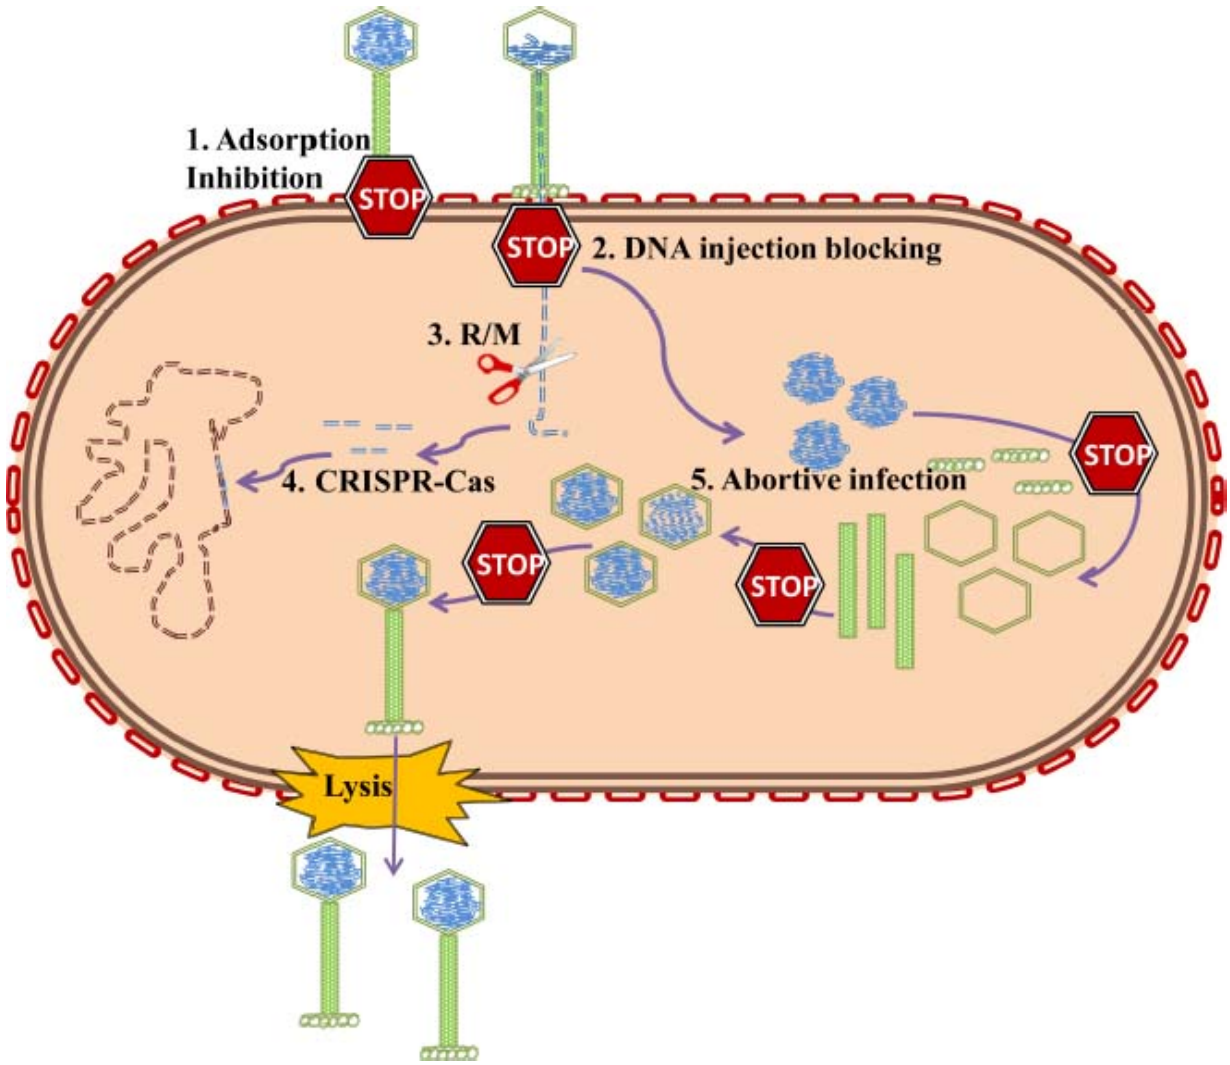

Figure 30.9. Schematic depicting the five known phage resistance systems that are active at the various stages of the phage cycle, from adsorption inhibition at the initial binding step to DNA injection blocking, R/M systems that cleave and modify the incoming DNA, CRISPR-Cas systems that provide immunity to "foreign" DNA, and abortive infection systems that may be active at the stage of DNA replication, assembly, or maturation of the phage particle.

S. thermophilus strains appear to rely mostly on CRISPR-Cas systems for phage protection, and their presence limits their ability to acquire plasmids that may encode phage resistance systems (among other traits), since this is recognized as "invading DNA" in the same way as phage DNA. A few R/M systems have been

reported among some *S. thermophilus* strains, but these are rare. Lactococci, on the other hand, do not appear to encode active CRISPR-Cas systems and are reliant on the other phage resistance mechanisms listed above for protection against phage infection or development. In fact, the genomes and plasmids of lactococci are observed to stack multiple phage resistance systems to provide the widest possible array of antiphage activities, as individual systems may have a limited effect.

It is important to note that the evolutionary process is a continuous one, with phages responding to the presence and activities of specific resistance mechanisms. For example, by mutating the phage-encoded target of the abortive-infection, R/M, or CRISPR system, the phage can overcome these particular barriers to infection. In turn, this requires that the host evolve to prevent the next generation of phages from infecting, and so the process repeats itself to ensure the survival of both antagonists. Knowledge of their presence and of the modes of activity of phage resistance systems in LAB is beneficial for the development of starter cultures with increased technological and phage robustness, and, as outlined below, this knowledge has been successfully harnessed to generate improved strains for the dairy fermentation industry.

Development of BIMs

The identification of new cultures that produce cheese with characteristics similar to the ones that they are replacing when they have succumbed to phage infection is a time-consuming and labor-intensive process involving the identification of phage-unrelated strains, screening to ensure that they exhibit the appropriate technological characteristics, and performing small-scale production trials. An alternative to the identification of new strains is to develop bacteriophage-insensitive mutants (BIMs) of the originals through simple exposure of the relevant phagesensitive component to its infecting phage and selecting for the presumed phage-resistant survivors. BIMs of thermophilic starter cultures such as *S. thermophilus* are readily produced, while many mesophilic cultures

are not amenable to spontaneous BIM generation. The genetic basis of this phenomenon was recently discovered to be due to the presence of active CRISPR-Cas systems in *S. thermophilus* and *Lactobacillus* spp., where the incorporation of a spacer sequence can occur at relatively high frequency, resulting in resistance. In contrast, lactococcal strains, which generally do not contain CRISPRs, instead rely on incorporating mutations in the receptor-encoding genes in many cases, a process which occurs at a much lower frequency than CRISPR-mediated spacer incorporation.

BIM development is a critical but short-term solution to phage infection; mutations and spacer incorporations can readily be overcome by single point mutations in the phage genome. Therefore, longer-term strategies must be considered which will inevitably be based on the knowledge that is being generated through the genomics and detailed structure-function studies of different phage-host systems of LAB. These are discussed in more detail below.

IDENTIFYING NEW STRAINS FOR APPLICATION IN STARTER CULTURES

To ensure the continued success of dairy fermentations and also to meet demand for cultures with novel organoleptic or technological characteristics, starter culture providers and producers alike continually seek to expand their catalogue of cultures and component strains. This traditionally involved the application of empirical methods based on screening for novel strains or, alternatively, adapting existing cultures using traditional or modern knowledge-based systems. The section below deals with each of these aspects.

Evolution of Strain Characterization Processes

Since the starter culture industry began, the standard method for identifying new strains and adding them to the catalogue on offer to

the fermentation industry has typically involved isolating strains from sources known to be rich in LAB and subjecting these to a range of tests to ensure that they met the criteria for whichever process they were intended for. These included rate of acid production, range of sugars metabolized, proteolytic and autolytic properties, the ability to produce compounds such as bacteriocins and EPS, antibiotic resistance profiles, lysogenic status, and phage sensitivity patterns (Fig. 30.4). More subtle tests, such as measuring production of volatile compounds using gas-liquid chromatography, later became a part of the screening process. While assessing the characteristics of such strains in this manner is still valid, the approach is time-consuming and laborintensive. In addition, screening for particular traits is often hampered by the lack of good screening methods, while upon scaling up, some of the strains do not perform as well as they did in the small-scale laboratory testing, leading to loss of time and profit. Therefore, it was clear that new approaches needed to be adopted.

In the 1980s, the application of molecular biological methods provided, for the first time, new information regarding the technologically important traits of the LAB, with the most notable early work being focused on members of the genus *Lactococcus*. Thus, the plasmid location of genes for many key traits of lactococci (lactose metabolism, proteinase production, citrate uptake, and phage resistance) explained the frequent phenotypic instability of these properties. Furthermore, it was often possible to demonstrate that such plasmids possessed genes that allowed them to be transferred to other hosts by conjugation. This raised the possibility of transferring desirable traits (particularly those associated with phage resistance) to industrial strains in a nonrecombinant manner. Thus, it was by this method that commercially desirable cultures were generated following conjugal transfer of (often multiple) phage resistance plasmids from donor strains. These did not require regulatory approval before deployment in the field and they have been used quite successfully for the past 30 years. Such constructed

strains represent the first generation of “knowledge-based” improved starter cultures.

However, this approach too was limited largely to the development of phage-resistant derivatives of existing strains and was confined to the specific antiphage systems that were encoded on the particular plasmid(s) that were transferred, which in many cases exhibit a limited range of activity. This approach was also limited by the relatively small number of phage resistance plasmids with conjugative functions, thereby restricting the adaptability of the cultures.

Most recently, the advent of high-throughput genome sequencing and the ensuing explosion in the number of complete and draft genome sequences of LAB that are now available in public databases (Table 30.2), combined with ground-breaking biochemical and biophysical studies, have resulted in a significant leap forward in our knowledge of dairy strains (and their phages). Indeed, such technologies have been very significant contributors to our wider understanding of other technologically important traits, such as proteolysis and ripening, in addition to other metabolic activities. Thus, it is now almost a universal practice for starter culture companies to routinely sequence newly isolated strains that exhibit potential for application or novelty and subject them to comparative genome analysis with previously sequenced isolates, which may lead to the identification of conserved, differentiating, or even unique features that could enhance their commercial relevance. An example of this approach is the identification of strains possessing different *cwps* phage receptor genotypes (and/or subgenotypes) and, based on this information, development of strain blends that can be scientifically certified as phage unrelated. Such approaches can be expected to eliminate the need for labor-intensive, timeconsuming, and high-cost starter selection and rotation systems designed to limit the risk of phage infection while simultaneously achieving the desired flavors, textures, and aromas in the final product.

Starter cultures encode myriad metabolic functions that render them technologically robust and/or desirable. Genomic data can be used to identify the extent of genetic diversity, the level of adaptation to the dairy environment, and the presence of specific metabolic pathways or factors that may influence their application in starter culture blends or rotations. For example, the two subspecies of *L. lactis* that are widely employed in the dairy industry, *L. lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris*, show significant differences in their genetic detail. *L. lactis* subsp. *cremoris* strains exhibit extensive genome decay, which is reflective of their adaptation to the dairy environment and the associated heavy reliance on milk as a rich source of direct nutrients. As a further adaptive measure, *L. lactis* subsp. *cremoris* strains are observed to harbor a more extensive plasmid complement than *L. lactis* subsp. *lactis* strains, which encode functions such as lactose and casein utilization, among other advantageous functions for the dairy fermentation environment. *L. lactis* subsp. *cremoris* strains are used preferentially in the production of Cheddar-style cheeses due to their general ability to generate more desirable flavor profiles, while *L. lactis* subsp. *lactis* strains are associated with faster growth and higher acidification rates and are preferred in European continental cheeses such as Brie.

Detailed genome analysis provides the means to generate a database of genetic characteristics of starter cultures. Knowledge of the predicted genetic functions of a culture is useful in selecting strains for targeted cheese trials to assess the functional capabilities and technological appropriateness of such cultures. Therefore, genomic approaches afford starter culture providers with the information to guide preemptive assessments of particular strains and strain blends. However, while this approach is very powerful and facilitates the identification of novel strains, there remains the challenge of adapting strains (where required) in a manner that is acceptable to regulatory bodies, i.e., in a non-GMO (genetically modified organism) manner.

The above-mentioned genomic approaches to analyzing starter cultures and their functional properties have revealed that there is limited genetic diversity among lactococcal and *S. thermophilus* strains. This implies that although commercial starter culture providers may have large collections of strains, many of these may be closely related, thus causing a certain level of redundancy in terms of functional and/or genetic diversity. Furthermore, strains in the collection may be phage related, which would pose major problems in terms of building good strain partnerships for the widely used DSS culture systems. Therefore, it is imperative that starter culture providers continue to adopt the parallel approach of sourcing novel strains as well as modifying and improving existing strains which already exhibit desirable traits and meet the required performance criteria in commercial practice.

CONCLUSIONS

The business of producing fermented foods has a very long history and has undergone significant evolution, especially in the past century. However, even though most consumers' experience of fermented foods relates to those that are produced on an industrial scale, there still remains a positive association with the artisanal, traditional, and healthful characteristics of the original, preindustrial products. The successful transition from small-scale, local, artisanal production to a large-scale, factory-based activity that retains the qualities that are attractive to the consumer can, to a major degree, be attributed to the development of high-performance starter cultures. These have been continuously and successfully adapted and refined to meet the ever-changing challenges posed by changing consumer preferences and increasingly stringent manufacturing and technological demands. This transition could not have occurred without the application of scientific studies which were essential in unravelling the underlying basis for the key functional and technologically important properties that allow starter bacteria to successfully perform in

highly intensive industrial settings. As the demands on starter cultures have increased in the modern era, so too have the advances in our knowledge of these microorganisms, thanks to the effective application of the modern -omics and other analytical technologies. Indeed, the era of constructing and engineering specific starter strains for particular industry needs is rapidly approaching, notwithstanding the restrictive regulatory environment in many jurisdictions. However, it is also important that the food fermentation industry retains its values of providing products that maintain their link with the "natural goodness" and the highly diverse organoleptic characteristics long associated with traditional fermented foods. This tension between the demands of modern manufacturing processes and the need to maintain the wholesomeness and traditionality of fermented products will remain an interesting challenge for those who provide and use starter cultures in the future.

Diet, Health, and the Gut Microbiota

INTRODUCTION

The traditional view of the human body is that eukaryotic cells form the structures and superstructures that make up the body. More recently, this view has been updated to include the microbes that live in and on us. These communities of microbes, known as the microbiota, have previously been a neglected area of research. They consist of bacteria, fungi, and viruses and provide a range of potential functionality due to the large size of the metagenome. This functionally diverse population is known as the microbiome, and it is now known to be essential for our health and well-being. A number of factors contributed to a lack of awareness in the wider scientific community of the importance of our microbiota. Most important of these was the lack of research tools that would allow us to characterize these communities. This resulted in a naïveté within the wider scientific community regarding the symbiotic relationship between eukaryotic and prokaryotic organisms, which led to a eukaryote-centric view of our health. Now, the microbiota is increasingly regarded as an auxiliary organ of the human body and is considered an important factor for an individual's health and response to illness. In this chapter, we discuss the importance of the microbiota diet relationship and how this relationship influences our health.

History of the Microbiome

The bacteria in our guts have evolved within with us over the millennia. This closely knit evolution has allowed these organisms to form mutually beneficial relationships with their human hosts. The human microbiome covers every surface in and on our bodies and is one of the most complex and diverse biological systems ever observed. If we consider the number of cells and the genetic information and functionality that these organisms contain, it is no surprise that these organisms are key regulators of our development and health. Diet-health associations are well established in the scientific literature, with well-balanced diets that contain a mixture of proteins, fats, and carbohydrates from plant-based foods being regarded as optimal in the maintenance of the health and well-being of an individual. What is perhaps less appreciated is the impact that our microbiome has on how this diet influences our overall nutrition and health.

The vast majority of the research to date on the associations between microbiome and diet has focused on the fecal microbiota, which is used as a proxy for the proximal colon. This is primarily because fecal material is readily available, in contrast to colonic biopsy samples, which tend to be difficult and expensive to harvest. The gut microbiome is the most heavily studied human microbiome due to the direct association between fiber in a diet and the utilization of this fiber by bacterial species. Therefore, this chapter focuses on the gut microbiota.

The Gut Microbiome

Traditional research on the gut microbiome was carried outusing culture-dependent techniques, such as cell counts, to characterize a few easily cultured organisms. This method provided a distorted view of the composition of our microbiome, with organisms such as *Escherichia coli* and *Bifidobacterium*, which are present at low levels in adults, being extensively studied due to their ease of cultivation, and failed to provide information on the full gut microbe composition.

The 16S rRNA gene is evolutionarily conserved across bacterial species and can be used to identify the taxonomy of a bacterium by comparing it to a reference database. With the advent of high-throughput sequencing, it became possible to characterize the microbiota through the sequencing of this 16S rRNA gene amplicon sequence. This is one of the two most common ways to characterize the microbiota, with the second being the use of whole-metagenome sequencing, which characterizes the microbial genes and thus reveals the functional potential of the microbiota.

Because of the ability to characterize both the microbiota (taxonomy) and the microbiome (genes, genomes, and potential functionality), the study of communities of microbes has become an exciting and rapidly expanding field of research, as seen by the rapid increase in the number of microbiota papers. These studies have allowed us to identify the huge impact of the microbiome on our health, nutrition, and even well-being, with almost 90% of all disease and disorders being associated with microbiota or microbiome alterations. The microbiota is now seen as an auxiliary organ of the human body and is thus considered an important factor for an individual's health and response to illness.

When we discuss the microbiota, it is important to understand the different levels of taxonomy that a bacterium can belong to. At the highest level is the domain, *Bacteria*. This domain is subdivided into phylum, class, order, family, genus, and species. Each bacterial species can be further subdivided into strains, which are genetic variants or subtypes of the species. The gut microbiome is dominated by two main phyla, *Firmicutes* and *Bacteroidetes*, which account for 90% of the abundance of taxa in our gut, with *Proteobacteria* and *Actinobacteria* accounting for most of the rest (1). The genera *Prevotella* and *Bacteroides* of the phylum *Bacteroidetes* are two of the most common genera in our gut. They are functionally similar and tend to be negatively associated with each other, so that an individual can be said to have *Bacteroides* predominance or *Prevotella* predominance. As will be discussed, this strong negative association forms the basis for two of three

subject groups in the enterotype model of the human gut microbiome (2), with the third group, “other,” tending to be the genus *Ruminococcus* of the phylum *Firmicutes*. There are a large number of genera within the phylum *Firmicutes*, with some of the most common genera in the gut being *Lactobacillus*, *Roseburia*, *Clostridium*, *Ruminococcus*, *Blautia*, *Dorea*, *Lachnospira*, and *Faecalibacterium*. Other abundant taxa in the human gut include the genus *Akkermansia* in the phylum *Verrucomicrobia* and the genus *Bifidobacterium* in the phylum *Actinobacteria*.

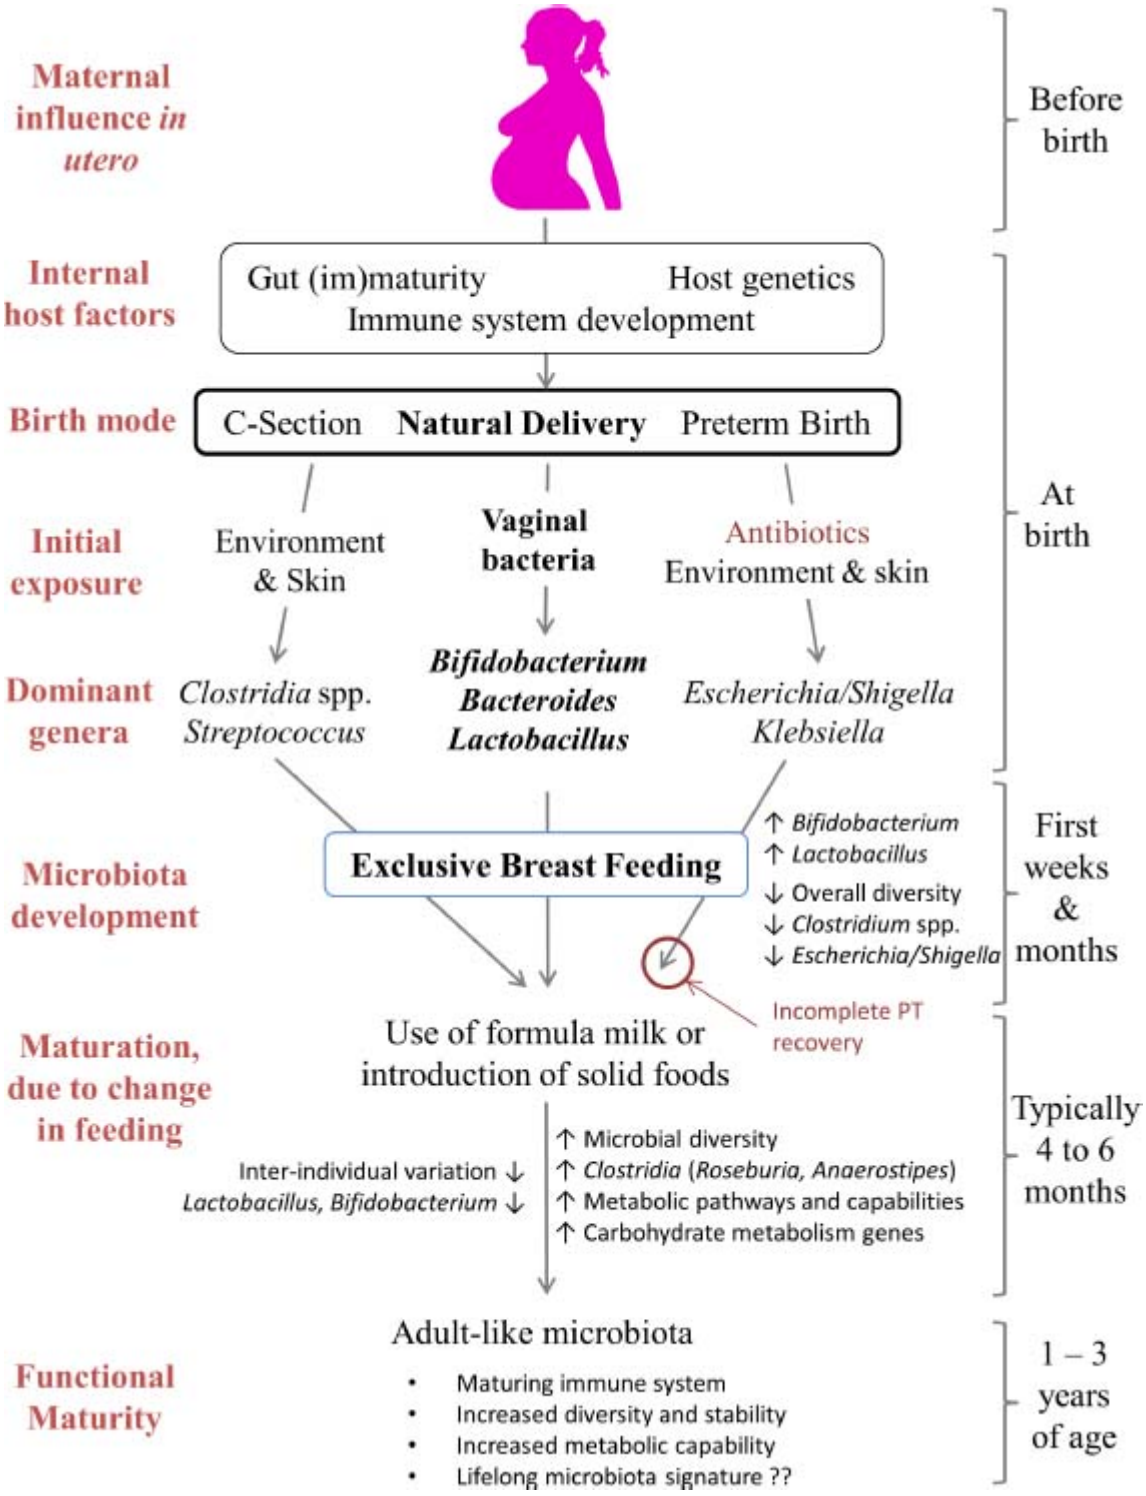
The microbiota is viewed as being essential to health throughout life. The microbiome forms over our lifetime through the acquisition of microbes from our environment. Therefore, the majority of differences in the microbiome between individuals can be described as stochastic. However, it is notable that the initial acquisition of bacteria occurs at birth. In the days and weeks after birth, the evolving neonatal gut acquires a nascent microbiota of low diversity and high instability. It has been suggested that if the establishment of the stable adult microbiota is programmed in infancy, this early microbiota profile leaves a lifelong signature with a potentially significant effect on lifetime health.

MICROBIOME AND DIET IN EARLY LIFE

As with adults, the most extensively studied microbiota niche in infants is the gut. There has been an explosion of interest in the infant microbiota in the past 10 years, as researchers have begun to recognize the potential importance of early-life programming of the microbiota. In this overview, the gut microbiota is the primary focus, with a brief mention of other populations where appropriate, such as the skin and oral microbiota. The most important determinants of the gut microbiota at 1 month of age have been found to be the mode of delivery, type of infant feeding, gestational age, infant hospitalization, and antibiotic treatment of the infant. The main factors responsible for the development of the infant gut microbiota are illustrated in Fig. 31.1, which also illustrates how the

microbiota may influence the health of the infant. There is likely maternal influence on the establishment and subsequent maturation of the infant microbiota via vertical transmission.

The microbiota establishment is now thought to be initiated *in utero*, so the evidence for this hypothesis is discussed first, and then how birth mode affects the initial founder bacterial populations and how these are subsequently succeeded by increasingly diverse bacterial populations as the neonatal gut matures are reviewed. A crucial factor after mode of birth is the feeding regimen of the infant, which may be exclusive breast-feeding, bottle feeding, or a mixture. The concurrent development of the infant immune system with the microbiota is currently not well understood from a mechanistic viewpoint, but it is acknowledged that there is likely to be close interaction between the two. This section on the early-life microbiome describes current knowledge on the development of the infant microbiota, from an early period of instability and low diversity to a more adult-like microbiota with increased stability and diversity. Despite recent advances in identifying the sources of the neonatal microbiota, many questions remain regarding the true origin of the bacteria which colonize the newborn and the factors which drive the high level of interindividual variation observed in the gut microbiota.



Maternal influence *in utero*

1 – 3 years of age

Figure 31.1. Factors influencing the establishment of the infant microbiota. The development of the microbiota from the womb to adult-like functional maturity as a toddler is influenced by a myriad of factors. An overview of some of the current knowledge surrounding this developmental process is outlined conceptually.

MATERNAL INFLUENCE AND PREBIRTH FACTORS

Transmission of Bacteria from Mother to Neonate

An extensive review details the universality of vertical transmission in the animal kingdom (3), arguing that it is so important that it "should be viewed as an additional and important mechanism of genetic and functional change in human evolution." With this in mind, maternal health parameters, particularly microbiota populations from various body sites, should be investigated in infant microbiota studies as a potential source of influence on the establishment of the microbiota. Maternal prepregnancy body mass index (BMI) has been found to influence the microbiota of the offspring, and it has yet to be demonstrated if this effect is maintained as the infants age. A study of lifestyle factors found no difference in the overall microbiotas of mothers or their infants despite large differences in lifestyle between the two groups studied but did find a change in the abundance of specific genera, such as an increase in *Bifidobacterium* and a decrease in *Bacteroides* and *Veillonella*. *Bifidobacterium* in particular is a keystone bacterium in the developing microbiota, with *Bacteroides* also being important in the infant gut. Previous studies have found a significant effect of environment on the infant microbiota: infants in Malawi and rural Burkina Faso were found to have microbiota compositions very different from those of infants in metropolitan areas of the United States (4, 5). The authors hypothesize that the different diets that the infants receive may drive this significant effect, in addition to the potential environmental influence.

Maternal Microbiota Alterations during Pregnancy

Specific maternal microbiota change occurs during pregnancy, with alterations in both the vaginal and gut microbiota, which is significant, as they are the two main sources of vertical bacterial transfer from a mother to her naturally delivered infant. These changes are likely part of an adaptive response to protect and promote the health of the newborn infant by providing a specific bacterial inoculum at birth. Aagaard et al. (6) found that microbiota diversity was lower in the vaginas of pregnant women and there was a dominance of *Lactobacillus* species, especially during later gestational stages. The changes in the maternal gut are suggestive of a greater energy harvest to support both the fetus and the mother.

ESTABLISHMENT OF THE MICROBIOTA BEFORE AND AFTER BIRTH

The founding bacterial populations of the infant microbiota at birth are significantly dependent on birth mode (7–15). Twenty-four hours after birth, infants born by spontaneous vaginal delivery (SVD) are found to have acquired bacterial communities resembling the vaginal microbiota of the mother, while communities in infants delivered by cesarean section (CS) resemble the skin microbiota of the mother (16). This is due to SVD infants receiving an inoculum of bacteria from the birth canal during delivery, which is absent in a CS birth. This study also showed that there was no significant difference between the microbiotas of different body niches (oral, skin, and gut) at this early time in the infant life.

The differentiation of microbiota across different body niches occurs within 1 week, and birth mode has been shown to have a significant effect on the infant oral microbiota at 3 months of age (17). The microbiota of an SVD infant is more closely related to its own mother's vaginal microbiota than that of a random mother, while microbiotas of CS infants are no more closely related to their own mother's than to that of a random mother (16). This suggested

a strong environmental influence on CS infants, which was confirmed in a separate study showing that the microbiotas of infants in neonatal intensive care units (NICUs) had bacteria that resembled those found in swabs of the NICU ward environment, including from equipment, general surfaces, and the hands of healthcare providers and parents (18); worryingly, these included bacteria harboring antibiotic resistance genes. The developing neonatal microbiota is characterized by low diversity and high variability (4, 19). A high proportion of *Bifidobacterium* species has been consistently associated with SVD and shown to have a lower relative abundance in CS infants (8, 20–22). There is also a greater proportion of *Bacteroides* and *Lactobacillus* in SVD infants than in CS and preterm (PT) cohorts (23).

Infants born by CS continue to have an altered microbiota profile in the first weeks of life, regularly characterized by underrepresentation, or delayed acquisition, of *Bifidobacterium, Escherichia-Shigella*, and *Bacteroides* species. In addition to specific changes, the initial overall diversity of the microbiota is often found to be lower in CS infants than their SVD counterparts.

EFFECT OF FEEDING TYPE ON INFANTS' GUT MICROBIOTAS

Nutritional Composition and Importance of Breast Milk

Breast milk is the only food source that has coevolved with humanity and, as such, is the gold standard food source for neonates. Jain and Walker's review (24) gives an excellent overview of how, in addition to providing pronutrient effects, the microbiota can be stimulated by breast milk to limit nutrient resources available to potential pathogens, by physically occupying niches within the gut and out competing them for metabolic substrates. Mother's milk contains a number of bioactive ingredients to aid the development of the growing infant, including lipids, secretory IgA, live bacteria, and antimicrobial proteins, which can have a large

influence on the development of the gut microbiota. Live bacteria are present in breast milk, including *Streptococcus*, *Lactobacillus*, and *Bifidobacterium*. Breast milk changes over time to reflect the changing nutritional needs of the infant, from colostrum to less diverse milk as lactation progresses, while milk composition has even been found to be altered depending on the gender of the offspring among rhesus macaques (25).

Exclusive Breast-Feeding versus Partial Breast-Feeding

It is generally accepted that exclusive breast-feeding increases the proportional amount of *Bifidobacterium* in the infant gut. CS infants who are breast-fed may rapidly increase the proportion of *Bifidobacterium* in their gut microbiota. Maternal milk also contains a wide range of human milk oligosaccharides (HMOs) which cannot be digested by the host and require specific bacterial strains to break down (26). Certain bifidobacterial species, such as *Bifidobacterium infantis*, are of great importance, as they are capable of digesting these HMOs into metabolically useful substrates. Similarly, *Bacteroides* species prevalent in breast-fed infants are also capable of consuming HMOs as a sole carbon source. It is clear that the species (or indeed strains) of bacteria present in the infant gut are an important factor in the infant's efficacy in metabolizing milk and extracting the maximum nutritional benefit from it. A recent study demonstrated that bovine milk oligosaccharides promoted the growth of *Bifidobacterium* in formula-fed infants (27).

The use of formula milk has been shown to impact metabolism (28) and development of the neonatal immune system (29). Breast-feeding has been associated with a higher abundance of bacterial cells but less diversity than formula feeding, as the introduction of formula milk or solid food perturbs bacterial colonization and may lessen the benefits of breast-feeding. It has been shown that when breast-fed infants receive even a small proportion of their nutrition

from formula milk, the microbiota closely resembles that of infants fed formula only and that this alteration is similar to the one observed when the switch is made to solid food (30).

Interestingly, shotgun data have revealed that the cessation of exclusive breast-feeding appears to be the main driver of the metabolic shift in the gut, rather than the introduction of solid food (15). In that study, exclusive breast-feeding for a prolonged duration was associated with a younger functional "microbiota age," with lower diversity and reduced levels of central carbohydrate metabolism genes.

GUT DEVELOPMENT IN PT INFANTS

PT neonates have several unique challenges to the establishment of their microbiota. They are typically delivered by CS, have maternal and/or neonatal exposure to antibiotics, are incubated in the sterile environment of the NICU, and have an immature immune system and a compromised gut mucosa, all of which can significantly alter the natural pattern of acquisition of gut microbiota. The microbes in the NICU resemble those found in the PT gut (18), indicating a clear environmental influence in this crucial early period of bacterial colonization. Worryingly, antibiotic-resistant microbes from the hospital environment were among those found colonizing these infants' guts in the NICU.

Early-life perturbations of the PT infant's gut microbiota result in an atypical microbial profile, with the proportion of *Bifidobacterium* in guts of PT infants being commonly found to be very low until at least 1 month of age (31, 32). Nutrition may also be affected in PT infants, as they may be fed cow's-milk-based formula, pasteurized donor breast milk, or human milk fortifiers, rather than breast milk from their own mothers. This can create a different metabolic environment in the gut and thus favor a different microbial community. The strong influence of breast-feeding is discussed above, and even when PT infants are breast-fed, mothers of PT

infants produce significantly altered milk with a novel mix of HMOs that could influence microbial growth. Despite these challenges, the PT gut can progress to a gut microbiota resembling that of an SVD infant if it is not repeatedly exposed to antibiotics and if breast-feeding is continued.

The significant perturbations to PT infants' gut microbiotas strongly indicate that they may be a suitable target for intervention or modulation of their microbiotas at an early age to restore the microbiota to a more beneficial population.

GUT MATURATION AND IMMUNE SYSTEM DEVELOPMENT

The gut microbiota plays a vital role in the maturation of the infant gut, including barrier function, integrity, and immune response, which has been extensively reviewed elsewhere (24, 33), and a detailed discussion of specific associations is largely beyond the scope of this overview. In brief, a symbiotic relationship exists between the gut microbiota and the developing infant gut. CS infants demonstrated reduced responses from a type of T helper cell called Th1 during the first 2 years of life, enforcing this theory. The nutrient-rich environment provides an ideal habitat which the microbes can rapidly colonize to form a stable ecosystem. This, in turn, provides a new range of metabolic substrates for the gut, which increases the digestive capacity and the energy harvest of the infant. Inflammatory responses to bacterial exposures can activate both the innate and adaptive immune responses by a variety of methods, including interaction with the mucus layer; activation or deactivation of Tolllike receptors, interleukins, and cytokines; activation of B cells in the mesenteric lymph node system; and many more.

Understanding how the adaptive immune system identifies antigens from commensal bacteria, and how it responds in conjunction with the innate immune system, holds immense potential for identifying

the initial drivers of immune disorders, in particular autoimmune disorders, which occur at a higher rate in CS infants. Elucidating the exact mechanisms underpinning this response may identify the roles of the initial founder populations of gut bacteria, if any, in the progression of such disorders. It is likely that the combination of relatively low (breast-fed infants), high (formula-fed infants), or delayed (CS and PT infants) exposure to specific antigens and the resulting inflammatory responses in this crucial window of dynamic host-microbiota interaction profoundly influence the long-lasting gut and systemic health of the individual throughout life.

PROGRESSION TO AN ADULT-LIKE STABLE MICROBIOTA

As the infant ages and begins weaning, significant development occurs in the microbiota composition. The cessation of breast-feeding and/or introduction of complementary feeding induces the replacement of the breast-feeding-associated microbiota, as characterized by lactobacilli and bifidobacteria, with a more adult-like microbiota often dominated by *Clostridiales* spp. and *Bacteroides* spp. The overall diversity increases, with increased functional similarity to the maternal microbiota occurring by 1 year of age (15). The 1-year-old gut environment has been found to be enriched in genes involving the degradation of complex sugars and starch and genes involved in central carbon metabolism. This suggests that the microbiota adapts to availability of nutrient substrates as the infant ages. In developed countries, the infant gut microbiota appears to mature to an adult-like status more quickly than that of infants in developing countries, but differences in functionality remain as development is ongoing. As development progresses to an adult microbiota type, it is clear that environmental, diet, and lifestyle factors combine to greatly influence the microbiota, as evidenced by the distinct difference between gut microbiota compositions observed in individuals in

urban areas of the United States and those of individuals in developing countries (4).

THE MICROBIOME AND LONG-TERM DIET IN ADULTHOOD

This section describes the composition and functionality of the gut microbiome of healthy adults. The gut microbiota of healthy adults is commonly dominated by two bacterial phyla, *Firmicutes* and *Bacteroidetes*, with interindividual variability in their proportions. Members of the *Proteobacteria*, *Actinobacteria*, and *Verrucomicrobia* are present at lower abundance (1). Although there is great inter- and intrasubject variability, a well-established categorization of microbiome profiles of individuals based on the most abundant genus in their gut microbiomes is widely used to simplify the research area. The classification is based on the idea that all the subjects may be classified into three groups, called enterotypes, based on the prevalence of *Prevotella*, *Bacteroides*, or *Ruminococcus* in their gut microbiota (2). This classification, although appealing for understanding microbial change in health and disease, has been accused of leading to an oversimplified vision of the gut microbiome (34, 35). Indeed, it is probable that associations of dominant taxa within the gut may vary smoothly in the human population, going from one enterotype to another with only a weak association. Nevertheless, it is a useful tool when presenting the microbiome literature and allows a generalized discussion of the most common microbiota compositions. With these limitations in mind, the general associations in the literature are as follows: studies have associated the *Bacteroides* enterotype with a high-fat, low-fiber diet, while the abundance of *Prevotella* was linked to a diet rich in fiber and low in animal products (36).

While both *Prevotella* and *Bacteroides* possess a large catalogue of genes for carbohydrate-utilizing proteins, the *Prevotella* enterotype tends to be associated with high-fiber diets while the *Bacteroidetes*

enterotype tends to be associated with low-fiber diets, an apparent paradox due to the similarity of the potential functionality encoded by their genomes. This can be partially explained by a mouse study (37) which examined the mucin-degrading abilities of *Bacteroides* and provided evidence that *Bacteroides* species preferentially utilize dietary fiber when it is available; however, when the mouse was provided with a low-fiber diet, some *Bacteroides* organisms had the ability to utilize mucin as an alternative energy source, which may deplete the protective layer of the epithelium. Differences such as these may explain the health associations between the microbiota and the number of diseases and disorders.

These studies were pioneers in highlighting the power of long-term diet in shaping gut microbiome and how a short-term dietary switch from a high-fat, low-fiber diet to a high-fiber, low-fat diet can rapidly stimulate changes in a number of taxa within the gut microbiome. However, these short-term changes are not durable, and therefore, the long-term habitual diet seems to be more important in shaping the gut microbiome (36). Basically, what is food for humans is also feeding our commensal microbes.

DIET, THE MICROBIOTA, AND BMI

Obesity is associated with a range of serious diseases and health conditions. The percentage of the world population that is overweight has been steadily increasing. An area of much controversy in the literature on the microbiome and further afield is the factors that contribute to obesity. Dietary type, consumption of excess calories, and genetics all have roles to play in the worldwide obesity epidemic. Recently, the microbiome has been implicated in the obesity epidemic, with Turnbaugh et al. (38) showing that obesity is associated with a reduced bacterial diversity and an altered functional potential encoded by the bacterial genes. This area of research is complicated due to confounding effects of associations between diet and BMI, microbiota and BMI, and diet and microbiota. Indeed, Davis et al. showed that for increased BMI,

the influence of diet was greater than the influence of the microbiota (39). However, even if the effect of the microbiota is modest, it cannot be ignored as a confounding factor, as even a modest effect could represent large changes at the population level.

The link between the microbiota and BMI has been firmly established in animal models, with Ley et al. (40) showing that genetically obese mice had an altered microbiome profile, with increased proportions of *Bacteroidetes* and decreased proportions of *Firmicutes*, as well as a reduced diversity compared to their lean siblings. They formulated the first theory of how the microbiota influences body weight by postulating that the obese mice were more efficient at extracting and/or storing energy, which pushed the individual animals into a high-BMI state. However, the microbiota taxonomic alterations observed to be associated with high BMI are not consistent between studies (41).

Sze and Schloss showed that there were few if any consistent taxonomic alterations seen in studies looking at high-BMI versus normal-BMI individuals (41). Low diversity and the associated metric, low gene richness, have been identified as being associated with high BMI (42). Sze and Schloss confirmed that there is indeed a small but significant association between low diversity and high BMI.

WESTERNIZED VERSUS TRADITIONAL DIETS

In Western countries, dietary and lifestyle habits have changed extensively in recent decades, with an increase in the consumption of red meat, high-fat foods, and refined sugars. The "Westernization" of the diet is surely involved in the increase in the incidence of inflammatory disorders, such as obesity, diabetes, cardiovascular diseases, and allergies. However, a strictly food-based view of these conditions, while useful, may miss some important details. The French paradox, for instance, is the fact that

on average, the French eat a high-fat diet but do not have the same high rates of coronary heart disease as other Western populations. To investigate the influence of the microbiota on these diseases, several studies have looked at rural populations living in South America or Africa as a model of traditional, healthful diets, to understand how the Westernization of diet and lifestyle influenced our gut symbionts. All these studies consistently found that the composition of the gut microbiota dramatically differs between urbanized, Western people eating a high-fat and high-protein diet and rural populations, usually hunter-gatherers or agriculturalists, still consuming a subsistence, agrarian diet, with low intake of animal-origin products and high consumption of fibrous foods, such as fruit, vegetables, tubers, and roots. Western populations often show a loss of microbial diversity (5, 43, 44), with a decrease or disappearance of fiber-degrading bacteria, such as *Prevotella*, *Treponema*, *Succinivibrio*, and *Lachnospira*. In particular, *Treponema* was found only in gut microbiotas of nonhuman primates (45–47) and human populations with more traditional lifestyles from Africa and South America (5, 43–45), suggesting that this member of the gut microbiome was recently lost in urbanized people. Moreover, genomic analysis showed a selective adaptation of this genus to the gut environment and to the use of complex polysaccharides (43). In contrast, Western gut microbiotas are often enriched in bile-tolerant microorganisms, such as *Bacteroides*, *Alistipes*, and *Bilophila*, associated with the consumption of a diet rich in fat and protein and poor in indigestible carbohydrates (44, 48).

Gomez et al. (49) compared the gut microbiomes of two traditional African populations (BaAka and Bantu) with those of American controls. The two rural populations had different lifestyles and dietary habits: the BaAka are hunter-gatherers living in the rainforest and consuming a diet rich in fibrous tubers, such as manioc roots and wild yams, while the Bantu recently switched to a subsistence agriculture. Interestingly, the authors observed a progressive decline in the abundance of fiber-degrading bacteria

from the BaAka to the American controls, with the Bantu showing intermediate features, reflecting the consequences of a recent change in their lifestyle (49).

A high diversity of microbiota organisms will be reflected in an increased functional potential and increased functional redundancy. The microbiomes of Hadza hunter-gatherers were found to contain plenty of genes that encode enzymes able to break down a broad set of polysaccharides, in contrast to the microbiomes of Italians (50). This highlights the enrichment in metabolic pathways related to the degradation of several xenobiotics of human origin in the latter (50). Moreover, a Westernized diet selects a gut microbiome with a higher capacity to degrade amino acids and bile salts, as well as simple sugars (4).

THE GUT MICROBIOME AND THE PRODUCTION OF METABOLITES

The gut microbiome is responsible for the production of several metabolites that may positively or negatively affect host health and are collectively defined as the gut metabolome. The gut metabolome reflects both the chemical diversity of the substrates available and the different metabolic potential of the gut microbiota. Therefore, it is influenced both by the gut microbiota composition and by the type of nutrients we feed it. Indeed, traditional and Westernized populations show distinctive fecal metabolomes (Fig. 31.2). Most studies focused on fecal levels of short-chain fatty acids (SCFAs), in particular, acetate, propionate, and butyrate, that are produced by bacterial fermentation of indigestible polysaccharides in the colon and are associated with several health-promoting effects, such as anti-inflammatory and anticarcinogenic effects (51, 52). Indeed, fecal SCFA levels were significantly higher in the agrarian and rural populations studied around the world (5, 44). Undoubtedly, this is explained by the substantial enrichment in fiber of their diet, which selects for a fiber-degrading and SCFA-producing gut microbiota.

Besides SCFAs, gut microbiota can produce other metabolites, with a potentially beneficial effect on the host health (Fig. 31.2).

Phytochemicals and micronutrients entrapped in plant cell walls are released by microbial fermentation in the colon, where bacteria can metabolize them and convert them to a wide range of bioactive molecules (53). As an example, daidzein, a soy isoflavone, can be converted to equol, which may be associated with anticarcinogenic properties (53). However, due to the wide diversity of chemical molecules commonly included in the phytochemical group, it can be expected that different gut microbiota members may be involved in their degradation, with the resulting production of a comprehensive assortment of bioactive metabolites. Gut microbiota can also produce detrimental metabolites (Fig. 31.2). Fermentation of aromatic amino acids produces phenylacetic acid, phenols, indoles, and *p*-cresol, associated with a proinflammatory and carcinogenic effect (51), while the catabolism of sulfur amino acids and taurine by sulfate-reducing bacteria leads to proinflammatory and toxic sulfides (52). Moreover, amines derived from microbial fermentation of proteins in the colon can be nitrosated to produce *N*-nitroso compounds, which were previously correlated with the incidence of colorectal cancer (54).

In addition, a high-fat diet leads to an increase in bile secretion and consequently to a higher quantity of bile acids in the colon, where they are converted into secondary bile acids. The gut microbiomes of African Americans were found to be enriched in microbial genes encoding secondary bile acid production compared to those of rural Africans, which showed lower levels of fecal bile acids and a lower risk of colorectal cancer (55).

Another important microbial metabolite associated with a detrimental effect on host health is trimethyl amine-*N*-oxide (TMAO) (Fig. 31.2). Intestinal microbiota metabolism of phosphatidylcholine, choline, and l-carnitine produces trimethylamine, which is oxidized in the liver; the synthesis of TMAO was recently implicated as a risk factor in the development of

cardiovascular diseases (CVDs) and atherosclerosis (56, 57). One commonly observed contradiction to this observation is that saltwater fish are rich in choline and carnitine and are therefore a potential source of TMAO, but the consumption of fish is associated with lower rates of CVDs and atherosclerosis.

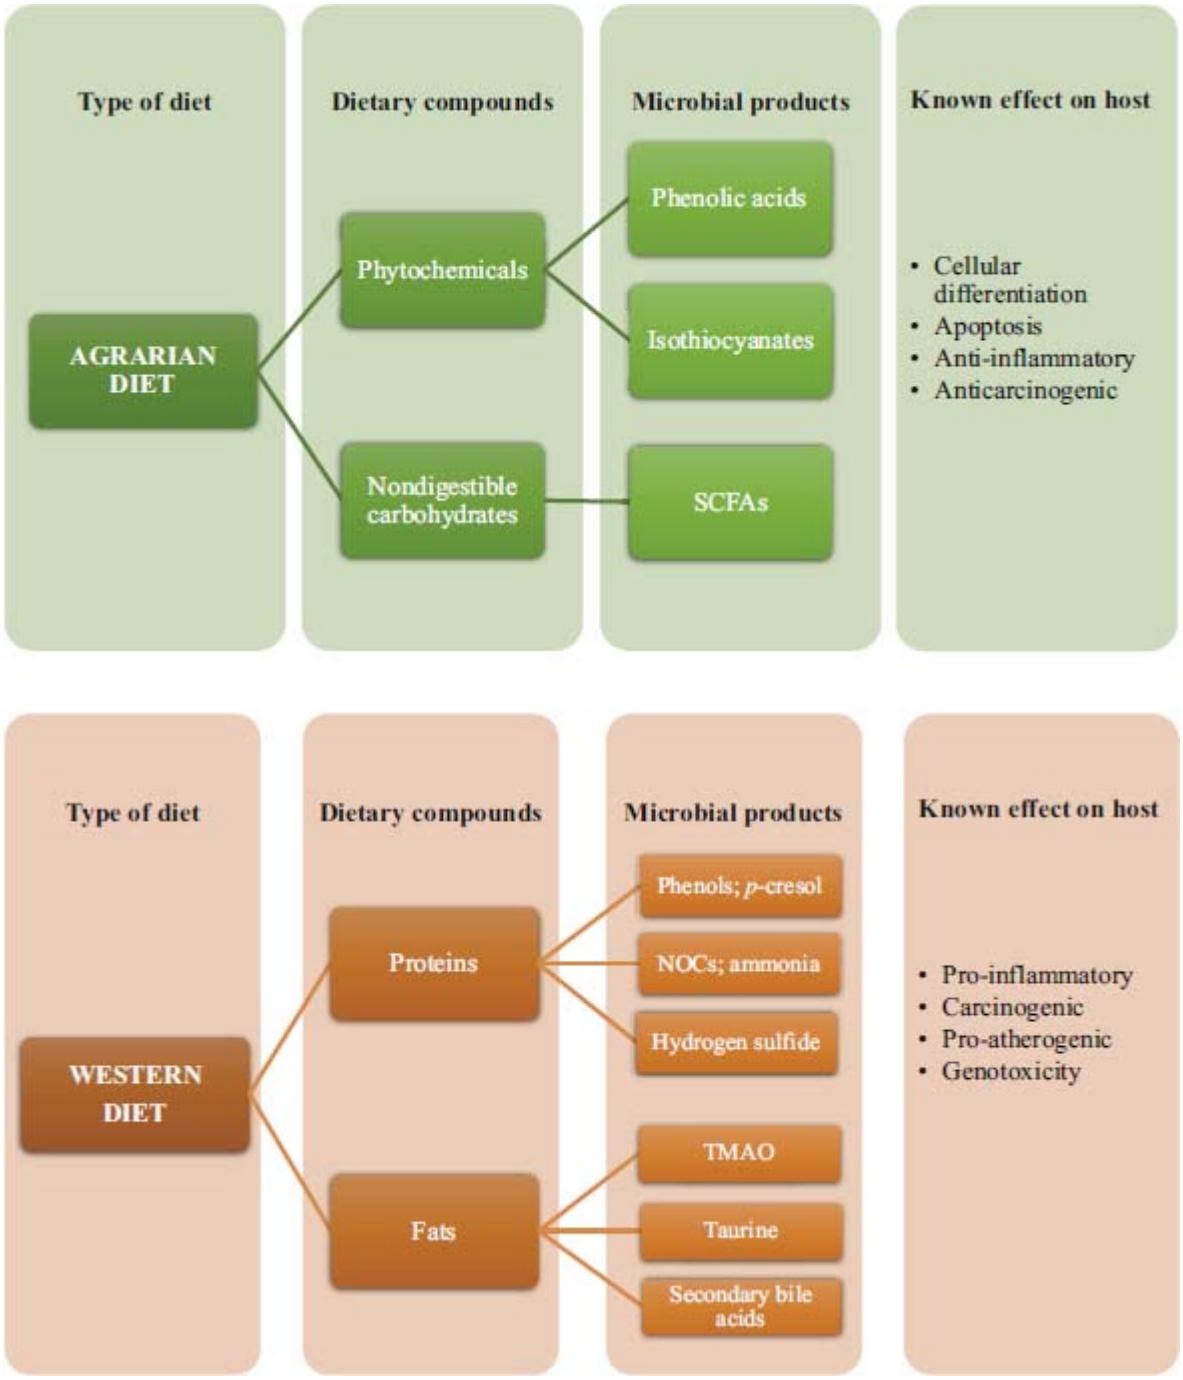

Figure 31.2. Microbiome-diet interaction. The type of diet consumed affects the quantity and nature of the microbial metabolites produced. These metabolites can have beneficial or deleterious effects on the host. NOCs, *N*-nitroso compounds.

A potentially important but less well-known risk factor for atherosclerosis may be the production of bacterially derived lipids

that are quickly absorbed by the digestive tract. We assume that the lipids in our circulatory system are derived from our diet; however, recent evidence points to the presence of lipids produced by *Bacteroidetes* in our blood, and these may be causative of CVDs and atherosclerosis due to their inflammatory nature. Immune cells that are present on the blood vessel walls recognize these lipids as foreign and bind them. Furthermore, the *Bacteroidetes* lipids may be broken down by enzymes in the body, leading to the production of inflammation-enhancing molecules. Together, these processes may lead to an inflammatory response with negative health outcomes (58).

THE MICROBIOME AND DIETARY TYPES

Western diet-microbiota interactions are not always detrimental. Indeed, the number of people choosing a vegetarian or vegan diet has surprisingly increased in the last few years. According to an American poll in 2016, approximately 3.3% of American adults are vegetarian or vegan (59). Although these dietary patterns are becoming more prevalent, few studies have tried to characterize the microbiota of the vegetarian's or vegan's gut. De Filippis et al. (60) recently explored the gut microbiomes and metabolomes of 153 Italian vegetarians, vegans, and omnivores. Consistent with the higher dietary intake of fiber, vegans and vegetarians showed higher abundances of plant-degrading bacteria, such as *Lachnospira* and members of the family *Prevotellaceae*. Vegans had significantly higher abundances of fecal SCFAs than omnivores, while vegetarians showed intermediate levels. In addition, the urinary abundance of proatherogenic TMAO was higher in omnivores (60). Indeed, Wu et al. (36) found striking differences in the plasma metabolome of a smaller cohort of vegans and omnivores, with higher levels of metabolites likely derived from microbial catabolism of plant polyphenolic compounds, as well as of equol. Differences in equol concentration were not associated with a significant variation in the consumption of food rich in its

precursors (such as soy-based products). Indeed, only about 30 to 40% of Western adults are able to convert isoflavones to equol, regardless of their dietary intake (61), emphasizing that both the intake of the right substrates and the presence of specific microbial players are necessary for the development of a health-promoting metabolome.

Without reaching the extreme of a vegetarian or vegan diet, the habitual consumption of a healthful dietary pattern, such as that based on the Mediterraneanstyle diet, can help to develop a health-associated microbiome and metabolome, without completely renouncing meat and animal-origin products. The Mediterranean diet is characterized by high intake of fruit, vegetables, legumes, nuts, and whole grains, moderate consumption of fish, and low intake of saturated fat, meat, and dairy products (62), and it has been demonstrated to be beneficial for the treatment of obesity, type 2 diabetes, and inflammatory and cardiovascular diseases (63–65). Indeed, in the study mentioned above (60), the adherence level to the Mediterranean dietary pattern was evaluated. The authors observed a progressive increase in fecal SCFAs going from low-adherence to high-adherence subjects and an opposite trend for urinary TMAO. Interestingly, even when omnivore subjects alone were considered, a higher adherence to the Mediterranean diet correlated with a higher abundance of SCFAs. This study highlighted the idea that a healthful dietary pattern can deliver the proper substrates and shape the gut microbiome to boost the production of health-promoting metabolites even in an overall omnivore-type diet.

AGE-RELATED CHANGES IN THE GUT MICROBIOME

As people transition from middle to late adulthood, the microbiota composition, which has been relatively stable over the previous few decades, starts to undergo changes. These changes are particularly

evident in centenarians, where decreased levels of *Faecalibacterium* and *Bifidobacteria* and an increase in the mucin-degrading bacterium *Akkermansia* have been reported (66).

The ELDERMET project investigated the microbiome changes that occur after the age of 60 and found that both the microbiota and the metabolic activities of the microbiota change in the elderly in a diet-dependent manner (67). The diet in an elderly population can change for a number of reasons, including institutionalization, loss of taste sensation, frailty, tooth loss, and difficulties with chewing or swallowing. For this reason, the diet of elderly persons tends to be less diverse, with a reduction in the proportion of calories coming from unprocessed plant-based sources and an increased consumption of processed, high-sugar, high-fat foods.

As mentioned above, changes in the long-term diet have a significant impact on the microbiota, and this is also true for the elderly population, in whom a dramatic observable reduction in a number of key taxa, such as *Faecalibacterium*, *Ruminococcus*, and *Blautia*, is observed. Between healthy young adults and the general aged population, there is a reduced abundance of *Blautia* and *Ruminococcus* species and an associated increase in *Escherichia*, of which *E. coli* is a member (67).

However, these changes do not occur in a uniform manner across the elderly population. It is observed that the decline is strongly correlated to the decline in the diversity of plant-based foods that have been consumed, and in a subsequent study, it was shown that there are only subtle differences between the microbiomes of healthy elderly individuals and those of healthy adults (67, 69). Therefore, within the elderly population, there are a large number of microbiome states, ranging from one that is indistinguishable from that of young healthy adults to distinct microbiome profiles that can be related to varying health phenotypes.

The changes in the microbiota that can occur can be summarized into three trends: the loss of commensals, the loss of fiber-responsive taxa, and the gain of pathobionts. The loss of the fiber-

responsive taxa and, to a lesser extent, that of the commensals are associated with a reduction in the diversity of the microbiota. The loss of these taxa and the subsequent low diversity are associated with a prefrail state (70). We can speculate that it is at this stage where a dietary intervention to prevent this loss would be most effective. As people age further, a proportion of the population continue to lose taxa, becoming very low-diversity individuals. However, these individuals are in the minority within the frail aging population, with the majority of frail individuals experiencing a small increase in diversity compared to the average microbiome. This increase in diversity is the gain of rare taxa that are present at low levels in healthy young adults but whose increased presence in the elderly is associated with an altered immunological and metabolic state and a large increase in frailty. These increases in rare taxa, though not directly associated with diet, are associated with the risk of malnutrition. Also, the gain of these potentially pathobiont rare taxa seldom occurs before the loss of the more abundant fiber-responsive proportion of the microbiota.

These changes in diversity are associated with changes in the predominant taxa within the microbiota profile. As mentioned above, the two main phyla within the gut microbiota are the *Bacteroidetes* and *Firmicutes*. The genus-level alterations in the *Bacteroidetes* go from a predominantly *Prevotella*-associated microbiome to a predominantly *Bacteroides*-associated microbiome as people move from a high-diversity microbiome to one that is low diversity. The *Bacteroidetes*-associated taxa that are associated with the increase in frailty are *Parabacteroides* and *Alistipes*. The *Firmicutes* that are generally lost as elderly individuals become frailer are *Roseburia*, *Lachnospiraceae*, *Ruminococcus*, and *Faecalibacterium*.

These alterations in the taxonomic profiles are associated with an altered functional potential. The utilization of nitrogen sources is increased, with a detectable increase in the proteolytic functions (71). We also see a decrease in the production potential and the amount of SCFAs produced due to the reduced consumption of fiber

and the associated reduction in key genes necessary for SCFA production (67). We can associate these changes with the reduction in abundance of several key butyrate producers belonging to *Clostridium* clusters XIVa and cluster IV (67, 72, 73). In the study of elderly individuals, the authors also demonstrated that there were a reduced number of gene types in the elderly gut that were related to the production of butyrate, acetate, and propionate production in the fecal metagenome of the oldest, frailest individuals (67). Previous reports also indicate that an increase in the abundance of facultative anaerobes, of which *Escherichia* is a member, is associated with increased immune activity associated with aging, sometimes called “inflammaging” (72).

The loss of taxa, and potential functionality, associated with frailty is strongly associated with the quality of the diet of the individual (68). However, this does not exclude the possibility that the composition of the gut microbiota can vary due to a number of physiological and immunological factors, such as a reduction in immune system functionality, loss of epithelial barrier integrity, gastrointestinal motor function, altered food transit, and altered functionality of the intestinal wall (74).

GUT MICROBIOME MODULATION AND DIETARY INTERVENTIONS

Although long-term dietary habits seem to be the main force shaping the gut microbiome, several studies suggest that the appropriate dietary intervention can boost the development of beneficial microbes in the gut. These studies focused on the addition of indigestible fiber to the diet and highlighted the possibility of boosting the development of fiber-degrading bacteria in the gut (75). These changes in the gut microbiota were often associated with the increase of beneficial metabolites, such as SCFA, and with the reduction of inflammatory markers (76, 77). The presence of diet-responsive gut microbiome members highlighted

the possibility of modulating the gut microbiome through the appropriate diet for therapeutic purposes. However, it is still not clear how and to what extent these changes may occur in a predictable way. Indeed, recent findings suggested that the response to a dietary intervention is person specific and strongly connected to the gut microbiome configuration. During a dietary intervention with barley kernel fiber, Kovatcheva-Datchary and coworkers (78) observed that only a fraction of the population studied showed improved glucose metabolism after the intervention and that only the responders showed increased levels of *Prevotella copri*. Therefore, a personalized intervention considering differences in the gut microbiome across subjects is often necessary. Accordingly, people eating identical meals showed different metabolic responses, consistently associated with gut microbiota features (79). Integration of gut microbiota signatures in a complex algorithm that included anthropometrics, blood parameters, and dietary habits allowed a precise prediction of postprandial glycemic response, associated with type 2 diabetes development (79). Moreover, this algorithm may be successfully used for defining personalized dietary intervention to lower postprandial blood glucose. These results emphasized the possibility of personalized medicine based on a patient-tailored modulation of the gut microbiome, which may help in the treatment of a wide range of disorders in the near future.

CONCLUSION

A wealth of knowledge clearly exists surrounding diet and the microbiota. Diet is a major determinant of the microbiota populations in our gut. In early life, diet is a driver of the microbiota as initial populations are replaced. As we progress into adulthood, a healthful plantbased diet is associated with a high-diversity microbiota which encodes a range of beneficial functionalities. As we approach the end of our life span, the beneficial microbiota may become depleted, and this is strongly associated with dietary changes.

It is clear from the literature that there are a wide number of factors outside diet that also affect the dynamic process of bacterial acquisition and retention. A broad, holistic approach is necessary to gain insight into the specific mechanisms for the sequential replacement and change in bacterial populations over time as individuals progress from a fetus through birth to adulthood and old age. Nevertheless, the diet is a key determinant of the microbiome and may therefore be utilized in interventions to maintain health, life span, and overall quality of life.

Probiotics and Prebiotics

For decades, probiotics and prebiotics have been studied for their beneficial health effects. More recently, research on the composition and activities of the microbes colonizing the human body has established the important role the microbiota plays in health. A convergence of these fields has increased awareness of the value of probiotics and prebiotics as tools to improve the function of the microbiota and thereby improve host health. Clinical evaluations have accumulated, with positive results leading to probiotics being included in some medical guidelines (1, 2). Probiotic and prebiotic targets have expanded considerably beyond the original focus on the gut to the oral cavity, vaginal tract, brain function, metabolic endpoints (diabetes, obesity, and cardiac risk factors), nutritional factors (mineral absorption, vitamin production, and lactose malabsorption), and the immune system. The range of target hosts for probiotic and prebiotic interventions has expanded beyond humans to include numerous agricultural species (mammalian, aquatic, and avian) and companion animals. Mechanistic understanding of how probiotics and prebiotics function has also advanced considerably. Knowledge of how prebiotic structure relates to function has increased (3), providing insights into the ability of these substances to stimulate beneficial commensal (autochthonous) microbes. As externally introduced (allochthonous) microbes, probiotics have been shown to both directly (through interactions with epithelial and immune cells) and indirectly (through interactions with autochthonous microbes and metabolic end products) impact the host (4). Many model probiotic

strains amenable to focused genetic manipulation have been developed and investigated via "-omics" technologies, leading the way for developments in strain improvement, mechanistic studies, and construction of genetically modified strains capable of functioning as vaccines or delivering other biologically important molecules (5). Finally, global markets have increased product options for consumers and health care professionals. Notably, although most commonly found in food and supplement products, probiotics and prebiotics are being developed and investigated to address therapeutic needs related to microbiome manipulation. This chapter reviews the science behind these dynamic substances.

PROBIOTICS

Definition of "Probiotics"

Probiotics, first popularized at the beginning of the 20th century by the Russian Nobel laureate Elie Metchnikoff (Fig. 32.1), have undergone numerous definition revisions. The term "probiotic" does not entail a legal definition in most countries, but a definition of "probiotics" was adopted by a joint United Nations Food and Agricultural Organization/World Health Organization working group in 2001, and it is currently one of the most widely recognized definitions of these microorganisms (6). This definition was refined (and grammatically corrected) by a consensus panel of experts convened by the International Scientific Association for Probiotics and Prebiotics (ISAPP) to "live microorganisms that, when administered in adequate amounts, confer a health benefit on the host" (7). Figure 32.2 shows substances that fall under the umbrella of this definition and distinguishes between substances that are probiotics and those that are not. The wide acceptance of this definition has not deterred some from proposing many related terms, which may serve specific purposes (Table 32.1). Important implications of this definition are that a probiotic must be administered alive and must have been shown in a properly

controlled study to confer a health benefit. In order to be the subject of research, the probiotic must be taxonomically identified and suitably defined, which precludes inclusion of undefined microbial mixtures such as those found in some fermented foods and in fecal microbial transplants. The definition of a probiotic applies to any type of health benefit for any type of host and spans regulatory categories, which, as long as the definition is met, could include foods (those consumed by humans, animals, marine animals, birds, etc.), dietary supplements, medical foods, therapeutics, medical devices (including nonoral applications), and cosmetics. Importantly, a probiotic must be safe for the intended use.

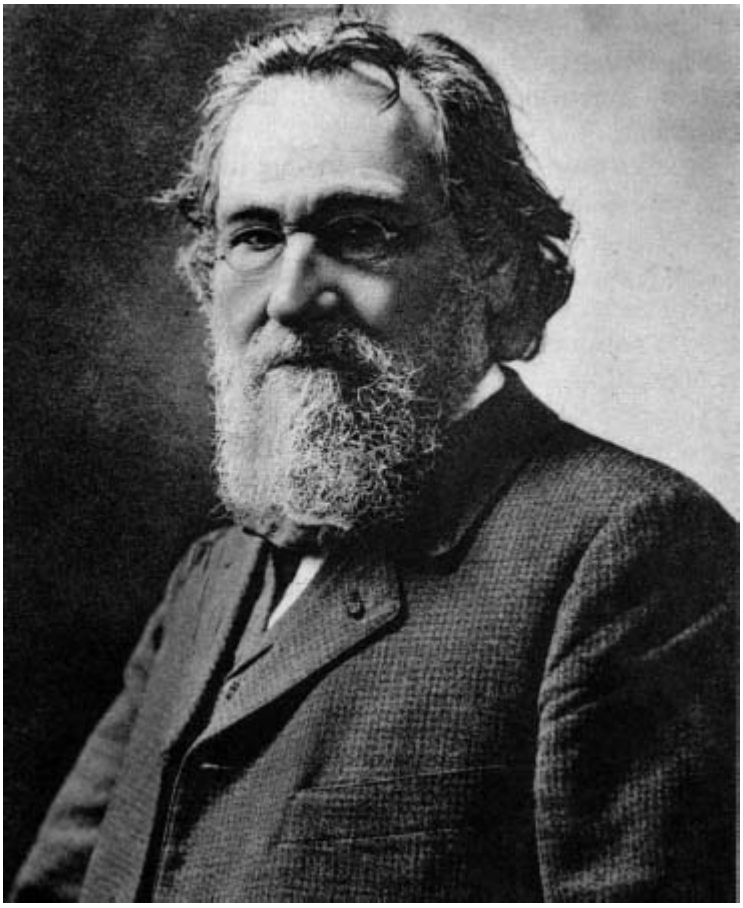

Figure 32.1. Elie Metchnikoff (1845–1916) (125).

There is also interest in the potential health effects of consuming killed bacteria or cellular components. Since the definition of probiotic stipulates use of a live microorganism, these products do

not fit the probiotic definition. Several terms have been coined to include nonviable microbial cells or products (Table 32.1). The preponderance of research, however, has been conducted using live microbes.

Mechanisms of Action of Probiotics

While the mechanisms through which probiotics exert their beneficial effects are not entirely understood on a clinical level, several major avenues exist through which probiotic cultures are likely to carry out beneficial activities (8, 9) (Table 32.2). Some key mechanisms are described here.

1. Interaction with the immune system. The intestinal tract is a prominent part of the immune system, and it constantly interacts with "non-self" components as they transit through the gut. Consumed foods, live microbes, microbial components, and commensal microbiota are in regular contact with gut-associated immune cells. Through *in vitro* assays, *in vivo* animal models, and in human studies, probiotic strains have been shown to interact in a strainspecific manner with immune cells. Some probiotics alter cytokine production by exposed macrophages and dendritic cells and can shift the production of cytokines from the inflammation-inducing to antiinflammatory pathways (10–12). Some probiotics can upregulate adaptive and innate immune function, to better respond to pathogen or cancer cell challenge, as demonstrated by improved seroconversion after vaccination (13). Research into effector molecules has identified ways that probiotics specifically interact with immune cells (9), such as the surface layer proteins of *Lactobacillus acidophilus* (14) and bacterial glycoproteins on the pili of *Lactobacillus rhamnosus* GG, which are important in the immunomodulation of the host (15). The net effect is that probiotic strains and their display of cell surface components can modulate immune function.

2. Strengthening the mucosal barrier. The barrier between the lumen of the intestine and the inside of the body is essential to maintaining health. This mucosal barrier is selectively permeable, allowing transit of nutrients while keeping outmost other luminal components. Dysfunctional barriers are associated with a number of disease states (16). Probiotics have been shown to reinforce and repair this barrier, in part by stimulating the production by intestinal epithelial cells of protective proteins, such as mucins (17).
3. Exclusion and inhibition of pathogens. Decadesold literature speaks of a concept known as colonization resistance (18). This phenomenon, likely the aggregate result of multiple functions of colonizing microbes, grew from observations from many different lines of research showing that an intact, normal microbiota enables the host to resist pathogens. Some of these mechanisms demonstrated by colonizing microbes are found in probiotic bacteria as well, including production of antimicrobials (bacteriocins, organic acids, and others), preemptive binding of probiotics to receptor sites to block pathogen adhesion, and stimulation of host cells to produce mucin, thereby tightening the mucosal barrier and others (19).
4. Production of bioactive substances. Probiotic growth in the intestinal tract can yield bioactive substances with a range of physiological activities (20). For example, certain probiotics can produce enzymes such as lactase, which can improve lactose digestion, or bile salt hydrolases, which can favorably impact circulating blood lipids. Probiotics may also produce, or enhance host or commensal microbiota production of, opioid substances that may contribute to gut pain alleviation (21, 22) and neuroactive substances such as gamma-aminobutyric acid, serotonin, catecholamine, and acetylcholine, which may contribute to antidepressive, antianxiety, and satiety effects (23).

5. Impact on colonizing microbiota. Although a common understanding is that probiotics "promote a healthy microbiota composition," research has shown that probiotics administered to healthy adults have minimal impact on fecal microbiota composition (24, 25), although -omics techniques to reveal taxonomic changes at the species and strain level have not been employed. Typically, transient increases in the species of the fed probiotic are detected, but no changes in overall bacterial community structure are observed. Recent evidence suggests that probiotic intervention in subjects with unstable or dysbiotic microbiota may lead to notable changes. Administration of *Bifidobacterium lactis* Bl-04 and *L. acidophilus* NCFM to colon cancer patients resulted in increased abundance of butyrate-producing bacteria in the tumor, nontumor mucosa, and fecal microbiota (26). Healthy newborn infants fed *Bifidobacterium infantis* EVC001 harbored increased levels of this species for 1 month postfeeding (27). *Bifidobacterium longum* AH1206 was stably maintained by about 30% of healthy subjects after cessation of oral administration (28). The microbiota of successfully colonized subjects was subsequently shown to be characterized by a low abundance of *B. longum*, suggesting the availability of an ecological niche that was exploited by this strain. Research into the impact of probiotics on microbiota functions has suggested that even though bacterial populations are not significantly altered by probiotic administration to healthy individuals, microbiota functions may be. Probiotic yogurt containing *B. lactis* fed to healthy subjects did not alter fecal microbiota composition but did alter microbiota transcriptomes (29). Eloe-Fadrosh et al. (30), using a transcriptomic approach, found that oral administration of *L. rhamnosus* GG to healthy elderly subjects resulted in enrichment of anti-inflammatory pathways expressed by resident microbes. This research area is ripe for exploration. It is possible that nontraditional probiotic species may more effectively change microbiota structure. Further, how the characteristics of an individual consumer's microbiota,

diet, and genes may influence microbiota responses to probiotics needs to be better understood.

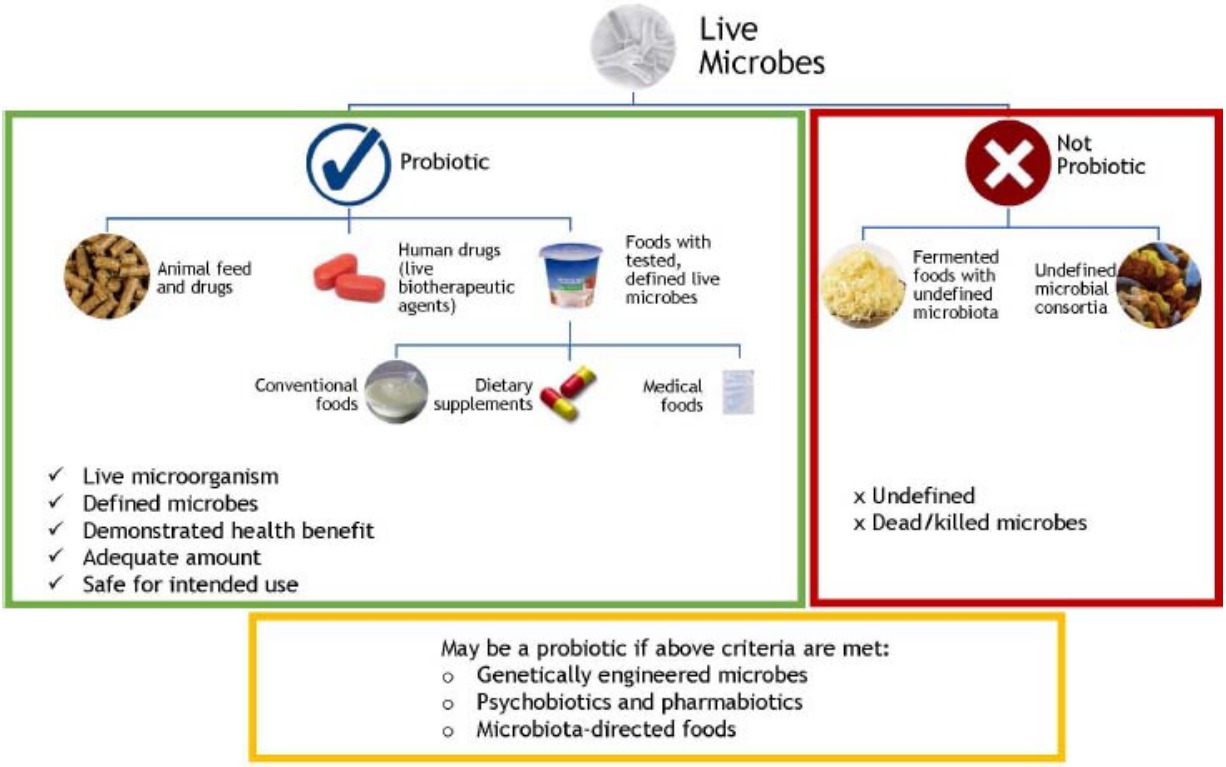

Figure 32.2. Probiotics: what is encompassed under this term. By definition, a health benefit must be demonstrated for a probiotic, either at a strain-specific level or at a taxonomic level where mechanisms are shared. Probiotics can be administered via different routes (oral, intravaginal, and topical routes and via mouth sprays) and are not limited to human use (i.e., they may also be given to companion animals, livestock, and fish). The probiotic definition is not restricted by regulatory category for probiotics and encompasses the spectrum from foods to drugs (live biotherapeutic agents). Dead microbes, microbial end products, microbial components, and undefined microbial mixes do not come under the probiotic classification. Adapted from reference 34 with permission.

Table 32.1. Terminology related to probiotics[a]

Term	Definition	Reference or comment
Probiotic	Live microorganism that, when delivered in adequate amounts, confers a health benefit on the host	7
Prebiotic	Substrate that is selectively utilized by host/commensal microorganisms conferring a health benefit	3
Synbiotic	Combination of prebiotics and probiotics	Prebiotic may (synergistic synbiotic) or may not (complementary synbiotic) be utilized by the probiotic
Antibiotic	Medicine that inhibits the growth of or destroys microorganisms	
Abiotic, postbiotic	Nonviable probiotic organism or cellular component thereof that exerts beneficial effects on health or well-being	128, 129
Pharmabiotic	Any form of therapeutic exploitation of the commensal flora, including the use of live probiotic bacteria, probiotic-derived biologically active metabolites, prebiotics, synbiotics, or genetically modified commensal bacteria	19

Immunobiotic	Bacterium that promotes health through activation of the mucosal immune apparatus	130
Psychobiotic	Live organism that, when ingested in adequate amounts, produces a health benefit in patients suffering from psychiatric illness	131
Probioceutical	Probiotic-derived factor	132
Live biotherapeutic agents	Biological product that contains live organisms, such as bacteria; applicable to the prevention, treatment, or cure of a disease or condition of human beings (not a vaccine)	133

[a] These terms differ with regard to the presence of live microbes, the intended effect, the mechanism of action, and the regulatory category.

Table 32.2. Mechanisms of action that may mediate health benefits conferred by specific probiotic strains

Stimulate intestinal mucin production
Pili expressed on bacterial cell surface enhance colonization/gut retention
Produce antimicrobial substances such as bacteriocins, targeting pathogens or shaping microbial ecosystem
Produce short-chain fatty acids
Produce enzymes, such as providing lactase to humans deficient in β-galactosidase
Enhance adaptive and innate immune function, to better respond to pathogen or cancer cell challenge
Downregulate inflammation, a risk factor for negative outcomes of many chronic disease states
Digest prebiotic fibers, to improve metabolic/growth opportunities in the gut
Improve gut barrier integrity
Modulate gene expression or activity of host microbiota, including cross-feeding and altered enzymatic activities such as bile salt hydrolase
Signal the central nervous system through production of neuroactive compounds
Produce vitamins

The final expression of a health benefit mediated by a probiotic or prebiotic may be due to the action of several different relevant mechanisms, leading to the overall observed effect.

Strain Specificity

Strain specificity of probiotic effects is a foundational principle underlying the science of probiotics. There are many examples of microbial traits, genetic and metabolic characteristics, and cell

physiology features that vary among different probiotic strains. This was investigated in human-derived strains of *Lactobacillus reuteri* using a comparative genomic approach (31). Although reuterin may not be made *in vivo* due to the lack of an essential precursor, glycerol, in the human gut, this example is still illustrative. Gene content was found to be highly conserved among clades within this species, yet only 70 to 90% of total gene content was shared. Differences in sequences occurred in genes related to bacteriophages, vitamin biosynthesis (B_{12} and folate), antimicrobial production (reuterin), arginine catabolism, and immunomodulation. Such observations have led to the widely held notion that each probiotic strain must be regarded as unique and any efficacy studies conducted on one probiotic strain cannot be extrapolated to another strain (although this notion is being refined; see below). What is less clear, however, is the extent to which measurable differences in expression of characteristics, even those presumed to be important mechanistically, impact an overall clinical benefit. Most clinical trials compare one probiotic strain or strain blend to a placebo, and a few compare different probiotics. Studies comparing different strains of the same species with regard to a clinical endpoint are rare. One example is a pilot study that looked at immune responses in subjects treated with the same dose of different strains of two species, *L. acidophilus* La-14 versus *L. acidophilus* NCFM, and *Bifidobacterium animalis* subsp. *lactis* Bl-04 versus *B. animalis* subsp. *lactis* Bi-07 (32). This study showed some differences in host immunoglobulin response to different strains compared to placebo, but unfortunately, the statistical comparisons between the different strains of the same species were not reported. Therefore, it is not possible to state that the strains are different from each other in the case of this clinical endpoint. A research need is for studies comparing different strains of the same species on clinical endpoints to determine the extent to which strain differences detected in preclinical tests translate into clinical differences.

Numerous systematic reviews evaluating the totality of evidence for a specific clinical benefit of different probiotics show that similar clinical benefits are achieved by many different strains (33). This of course does not mean that all strains can be expected to perform similarly, but it does suggest that certain determinative functions are likely shared among many different strains and that differences observed in some preclinical assessments may not predict differences in clinical outcomes. A 2014 consensus panel recommended that strains of certain well-studied species could reasonably be expected to provide some digestive benefits and therefore could be considered probiotics even at the species level. However, it is not possible to reach 100% assurance that any given strain will yield a given clinical benefit, since physiological fitness may be lacking or traits that override adequate expression of needed functions may exist.

This concept was developed further by Sanders et al. (34), who presented evidence for several mechanisms that are shared among probiotic taxonomic groups at higher levels than the strain level. The distribution of such mechanisms among all members of a taxon provides a rationale that some general probiotic benefits can be expected in a non-strain-specific manner. Indeed, the absence of certain mechanistic functions (in mutants or similar strains devoid of the function) has been shown to result in loss of physiological benefit. For example, compared to wild-type strains, loss of bacteriocin production by *Lactobacillus salivarius* UCC118 led to loss of protection against *Listeria monocytogenes* infection in mice (35), and a histamine decarboxylase-deficient *L. reuteri* mutant unable to generate histamine no longer suppressed inflammation-associated colorectal cancer in mice (36). Such results suggest that specific mechanisms might be essential for clinical benefit, and the expression of such mechanisms may be able to predict clinical benefit.

A cornerstone mechanism that likely contributes to many of the benefits attributed to probiotics is their ability to produce short-chain fatty acids (SCFAs). Metchnikoff, the founder of the probiotic

concept, proposed that a normal gastrointestinal microbiota dominantly engaged in metabolism of complex carbohydrates yielding SCFAs was preferred over a microbiota engaged in degradation of proteins, which results in putrefactive metabolites (37). Today, we better appreciate the important role that SCFAs—especially butyrate and propionate—can play in health and homeostasis. SCFAs are important to gut health through their action as signaling molecules and by inhibiting pathogens, but they are also important to the function of peripheral tissues, such as adipose tissue, skeletal muscle, and liver tissue (38). Although lactobacilli and bifidobacteria do not produce butyrate and propionate, their metabolic products (acetate and lactate) can increase levels of these important SCFAs through cross-feeding of other gut microbes (39). The metabolic pathway for production of lactate and acetate is conserved among all *Bifidobacterium* species and homofermentative (lactate) and heterofermentative (lactate and acetate) lactobacilli. These pathways are the most important metabolic pathways conserved among lactic acid bacteria and other probiotic genera.

Microbes Used as Probiotics

The most common microbes used as probiotics today are members of the genera *Lactobacillus* and *Bifidobacterium*. However, some nonpathogenic microorganisms that occur within niches in the host gut or tissues, such as *Bacillus* species, *Enterococcus*, *Escherichia coli*, and some yeast species, are also used as human and animal probiotics (Table 32.3). As studies have emerged correlating certain members of the normal gut microbiota with the absence of certain disease states, researchers have proposed an expanded list of microbes that may make suitable candidates for the next-generation probiotics (40). For example, *Akkermansia muciniphila*, which is inversely associated with metabolic disorders including obesity, diabetes, and cardiometabolic risk factors, has been proposed for inclusion in novel foods or drugs (41). *Eubacterium hallii*, a

butyrate-producing species which improves insulin sensitivity in mice (42), is being tested in humans.

Table 32.3. Examples of probiotic strains with research documentation in human subjects[a]

Species	Strain(s)
Lactobacillus acidophilus	NCFM, DDS1
Lactobacillus rhamnosus	GG, GR1
Lactobacillus casei-L. paracasei	Shirota, CRL431, DN 014 001, F19
Lactobacillus plantarum	299V
Lactobacillus reuteri	DSM17938, ATCC PTA 6475
Lactobacillus johnsonii	La1, Lj1
Lactobacillus salivarius	UCC118
Bifidobacterium breve	Yakult
Bifidobacterium animalis subsp. *lactis*	BB12, HN019, DN173 010
Bifidobacterium longum	SBT-2928, BB536
Streptococcus salivarius	K12
Saccharomyces boulardii	lyo CNCM I-745
Escherichia coli	Nissle 1917
Bacillus coagulans	BC30, IS2, MTCC 5856

[a] Strains researched as part of a multistrain blend are not listed.

Criteria for Selection of Probiotic Cultures

Different probiotic species and strains within a species exhibit distinctive properties that can markedly affect their survival in foods, survival through the digestive tract, and important probiotic properties. Therefore, strain selection becomes a critical parameter to ensure both the culture's stability and its probiotic performance.

Potentially useful traits for selection of functional probiotics are listed in Table 32.4, including minimum criteria needed to meet the probiotic definition, as well as criteria important to technological utility and *in vivo* functionality. Impacts on health targets are complex, because the underlying mechanisms by which probiotics exert these functional roles *in vivo* are multifaceted and not completely understood. An important research need is to better understand how results from *in vitro* assessments of these traits relate to *in vivo* functionality.

Our understanding of probiotic properties has been revolutionized by whole-genome sequencing and functional genomics. Genome sequencing projects examining the collective attributes of strains with probiotic properties have identified a number of similarities that suggest critical traits for these strains, including an extensive network of glycosyl hydrolases in bifidobacteria and oligosaccharide transport and metabolism enzymes in lactobacilli that allow metabolism of complex, indigestible carbohydrates available in human milk and the gut (43). Complete genome annotation and functional analysis support the identification of key genes that are expected to direct functions important in probiotic activity. For example, within the *L. acidophilus* genome (Fig. 32.3), a series of surface-associated proteins (e.g., mucin-binding and fibronectin-binding proteins) have been identified and correlated with the bacterium's ability to adhere to intestinal epithelial cells *in vitro*. Across several *Lactobacillus* species, a number of gene regions are implicated in probiotic activity, including bile salt hydrolase activity, acid tolerance, bacteriocin activity, prebiotic/oligosaccharide utilization, oxalate degradation, exopolysaccharide production, mucus and fibronectin binding, and communication with immunomodulatory cells of the host (5).

Table 32.4. Characteristics important for probiotic strains

Category	Criteria
Appropriateness	Ability to exert one or more clinically documented health benefits Taxonomic identification as determined by current genomic and phylogenetic methods Origin—although efficacious probiotics have been developed that are not normal inhabitants of the target species, there may be an ecological benefit to a strain that was isolated from a healthy individual of the target species Safety—nontoxic, nonpathogenic, and safe for the intended use
Technological suitability	Amenable to mass production and storage: adequate growth, recovery, concentration, freezing, dehydration, storage, and distribution Suitable viability retained during culture preparation, storage, and delivery Provides desirable organoleptic qualities (or no undesirable qualities) when included in foods or fermentation processes Genetically stable and consistent phenotypic properties Genetically accessible for research and potential genetic modification
Performance and functional properties often considered in strain selection[a]	Functionally capable of survival, proliferation, and metabolic activity at the target site, *in vivo* (e.g., gastrointestinal tract, mouth, vagina, skin, etc.), if required for the specific mechanism of function Resistant to bile Resistant to acid Compete with the normal microbiota, including the same or closely related species

	Resistant to bacteriocins, acid, and other antimicrobials produced by residing microbiota Adheres or interacts with the mucosal epithelium Adequate retention to achieve beneficial effects Ability to metabolize wide range of carbohydrates in the host environments (e.g., gastrointestinal tract and vaginal tract) as an energy source to maintain survival and probiotic functionality Antagonistic toward pathogenic/cariogenic bacteria Produces antimicrobial substances (bacteriocins, hydrogen peroxide, organic acids, or other inhibitory compounds) Immunomodulatory (stimulation or downregulation of immune responses, as needed for particular use) Antimutagenic Production of bioactive compounds (enzymes, bacteriocins, vaccines, peptides)

[a] Listed properties *may* be useful, depending on desired probiotic functions, expected site of action, and target host. Methods used to assess these properties typically are not standardized or validated, so results must be interpreted with caution.

Probiotics for Human Health

Substantial research has been conducted to examine the clinical effects of probiotic microorganisms. A thorough review of this research is beyond the scope of this chapter and has been presented in other publications (see reference 2 for a summary of gut-related clinical evidence; Sanders and coworkers [134] have prepared a summary of clinical evidence). A list of studied health outcomes related to probiotic consumption is compiled in Fig. 32.4. Compelling evidence has accumulated for several clinical outcomes, including treatment of infantile colic (44), prevention of antibiotic-associated diarrhea (1), prevention of necrotizing enterocolitis (45), prevention of *Clostridioides* (formerly *Clostridium*) *difficile*-

associated diarrhea (46), reduction of incidence and duration of common infectious diseases (47), adjunct treatment of *Helicobacter pylori* (48), adjunct treatment of bacterial vaginosis (49), and treatment of acute pediatric diarrhea (50). However, the body of efficacy research on probiotics comprises a heterogeneous compilation, with studies using different strains, doses of viable cells delivered, product formulation, clinical endpoints, study subject characteristics, and study design. The study quality has also varied over the years, with earlier studies more often being underpowered and not conducted or reported according to CONSORT guidelines (51), resulting in outcomes marred by a high risk of bias. Further, there are few studies that compare dose, different probiotic strains or strain blends, carrier matrix material for the probiotic microbes, or timing of administration, leaving a gap of knowledge regarding how important these parameters are to clinical success.

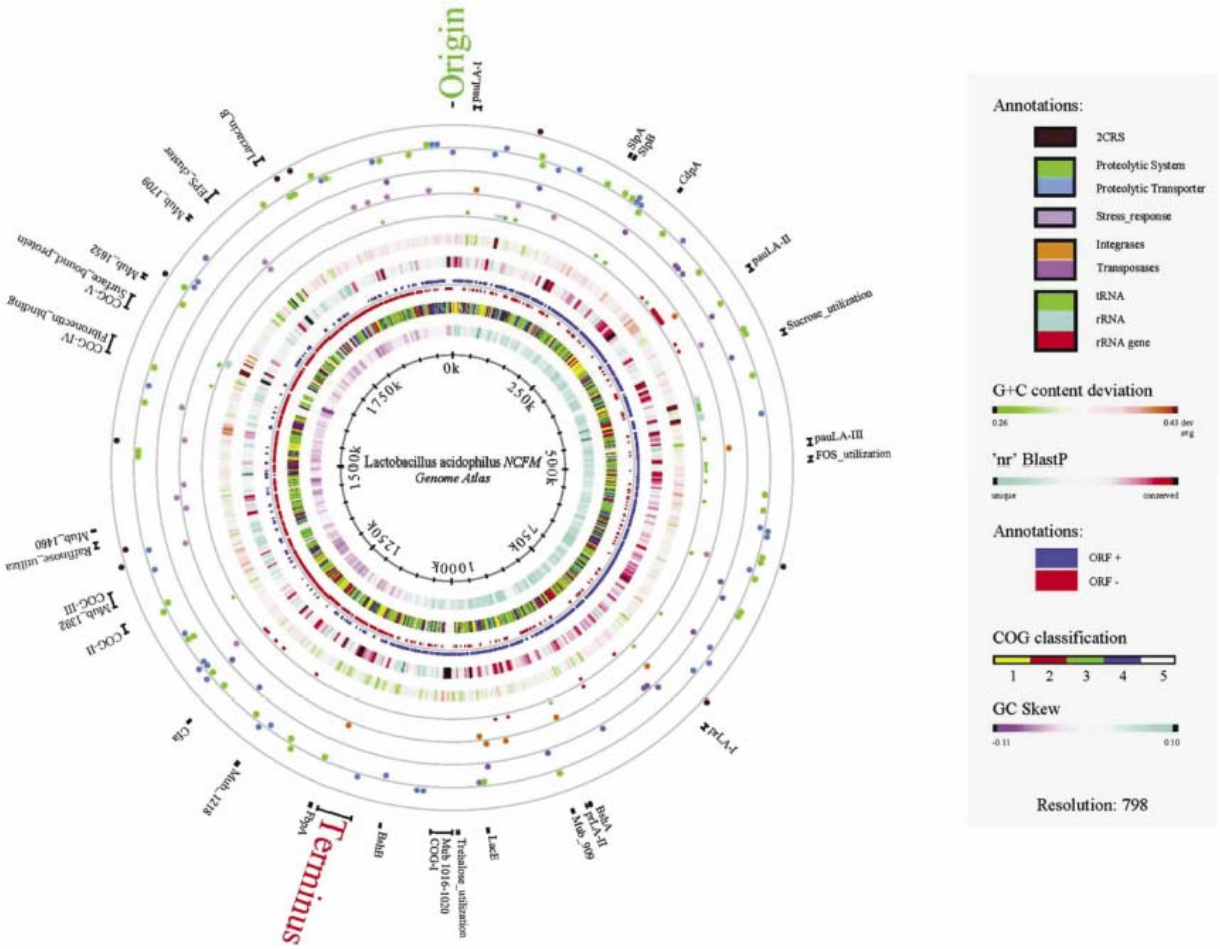

Figure 32.3. Genome atlas of the probiotic *L. acidophilus* strain NCFM, presenting a circular view of the complete genome. The key describes the single circles in the top-down outermost-innermost direction (126).

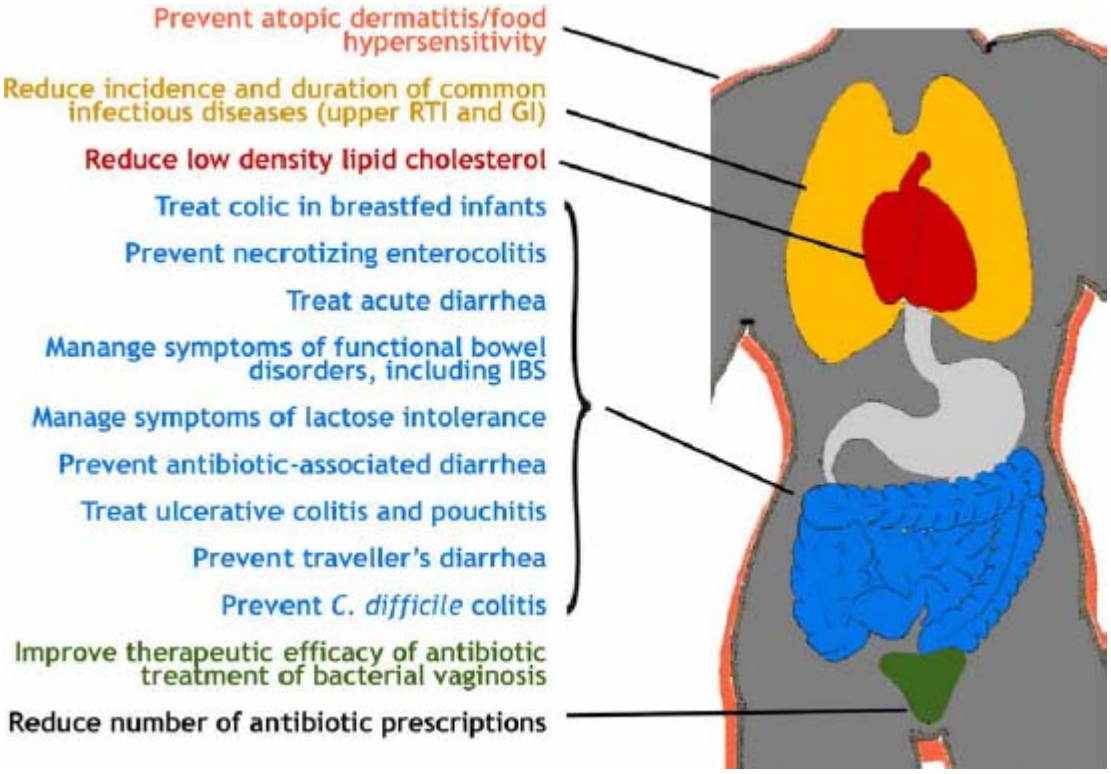

Figure 32.4. Overview of indications where probiotics have been researched with varying but solid evidence for clinical benefit. RTI, respiratory tract infection; GI, gastrointestinal.
