## INTRODUCTION

The image of a *child at work* encompasses a broad range of activities in diverse contexts. It could be an image of a child *working* on a school assignment, *working* to finish a model volcano for the science fair, *working* on household chores to earn an allowance, *working* to care for younger siblings, or *working* alongside a parent on a farm, in a small

family-owned business, or in an office during an annual take-your-child-to-work day. It could also invoke unsettling images of children *working* in hazardous jobs (e.g., mining, street trade), performing dangerous tasks (e.g., rag picking, operating heavy farm machinery), or in exploitative activities (e.g., prostitution, armed conflict, prize-fighting, illicit-drug trading). Of course, when we think of *children at work*, we must also consider the many employed teenagers who serve us our favorite fast-food sandwiches, who trim our lawns, who babysit our children, and who help us find the perfect pair of sunglasses at the sporting-goods store.

Because *children at work* is too broad a topic for one chapter, here we focus on children's experiences in paid work in the United States and in other countries around the world. Our objective is first to highlight the diversity in early work experiences and then review studies that

---

Figures presented in this chapter are based upon analyses of cross-sectional data from the Monitoring the Future study, which is supported by a grant from the National Institute on Drug Abuse (R01-DA01411).

advance understanding of the short- and longer-term developmental and health consequences of child and adolescent experiences in paid work.

Our conceptual framework for this chapter draws from key principles of a life course perspective (Elder, Johnson, & Crosnoe, 2003; Mortimer & Shanahan, 2003). In this perspective, life course transitions, such as movement in and out of work, carry different meanings and result in distinct social and developmental outcomes depending on when they occur in life (i.e., the life course principle of timing). For instance, as we review in this chapter, children are likely to exhibit psychological distress and problem behaviors when they experience a high degree of autonomy, status, and earnings at work. For adults, these dimensions of work are coveted. A life course perspective also stresses how an individual's experiences and trajectories through work, school, and family are inherently interwoven with the life course trajectories of significant others (i.e., principle of linked lives). Children's experiences in paid work are affected by their parent's labor market experiences and attainments, as well as the expectations they have for their children. In a life course perspective, it is also assumed that youth are planful and make choices within the social and environmental constraints of opportunities (i.e., principle of bounded agency). Social forces such as poverty and poor labor markets can greatly limit opportunities for even the most agentic youth to establish themselves in the world of work.

Here we seek to understand how family background, prior experiences and orientations, interpersonal relationships, and macrolevel changes (e.g., economic shocks such as Great Recession, shifts in labor market structure) influence the timing of entry into work and the quality of initial jobs; how these early work experiences are linked to school achievement, other work activities (housework, schoolwork, volunteer work), social development, and problem behaviors; and the potential long-term consequences of early involvements in paid work with respect to health and well-being, as well as engagement and success in work, school, and family as young people make the transition into adulthood.

The chapter is divided into three parts: The first part considers youth employment in the United States, and much of this section draws from previous reviews and research on this topic (e.g., Mortimer, 2010; Mortimer & Staff, 2008; Staff, Messersmith, & Schulenberg, 2009). We examine when youth in the United States enter the labor force, with particular attention to the hours, type, and quality of these experiences, and how entry into work

varies by gender, race/ethnicity, and family background. Next, we highlight employment during the high school years. We consider the types, hours, and qualities of jobs that young people hold, and more generally, the functional form of these early "careers." We also examine how these work experiences are associated with prior orientations and behaviors as well as family socioeconomic background.

We then consider research on the correlates and consequences of youth work, highlighting four major perspectives on this topic. One view is that employment is developmentally, socially, and academically harmful, and it should be avoided. A second view is that the developmental consequences of employment depend on the quality of the job and the intensity of the involvement. A third view questions whether paid work has good or bad effects on development and instead suggests that these relations are spurious. The final view posits that the effects of teenage employment (both good and bad) depend on the worker.

To highlight some recent trends in youth employment in the United States, as well as descriptive associations of paid work with youth achievement and adjustment, throughout this section we present figures based on cross-sectional data from multiple nationally representative cohorts of the Monitoring the Future (MTF) project. The MTF project is an ongoing cohort sequential and prospective study of middle and high school students in the United States (Johnston, O'Malley, Bachman, & Schulenberg, 2013). Beginning in 1976, large, nationally representative samples of 8th, 10th, and 12th graders (approximate ages range from 13–14 to 17–18) were selected each year from both public and private high schools. Self-completed questionnaires were administered in classroom settings. Approximately 90% of students responded to these baseline surveys, with nearly all nonresponse due to absenteeism. For the interested reader, data from the public release version of these grade cohorts are available to download at the Inter-university Consortium for Political and Social Research (<http://www.icpsr.umich.edu/icpsrweb/ICPSR/series/35>). Details of the Monitoring the Future study are also available (<http://monitoringthefuture.org/>). In this chapter, cross-sectional data are used from 20 8th- and 10th-grade cohorts (from 1992 to 2010) and more than 30 12th-grade cohorts (from 1977 to 2010).

In the second section, we review the literature on child and adolescent employment in an international context, discussing some major themes in this diverse literature. Most

of our review focuses on children's employment in "developing" economies.<sup>1</sup> Our goal here is not to provide an exhaustive review of this literature. Instead, we aim to highlight some of the unique situations that young workers in developing countries face as they leave school and enter the labor market. Similar to the previous section, we examine recent trends in youth work, some of the reasons why children work, and the basic characteristics of the work that children and adolescents do in developing countries. We then apply the four perspectives to international studies of youth work, highlighting exploitative and beneficial forms of child labor, noting how child labor can serve as socialization for adult labor and the importance of children's work in the family economy.

In the final section, we discuss potential areas of new research on youth employment. These research areas include: the impact of the global recession, or of economic shocks more generally, on child and youth work in both the United States and worldwide; further examination of how different types and qualities of work relate to children and adolescent outcomes; and more studies that consider diverse trajectories of school and work involvement during the early occupational career.

## CHILDREN AT WORK IN THE UNITED STATES

We begin this section with an overview of the scope of youth work in the United States, highlighting the onset, intensity, job type, and demographic correlates of these early experiences in the labor market.

### Entering the Labor Force

Cross-sectional and longitudinal studies of young people in the United States have consistently shown that most children and adolescents work for pay. For instance, an estimated 80% to 90% of youth will spend time in a paid job before leaving secondary school (Hirschman & Voloshin, 2007; U.S. Department of Labor, 2000), although it is important to note there has been a steep decline in teenage employment rates in the years during and following the Great Recession (i.e., since 2008). Studies have also well

documented that high school students are more likely to be employed than middle school students. In addition, the average hours of employment per week, or the "intensity" of work, increases as youth progress through secondary school (U.S. Department of Labor, 2000).

In recent years, however, youth employment has become less prevalent. For instance, in Figures 9.1a and 9.1b, we use data from the MTF to illustrate cohort changes in the percentages of 8th and 10th graders who worked during the school years, as well as the percentages of youth who

**Figure 9.1a** Percentage of 8th graders employed (and average hours worked among working youth) during the school year by cohort year.

**Figure 9.1b** Percentage of 10th graders employed (and average hours worked among working youth) during the school year by cohort year.

Source: Monitoring the Future.

<sup>1</sup>According to the United Nations, countries with developing economies have low levels of income and human capital (see [http://www.un.org/en/development/desa/policy/cdp/ldc/ldc\\_criteria.shtml](http://www.un.org/en/development/desa/policy/cdp/ldc/ldc_criteria.shtml)). Many of the countries with developing economies are located in Latin America, Africa, Asia, and Eastern Europe.

worked moderately (i.e., an average of 1 to 20 hours per week during the school year) or intensively (i.e., averaging more than 20 hours of paid work per week). These figures show unweighted percentages based on pooled nationally representative and cross-sectional datasets of 8th- and 10th-grade students from annual MTF surveys. During 8th and 10th grades, the majority of students do not work in paid jobs during the school year (64% of 8th graders and 60% of 10th graders). As shown in Figures 9.1a and 9.1b, the percentage of nonworking youth has risen steadily over the years. In 1992, for instance, 54% of 8th graders did not work during the school year, whereas in 2010, 78% were not working. For 10th graders, 57% were not employed in 1992 compared to 75% in 2010. When 8th and 10th graders do work, the majority limits their hours to fewer than 21 hours per week. Only 1.5% of 8th graders and just over 3% of 10th graders average more than 20 hours per week during the school year.

As previously mentioned, employment is much more common by the end of high school. In 2010, for example, 59% of 12th graders in the MTF reported working during the school year. Similar to the 8th and 10th graders, the percentage of employed youth has declined in recent years. Figure 9.2 shows the percentages of employed 12th graders in the United States from 1977 to 2010. Employment rates show slight fluctuations with a moderate decline from 2000 to 2007, followed by a much more pronounced drop from 2008 to 2010. Other analyses (not shown) reveal that the loss of work was heavily concentrated among 12th grade “intensive” workers. In 2000, when teenage employment

rates were at a recent high, 79% of 12th graders were employed, with 34% of workers averaging over 20 hours per week and 45% working moderately. By 2010, the percentage of moderate workers was similar to a decade earlier, with 41% of youth working moderately. However, only 18% worked intensively, and 41% were not employed. It is clear that the recent economic downturn has reduced opportunities for teenage workers, who are often the last hired and the first fired. This decline in employment is especially true among youth who would have spent long hours on the job in prior decades.

### Demographic Precursors of Child and Adolescent Employment

Sociodemographic background factors, such as gender, race/ethnicity, parent(s) education, and household income influence the timing of entry into paid work and the intensity (or average hours per week) of these early experiences (Hirschman & Voloshin, 2007; Mortimer, 2003; Mortimer, Staff, & Oesterle, 2003; National Research Council, 1998; Pabilonia, 2001). For example, in 2010, 27% of 8th-grade boys in the MTF had worked compared to only 17% of girls. Almost all of this work was limited in hours (i.e., less than 1% of girls at this age worked intensively; 2% of boys). Gender differences in the rates of employment are less stark by the 10th grade (i.e., 27% of boys were employed in 2010; 23% of girls), although boys are still more likely to work intensively when they are employed. By the 12th grade, we see gender convergence: 58% of

**Figure 9.2** Percentage of employed 12th graders during the school year by cohort year.

Source: Monitoring the Future.

**Figure 9.3** Parent(s) education (z scored) by work status and hours, separately for 8th and 10th graders (combined 1992 to 2010 MTF cohorts).

Source: Monitoring the Future.

boys and 59% of girls are employed; 18% of boys and 17% of girls work intensively (Bachman, Johnston, & O'Malley, 2011).

Research also has documented that European American youth are much more likely than African American youth to work during the school year. In 2010, 53% of African American 12th graders in the MTF reported not working, compared to 35% of European American youth (Bachman, Johnston, et al., 2011). Latin American teenagers have a similar low employment rate compared to European Americans. When employed, however, African American and Latin American teenagers spend more time on the job (on average, African American and Latino/a American youth spend between 3 and 5 additional hours per week of work during the school year compared to European American youth; U.S. Department of Labor, 2000; see also the National Research Council, 1998).

Family socioeconomic background (i.e., parent(s) education, job status, income, and occupational prestige) influences both the age of labor market entry and the average hours of employment. In general, youth in lower income households enter the labor market at older ages than youth who reside in families with higher incomes (Sum, Khatiwada, Trubsky, & Ross, 2014; U.S. Department of Labor, 2000). However, research consistently shows that youth from disadvantaged backgrounds, as assessed by both household income and parent(s) education, average more hours when they are employed than their more advantaged schoolmates (Entwisle, Alexander, & Olson, 2000; Hirschman & Voloshin, 2007; Mortimer, 2003; Mortimer et al., 2003; Staff & Mortimer, 2008).

Figure 9.3 illustrates this pattern of selectivity into paid work with descriptive statistics from the MTF 8th- and 10th-grade cohorts. In this study, 8th- and 10th-grade youth reported the educational degree of their mother and father, which we averaged and then transformed into a z-score to ease interpretation. Figure 9.3 shows levels of parent(s) education for nonworking, moderately working (i.e., 1 to 20 hours of work per week during the school year), and intensively working (more than 20 hours per week) youth, separately for 8th and 10th graders. In both grades, nonworking youth have parents with slightly lower than average levels of education (by less than .05 of a standard deviation). However, it is clear in Figure 9.3 that intensively working youth are disproportionately drawn from families in which parents have limited education.

### Where Do Children and Adolescents in the United States Work?

Children and adolescents in the United States are most likely to be employed in the retail sector of the economy, and compared to earlier cohorts of youth, they are less likely to be employed in agriculture and mining, construction, and manufacturing industries (U.S. Department of Labor, 2000). Hirschman and Voloshin (2007), using data from the 2005 Current Population Survey, showed that over three-quarters of working youth the ages of 16 to 19 were employed in food service (primarily food preparation and serving), sales, and office administration.

The MTF study also contains detailed information on the types of jobs youth work in during the school year. The

majority of eighth-grade workers are employed informally during the school year, mostly working as babysitters (41%) or yard workers (21%; Staff et al., 2009). The percentage of working eighth graders employed in lawn work has climbed in recent years (from approximately 16% in 1991 to 26% in 2010), whereas work in newspaper delivery has almost disappeared. In 2010, less than 1% of working youth delivered newspapers. Perhaps the vanishing opportunities for delivering newspapers accounts for the recent increase in the percentage of youth working in lawn care.

By 10th grade, increasing numbers of working youth are employed in restaurants (16%), although 41% of youth still work in informal jobs. Store clerk and fast-food worker are the most common jobs held by 10th graders (7% each of workers). However, the percentage of 10th graders employed in fast-food jobs has tumbled in recent years. In 1991, for instance, over 10% of working youth were employed in fast food; in 2010, only 3% worked in these jobs. The percentage of 10th graders employed as store clerks showed a similar decline (from 10% in 1991 to 4% in 2010). Again, lawn work has increased from 9% in 1991 to 18% in 2010. By 12th grade, less than 10% of youth work in informal jobs. Instead, one-quarter of youth are employed as clerks, and 28% work in restaurants. Approximately 20% of youth in the MTF reported working in “other” jobs.

Sociodemographic background factors also influence the types of jobs young people have. In 8th grade, for example, girls are more likely than boys to work in babysitting (72%), whereas boys are most likely to work in lawn care (37%). Youth whose parents have high levels of education are most likely to work in office jobs, whereas those from more disadvantaged backgrounds are more likely to work in restaurants and especially in fast food. African Americans are also more likely than European Americans to work in fast-food jobs (see Staff, Schulenberg, Bachman, Parks, & VanEseltine, 2013).

In summary, youth in the United States begin working in informal jobs (babysitting for girls; yard work for boys) during the middle school years, and then transition into a broad range of jobs, indicating a high level of diversity in early work experiences (see also U.S. Department of Labor, 2000).

## PERSPECTIVES ON YOUTH WORK

Now that we have presented data that indicates how much and where U.S. teenagers work, we turn to consider

whether teenage employment is good or bad for youth development. There are four general perspectives on this issue that we discuss in this section.

### Perspective 1. Children and Adolescents Should Not Work

Think back to the jobs you held as a child (assuming that you worked, which as we mentioned earlier was the case for at least 8 out of 10 youth in the United States.). Did you learn anything on the job? What did you do with your earnings? Did you work with adults? In the groundbreaking *When Teenagers Work: The Psychological and Social Costs of Adolescent Employment*, Greenberger and Steinberg (1986) challenged the popular conception that teenage work was developmentally beneficial and instead argued that the context and quality of most teenage work experiences have changed for the worse. Whereas teenagers once labored alongside family members and other adults in factories, farms, and mills, developing vocational skills that could be used throughout their careers, teenagers nowadays typically work in the worst types of jobs that offer no experiences for learning or mentorship from adults. Following Greenberger and Steinberg’s argument about the detrimental character of adolescent work, and its adverse contexts, they would likely make a number of predictions. They would expect that you worked in a job that did not provide any useful skills or preparation for future work (the “educational context”). They would argue that these jobs were costly to your formal education because the more time you spent working the less time you had to devote to your schooling. They also would argue that you probably used your earnings for discretionary purchases (buying clothes, music, or fast food) rather than saving the money for college or for helping out with family expenses (the “economic context”). They would cast doubts that you worked alongside adults; instead you would be toiling in an age-segregated workplace with coworkers and supervisors who were also teenagers (the “social context”). It was likely that you faced task overloads, time pressures, and role uncertainties that exceeded your coping strategies, and this stressed you out. In addition, the more time you spent at work, the less time you probably had to participate in more developmentally beneficial activities, such as playing sports, volunteering, helping out with household chores, and spending time with family and friends in more structured activities. Instead, you probably spent more time with older coworkers and friends in unstructured settings that increased the chances of engaging in inappropriate

and possibly harmful adult-like behaviors (i.e., drinking, smoking, and sexual activity).

Are early work experiences in the United States really that bad? Does work undermine school pursuits and contribute to problem behaviors? Does it pose long-term “opportunity costs”? Do most teenagers only spend their earnings on themselves? Let us now examine the empirical evidence. Below, we consider each context in more detail.

### *The Educational Context*

In an influential report issued by James Coleman and other leading social scientists in the 1970s, teenagers were encouraged to obtain jobs (Coleman et al., 1974). The report noted that adults in the workplace could provide vocational guidance for young people by teaching them valuable job-related skills, by facilitating connections to other adult supervisors and coworkers, or by providing references for future employment opportunities. Adult coworkers and supervisors may also provide educational guidance by informing young workers about the educational credentials they will need for future professions, as well as helping them to apply at work what they have learned in school. Adults in the workplace could also teach young workers “soft-skills” that are valued by employers, such as how to be hardworking, responsible, and independent; how to conduct oneself in an interview; how to interact with customers, coworkers, and supervisors; and how to participate in cooperative activities. Perhaps most importantly, it was believed that working could effectively counter the common experience of age segregation among youth, helping smooth their transition from

school into work and more generally from adolescence to adulthood.

Greenberger and Steinberg (1986) did not disagree with the potential benefits of youth working with adults. Their claim, however, was that contemporary teenagers in the United States do not work alongside adults, but instead face an abundance of same-age coworkers (Steinberg & Cauffman, 1995). In such settings, adolescents who work primarily alongside teenage supervisors and coworkers will have few opportunities to learn vocational skills and positive work ethics from adult mentors. Youth employed in age-segregated jobs may also develop cynical attitudes toward work and a tolerance for poor work performance and workplace deviance (Greenberger & Steinberg, 1986). Much depends on the social context in which youth work. Research shows that adolescents who are employed alongside delinquent coworkers are more likely to be delinquent, both while they are at work and after they leave, compared to employed youth who do not labor alongside delinquent peers (Ploeger, 1997; Wright & Cullen, 2000).

Do teenagers mostly work with other teenagers? To help answer this question, for many years, the MTF study has collected information on the work experiences of successive nationally representative 12th-grade senior cohorts. In each cohort, youth were asked to report not only their work hours and the type of work they performed, but also the quality of these early work experiences. Figure 9.4 displays the percentage of employed 12th graders in the MTF study who reported working with mostly teenage coworkers, whose supervisor was Age 25 or younger, and who experienced a high degree of age-segregation (i.e., they reported

**Figure 9.4** Percentage of employed 12th graders who work with mostly teenage coworkers, whose supervisor is Age 25 or younger, and who experience an age-segregated workplace, by cohort year (combined 1983 to 2003 cohorts).

Source: Monitoring the Future.

that “nearly all” or “all” of their coworkers were teenagers *and* their supervisor was Age 25 or younger). These questions about the ages of supervisors and coworkers were asked to 20 senior year cohorts from 1983 to 2003, enabling us to examine trends over time.

As shown in Figure 9.4, only about 20% of employed seniors reported that “nearly all” or “all” coworkers were within 2 or 3 years of their own age. In addition, less than 20% of seniors worked with a supervisor who was 25 years or younger. Surprisingly, only 5% of 12th graders had a truly age-segregated workplace, with a supervisor under the age of 26 and almost all young coworkers. It is noteworthy that these trends are remarkably consistent over time (from 1983 to 2003). These basic descriptive statistics challenge the notion that most teenagers face a high degree of age-segregation in the workplace.

The MTF also contains information on the skill development and career potential of these early work experiences (Johnston, Bachman, & O'Malley, 2005). Seniors in high school were asked “to what extent did this job use your skills and abilities—let you do the things you do best” and “teach you new skills that will be useful in your future work.” Responses to these items ranged from 1 (“not at all”) to 5 (“a great extent”). Respondents also were asked to indicate the level of career potential in their senior-year jobs, such as the extent to which the job was “a job you could be happy doing for the rest of your life”; “the type of work you expect to be doing for most of your life”; or “a good stepping-stone toward the kind of work you want in the long run.” In 2003, the last year that information on work quality was collected in the MTF, 31% of working seniors noted that their job to a “considerable” or “great” extent taught them new skills that would be useful in future work, and 28% similarly expressed that the job made use of their skills and abilities, letting them do the things that they do best. In fact, more than 80% of working youth in 2003 felt that their job offered at least “a little” of these advantages. However, when asked if this was a job they could be happy doing for the rest of their lives, or the type of work they expected to be doing for the rest of their lives, 62% and 73%, respectively, said “not at all.” Furthermore, just over half of working seniors also replied that their current job was “not at all” a stepping-stone toward future career work.

These descriptive statistics challenge the notion that the educational context of work is indeed lacking for many young workers in the United States. However, paid work may still negatively impact educational outcomes if these early work experiences limit time that could be spent

participating in school activities, completing homework, meeting with teachers and tutors, or studying for exams. The compatibility of work with school has long been a salient issue for employed teenagers. Scholars have been especially worried that paid work interferes with academic pursuits (Marsh & Kleitman, 2005; Steinberg & Cauffman, 1995). Research shows that when employed teenagers feel that their work is interfering with school, they show higher levels of depressed mood, a reduced sense of well-being, and higher rates of school misconduct, alcohol use, and arrest (Mortimer, Harley, & Staff, 2002; Staff & Uggen, 2003). But when employed high school seniors in the MTF were asked if their jobs were interfering with their education, just under half replied “not at all” (Johnston et al., 2005).<sup>2</sup> The meaning of these responses is somewhat ambiguous, as youth who have little interest in school may report little interference, whereas youth who are highly motivated to be good students may be more sensitive to fluctuating work demands and report high work/school incompatibility.

To assess this key issue of work/school incompatibility, most research has compared students with different work conditions with cross-sectional data or has examined work-school associations longitudinally, controlling for lagged school outcome variables. In these studies, working and nonworking children show similar levels of school engagement and performance, which challenges the notion that working in adolescence is universally bad for early scholastic achievements (Mortimer & Finch, 1986; Steinberg, Greenberger, Garduque, Ruggiero, & Vaux, 1982; Warren, LePore, & Mare, 2000). However, when youth work intensively during the school year (i.e., average more than 20 hours per week), compared to when they work moderately or not at all, they show lower levels of school effort, engagement, attendance, and completed homework assignments (Carr, Wright, & Brody, 1996; D'Amico, 1984; Greenberger & Steinberg, 1986; Lee & Staff, 2007; Marsh & Kleitman, 2005; McNeal, 1997; Monahan, Lee, & Steinberg, 2011; Mortimer & Finch, 1986; Schoenhals, Tienda, & Schneider, 1998; Staff, Schulenberg, & Bachman, 2010; Steinberg et al., 1982; Warren & Lee, 2003). Intensively employed teenagers also report lower grade-point averages and achievement scores, as well as lower odds of high school graduation, than nonworking and moderately working youth.

---

<sup>2</sup>The percentage of youth reporting no work/school conflict has been remarkably consistent in the MTF over the years.

Intensive involvement in paid labor during high school is also associated with subsequent educational investment. For instance, heavy involvement in paid work during adolescence (more than 20 hours per week throughout high school) is linked to a lower likelihood of obtaining a 4-year college degree, compared to youth who limited their hours of work and worked steadily during high school (Bachman, Staff, O'Malley, Schulenberg, & Freedman-Doan, 2011; Carr et al., 1996; Mortimer, 2003; Staff & Mortimer, 2007). Moreover, adolescents who pursue intensive work hours obtain fewer months of higher education than do their nonworking or moderately working peers (Mortimer et al., 2003). Although some youth employment experiences are valuable for education (Leventhal, Graber, & Brooks-Gunn, 2001; Mortimer, 2003), research consistently demonstrates that heavy investment in work while still in school has short- and longer-term educational costs (Bachman, Staff, et al., 2011; Lee & Staff, 2007; Staff & Mortimer, 2007; Warren & Lee, 2003).

In sum, prior research supports the contention that education can be compromised if youth spend long hours on the job (which, as we have seen, has become less likely over time). The majority of youth also do not view their early work experiences as career-like. However, many youth perceive their jobs as valuable learning opportunities, and there is little evidence to suggest that working limited hours is detrimental to school success (in fact, evidence suggests it can be beneficial).

### *The Economic Context*

A long-standing critique of youth work is that for most children in the United States getting a job is economically unnecessary. As noted earlier, the majority of employed youth are from more advantaged family backgrounds (i.e., they reside in families with higher levels of household income and education). Among these youth, earnings from paid jobs are likely to be used for personal purchases or leisure spending. They are unlikely to be used for school expenses or saved for college. They are unlikely to be given to parent(s) for household expenses. If paid work poses unacceptable risks to education and social development (as some scholars have claimed), and the earnings are typically only used for leisure spending, then perhaps teenagers should delay their entry into the labor force until they are older.

Are teenagers in the United States really motivated to work only so they can buy things? In the Youth Development Study (YDS), a multigenerational longitudinal study of teenagers who initially resided in St. Paul, Minnesota

in 1988, over three-quarters of working youth from the 9th to the 12th grade (i.e., from 1988 to 1991) sought work "to buy things." However, in higher grades they were increasingly likely to seek employment in order to save for education and other purposes (Mortimer, 2003). An examination of how these youth spent their earnings shows that only small percentages of youth gave any of their earnings to their parents for the family's expenses, although much higher proportions used their earnings for school expenses and to save for future education (i.e., just under half of employed high school seniors). In 2010, over half of high school seniors in the MTF reported that they saved at least some of their earnings for future educational expenses, just under half (44%) contributed some of their earnings to pay family living expenses (groceries, housing), and only 19% spent "almost all" or "all" of their earnings on their own needs and activities, such as clothes, music, eating out, or other recreation.

It is clear that many students use their earnings for leisure spending. However, the fact that many employed students, especially in the later years of high school, used at least some of their pay for "nonleisure" spending (Shanahan, Elder, Burchinal, & Conger, 1996) challenges the notion that employed teenagers do not use their earnings in useful ways (i.e., helping their families make ends meet or saving for their future education). It might be assumed that high leisure spending among working teenagers is inherently bad, but little research has considered how youth's expenditures of their earnings from work relates to school success, problem behaviors, and parent-adolescent relationships. Shanahan et al. (1996), in a study of rural youth in Iowa, found that parent-adolescent relationships improved when youth used their earnings for clothes, shoes, school fees, or gave their money to parents. In fact, parents of teenagers are overwhelmingly positive about their children's employment and encourage them to work (Mortimer, 2003). Some believe that their children's paying jobs teach them the value of money and would prefer that they spend their own earnings for nonessential "leisure" activities, such as a prom dress or a concert, rather than relying on their parents for such expenses. Nonetheless, high discretionary spending among working teenagers may still have negative developmental and social consequences, especially if they are spending their money on cigarettes, alcohol, and illicit drugs, or if they develop a sense of "premature affluence" that is unsustainable when they leave the parental home (Bachman, 1983). We discuss these potentially negative effects of work on social development next.

### *The Social Context*

Paid work could harm social development in several ways. First, paid work could limit time that can be spent in organized, extracurricular activities, such as participation in sports, theatre, arts, and various other academic clubs and organizations. Extracurricular activities are generally viewed as developmentally and socially beneficial as they provide opportunities for youth to explore their potential interests and values in structured settings that are typically organized and supervised by adults (Csikszentmihalyi & Schneider, 2000). In fact, extracurricular involvement in sports and clubs during adolescence is associated with positive adjustment in high school, and these developmental benefits can reach into early adulthood (Barber, Eccles, & Stone, 2001; Eccles & Barber, 1999). However, some studies have found a positive association between sports participation and substance use during adolescence (e.g., Crosnoe, 2002; Hoffmann, 2006; Peck, Vida, & Eccles, 2008).

The zero-sum argument against teenage labor is that working youth will have less time available to engage in school-related activities, especially if they spend a lot of time at work. Working youth also may limit their extracurricular participation in academic clubs and athletics because their work schedules change from week to week and they are unable to commit to these scheduled school activities. Consistent with this argument, Osgood (1999) found that working youth were less likely to participate in extracurricular sports as work hours increased during the school year. Instead, employed teenagers may be more likely to hang out with friends in unstructured settings and without adult supervision (Safron, Bachman, & Schulenberg, 2001). According to routine activities theory, hanging out with friends and no "capable guardians" (i.e., parents, teachers, other adults) in an unstructured setting heightens the likelihood of delinquency, substance use, and precocious sexual activity. As mentioned previously, employment, especially among those working intensively, also provides teenagers with financial resources to spend on leisure activities, which can enable more unstructured and unsupervised socializing (Osgood, 1999). In fact, youth who spend long hours on the job are more likely to go to parties and bars, go on dates, and ride around in cars for fun, all of which are activities that increase the likelihood of delinquency and substance use (Osgood, Wilson, O'Malley, Bachman, & Johnston, 1996). Youth who work more than 20 hours per week are also more likely than nonworking and moderately working

youth to engage in delinquency and substance use (Apel, Paternoster, Bushway, & Brame, 2006; Greenberger & Steinberg, 1986; McMorris & Uggen, 2000; Mortimer & Johnson, 1998a; Staff, Osgood, Schulenberg, Bachman, & Messersmith, 2010; Steinberg & Dornbusch, 1991; Steinberg, Fegley, & Dornbusch, 1993).

In addition to heightening unstructured and unsupervised forms of leisure, youth employment may weaken the influence of significant others (i.e., teachers, parents and family members, coaches) in restraining problem behaviors. According to social control theory (Hirschi, 1969; Kornhauser, 1978), youth are less likely to be delinquent when they are strongly "bonded" to social institutions such as the family and school. For instance, social bonds that facilitate socialization and restrain deviant behavior include involvement in school and family activities, attachment to parents and teachers, and commitment to school and to long-term educational achievement. For some youth, employment may weaken these bonds to teachers and parents, especially if work is providing income for discretionary spending, autonomy from parent supervision (e.g., employment requiring late hours away from home), and a source of status outside the school setting (e.g., gaining status from peers due to discretionary spending; Staff & Uggen, 2003). Delinquent acts and other problem behaviors are more likely when youth reject the authority of parents and schools. The experience of working may also reinforce a sense of precocious adult independence, weakening ties to parents, and leading to greater freedom from parental control (Greenberger & Steinberg, 1986; Longest & Shanahan, 2007).

Indeed, scholars have long expressed concern that involvement in paid work may hurry adolescence and engender a precocious maturity of more adult-like role statuses and problem behaviors, including disengagement from school and parents; alcohol, cigarette, and illicit drug use; dating and sexual activity; inadequate sleep and exercise; and work-related distress (Bachman & Schulenberg, 1993; Greenberger & Steinberg, 1986; Newcomb & Bentler, 1988; Safron et al., 2001). Although negative associations between high-intensity work and adolescent adjustment have been well documented (as described), employed adolescents may take on precocious family roles and behaviors as well, such as initiation of sexual activity, pregnancy, union formation, and residence away from the parental home, before they are developmentally ready for these more adult-like roles and responsibilities (Greenberger & Steinberg, 1986). Bozick (2006) found that adolescents who worked intensively experienced

their first sexual intercourse earlier than their nonworking and moderately employed peers. Using nationally representative data from the National Longitudinal Study of Adolescent Health, Staff, VanEseltine, Woolnough, Silver, and Burrington (2012) found that teenagers who spend long hours on the job during the school year are likely to experience precocious family behaviors in adolescence, such as sexual intercourse, pregnancy, childbearing, residential independence, and union formation, earlier than youth who work moderately or not at all.

More generally, paid work may expose children and teenagers to more adult-like situations that they are inadequately equipped to handle. For instance, experiencing work stressors during adolescence is positively related to depressed mood and negatively related to self-esteem and self-efficacy, even after controlling prior mental health and other risk factors (Finch, Shanahan, Mortimer, & Ryu, 1991; Mortimer et al. 2002; Mortimer & Staff, 2004; Shanahan, Finch, Mortimer, & Ryu, 1991). Excessive demands and stressors at work are also associated with increased cigarette, alcohol, and substance use (Bachman & Schulenberg, 1993), as teenagers may be using these substances to cope with work-related distress. Youth may be especially sensitive to excessive work demands and high stressors if they have a strong orientation to school. As mentioned earlier, competing work and school demands have been shown to heighten depressed mood and reduce well-being (Mortimer et al., 2002). Furthermore, youth have higher rates of school-related misconduct, alcohol use, and contact with the police when they believe that their jobs are interfering with their academic pursuits (Staff & Uggen, 2003). Employed teenagers also face a relatively high risk of sexual harassment (Houle, Staff, Mortimer, Uggen, & Blackstone, 2011), partly because they have little power in the workplace and are perceived as easier targets (Blackstone, Uggen, & McLaughlin, 2009). Based on this research, high work demands, stressors, school incompatibility, and sexual harassment could have numerous undesirable effects on positive youth development.

In summary, although it is unclear whether all early work experiences are bad or whether certain jobs are better than others, there is considerable evidence that involvement in paid work during adolescence is associated with poor school performance, limited involvement in extracurricular activities, use of alcohol and illegal substances, minor delinquency, and precocious family formation behaviors as well as reduced educational attainment in young adulthood. Yet, these deleterious effects of paid work are mostly limited to youth who work intensively, and intensive work

has diminished markedly during the past decade. In the next section, we highlight studies that show short- and longer-term benefits of *moderate* work involvement during the high school years.

## **Perspective 2. Working During Adolescence Isn't All That Bad, and a Little Bit of Work Can Actually Be Good**

Whereas some studies suggest that contemporary teenagers are unlikely to find high-quality work experiences that are developmentally beneficial, recent research suggests otherwise, showing considerable variability in quality-relevant job characteristics. For instance, Hirschman and Voloshin (2007) found that youth working as lifeguards, athletic coaches, tutors, office clerks, or receptionists were in “good” jobs because they earned higher wages and worked fewer hours per week than youth who worked in retail, food service, or blue-collar jobs. Research by Mortimer and colleagues (Call & Mortimer, 2001; Mortimer, 2003; Mortimer et al., 2002; Mortimer & Staff, 2004; Staff et al., 2013) showed that the employment conditions of teenagers vary across other important dimensions as well, such as the amount of adult supervision and support; degree of learning opportunities and skill utilization; long-term career potential; stress; and compatibility with activities in other domains, including school, family, and friends. These studies suggest that not all teenagers work in bad jobs, and that some work experiences may be more beneficial than others.

First, as we showed in Figure 9.4, many youth work with adult coworkers and supervisors, and these jobs can offset age segregation among youth. In fact, social scientists have argued that teenagers should seek employment to develop “closer personal relations between adults and youth” (Coleman et al., 1974, p. 160; National Research Council, 1998). As mentioned before, adult mentors can provide numerous developmental and vocational benefits to young workers (e.g., teaching job-related and “soft” skills, providing educational guidance and references for future employment opportunities). In addition, it was believed that these early work experiences would *limit* the excessive and worrisome leisure activities of teenagers who were once perceived as an anti-adult “adolescent society” (Coleman et al., 1974).

Second, it is clear from the descriptive tables earlier that some youth work in jobs that they perceive as providing skills and workplace knowledge that may be useful in preparation for their future careers. Skill utilization and

learning opportunities on the job have been shown to promote the development of occupational values in adolescence (Mortimer, Finch, Ryu, Shanahan, & Call, 1996) and provide long-term vocational benefits in young adulthood (Mortimer, 2003). Skill utilization in the workplace can provide social benefits as well, improving relationships with family and peers and mental health (Mortimer & Shanahan, 1991; Shanahan et al., 1991). Youth are less likely to use illicit drugs and alcohol when early work experiences are connected to future careers and provide young people with opportunities to learn new job skills. For instance, Staff and Uggen (2003) using longitudinal data, found that work that provided opportunities to learn useful skills was negatively associated with substance use in the 12th grade, even after controlling for work hours and prior substance use. Similarly, Schulenberg and Bachman (1993) found that youth were less likely to drink alcohol and use illicit drugs when early work experiences were career relevant and provided opportunities to learn new skills.

Third, research shows that many working youth are able to balance their multiple commitments to teachers, parents, friends, and employers (Mortimer, 2003; Shanahan & Flaherty, 2001). For instance, Shanahan and Flaherty (2001), using longitudinal data from the YDS, examined how youth combined paid work, homework, extracurricular activities, volunteer work, household work, and leisure time with friends during the high school years. Using person-centered cluster analyses, the authors identified several distinct ways youth spent their time from 9th to the 12th grade. Importantly, youth adhering to the two most prevalent patterns of time use showed almost identical amounts of time spent completing homework, doing household chores, volunteering, and participating in extracurricular activities. However, those in one group did not work (20% of the 12th-grade sample), whereas those in the other group (35% of the 12th-grade sample) spent considerable time in paid work (averaging approximately 20 hours per week in the 12th grade). Furthermore, time spent with friends in nonstructured leisure activities, which according to routine activities theory (Osgood, 1999) is the most likely to foster problem behaviors, was fairly consistent across the various patterns of time use (ranging from 6 to 9 hours per week).

This detailed examination of time use in adolescence suggested that employed youth who limit their working hours make time for extracurricular activities as well as for household, school, and volunteer work. In addition, moderate hours of employment do not appear to limit one's use

of time, as most youth make time for nonstructured leisure activities. However, when young people are employed (both moderately and intensively), they tend to watch less television (Bachman, Safron, Sy, & Schulenberg, 2003; Osgood, 1999; Schoenhals et al., 1998). We are hardly experts on the developmental consequences of television use, but this does not strike us as an opportunity cost.<sup>3</sup>

Importantly, limited hours of employment during adolescence (20 hours or fewer per week during high school) do not harm school performance and may actually encourage success in school. For instance, research using diverse datasets and methodologies has shown that youth who work moderately, compared to youth who work intensively or not at all, tend to be the most involved in school activities, have the highest grade point averages, and have the lowest rates of high school dropout (D'Amico, 1984; Mihalic & Elliott, 1997; Mortimer & Johnson, 1998b). Moreover, studies show little difference between nonworking youth and those who work moderately in class rank, hours spent doing homework, or time devoted to reading outside of class (D'Amico, 1984; Schoenhals et al., 1998).

In one study, Bachman, Johnston, et al. (2011) used nationally representative longitudinal data from the MTF to investigate the long-term consequences of teenage employment for educational attainment. Multiple cohorts of eighth graders were followed for 8 years (modal ages 14 to 22), and 12th graders for up to 12 years (to modal ages 29 to 30). Bachman and colleagues used propensity score matching to compare nonworking, moderately working, and intensively working youth who had a similar likelihood of working intensively, to control for observed differences between students. The results showed that high-intensity workers were less likely to complete college than both moderate and nonworking youth. However, moderate work did not have long-term educational costs.

Other studies have shown that when youth maintain moderate hours of employment over the duration of high school, they are especially likely to attend and complete a 4-year college degree (Mortimer, 2003; Staff & Mortimer, 2007). Part of the reason for the long-term educational advantages of the "steady" workers, at least compared to youth who worked occasionally (i.e., limited hours and months of employment), sporadically (i.e., intensive hours but limited months of employment), or intensively (i.e., intensive hours and more continuous employment),

---

<sup>3</sup>We are not aware of research on whether employment leads to time trade-offs with other, increasingly prevalent, leisure activities, such as video games and Internet use.

was that they followed a similar balanced strategy of continuous employment and moderate work hours in the years following high school. This strategy of employment during secondary and postsecondary school especially benefited the long-term educational attainment of youth who displayed limited educational promise (low grades and aspirations) at the onset of high school.

Early work is associated with immediate and longer-term benefits in other developmental domains as well. For example, early work experiences may help adolescents gain a sense of responsibility, independence, and self-confidence (Aronson, Mortimer, Zierman, & Hacker, 1996; Elder & Rockwell, 1979; Greenberger, 1988; Greenberger & Steinberg, 1986; Phillips & Sandstrom, 1990). Paid work can provide additional developmental advantages by exposing teenagers to new challenges outside of school (i.e., dealing with customers), by promoting valuable coping skills (such as how to deal with stress from work), and by helping them gain status among peers (Mortimer, 2003; Mortimer et al., 1996; Mortimer & Shanahan, 1991, 1994). As mentioned before, working youth, especially in jobs with learning opportunities and skill utilization, have been shown to have more crystallized work values than nonworking youth. The development of occupational values in adolescence is perhaps especially important among recent cohorts of youth, given that they are often undecided on what occupation they would like to hold as adults (Rindfuss, Cooksey, & Sutterlin, 1999; Schneider & Stevenson, 1999; Staff, Harris, Sabates, & Briddell, 2010).

Youth who limit their hours of work (especially to 20 hours per week or less) make time for school-related leisure and work activities. In addition, moderately employed youth tend to have higher educational attainment than their peers who work intensively or not at all. However, some research shows that even intensive work roles in adolescence can benefit occupational attainment, at least in the short term. For instance, youth who worked intensively during adolescence had lower odds of unemployment and significantly higher wages in the years immediately following high school compared to nonworking youth and those who worked moderately (Stern & Nakata, 1989). Carr et al. (1996) showed similar occupational benefits in young adulthood (i.e., higher wages and likelihood of employment) among intensive high school workers. Moreover, teenagers with a lengthy work history (total years employed) have “greater employability” in young adulthood (Mihalic & Elliott, 1997). In the YDS, those teenagers who worked over 20 hours per week throughout

most of their high school years averaged the most months of full-time work, as well as the highest wages, in the years immediately following high school (Mortimer et al., 2003; Staff & Mortimer, 2008). Thus, it appears that even long hours of work during adolescence can have positive short-term occupational benefits in the years following high school, despite the negative association with educational attainment.

Finally, though work hours and problem behaviors are positively correlated during adolescence, intensive teenage work hours do not significantly predict problem behaviors in young adulthood. For instance, adolescent work hours were not associated with higher rates of alcohol, marijuana, or cocaine use in young adulthood (Bachman et al., 2002, 2011; McMorris & Uggen, 2000). However, Bachman et al. (2011) found that high-intensity teenage work in the 12th grade predicted higher rates of smoking at Age 28, even after controlling for past cigarette use. The authors suggested that intensive workers in high school who take up smoking may have great difficulty in kicking the habit. In addition, Mihalic and Elliott (1997) found that total years of adolescent work—not work hours—predicted higher rates of alcohol and marijuana use at Ages 27 and 28.

In summary, many studies have challenged the notion that all adolescent work experiences are bad and that youth are unable to balance their multiple commitments to family, friends, school, and employers. Indeed, a number of researchers have shown both short- and longer-term benefits in a variety of life domains (school, work, adjustment) when children and teenagers work moderately in “good” jobs that provide learning opportunities and skill utilization. Yet, as we discuss next, some scholars have questioned whether these associations are causal effects of work experiences or instead reflect the preexisting qualities and traits of youth who select into various work intensities of more or less quality.

### **Perspective 3. Paid Work Has Little Effect on Adolescent Achievement and Adjustment**

A third view of child and adolescent employment is that preexisting characteristics, motivations, and orientations of the individual, both observed and unobserved, explain work-related outcomes. For instance, intensively working youth may not receive lower grades because they have less time to devote to homework or studying than nonworking youth (e.g., Perspective 1). Moderately working youth do not necessarily earn higher grades than nonworking youth because their jobs teach them how to more effectively

**Figure 9.5** Homework, GPA, and sport participation (z-scored) by actual work intensity (for employed youth) and work intensity preference (for nonemployed youth) (combined 1992 to 2010 MTF 8th- and 10th-grade cohorts).

Source: Monitoring the Future.

balance competing commitments to school, family, and friends (e.g., Perspective 2). Instead, the relation between early work experiences and achievement may be spurious.

Students who display poor achievement and show little interest in school may choose to invest more time in employment than youth who have greater success in school (National Research Council, 1998). Longitudinal studies consistently show that poor school performance, low educational aspirations, and prior problem behaviors increase the likelihood of intensive work hours during high school. By contrast, youth with high motivation, academic ability, and other resources may know how best to balance investments in both school and work during the high school years and beyond, thereby maximizing their human capital acquisition through schooling, on-the-job learning, and other workplace knowledge.

Studies using data from the National Education Longitudinal Study (NELS 88) report little evidence of a relationship between paid work hours and school performance once accounting for prior differences between individuals (Schoenhals et al., 1998; Warren et al., 2000). Cross-sectional data from the MTF and other data sources show that a strong desire for paid work is associated with poor school performance, substance use, and other problem behaviors, irrespective of actual jobholding and hours of work (Bachman et al., 2003; Warren, 2002).

More recently, to address this selection hypothesis, Staff, Schulenberg, et al. (2010) used longitudinal data from three cohorts of 8th graders whose educational progress was tracked until the 12th grade. Using a within-person analysis (to control for time-stable unobserved factors), the authors found that youth performed worse in school

when they worked intensively compared to when they worked moderately or not at all. However, youth also had poorer school outcomes (low GPA, limited extracurricular involvement, low educational expectations, limited school effort, incomplete assignments, school misbehavior, truancy, and suspension), when they were not working but wished they could work intensively.

To illustrate this pattern, Figure 9.5 displays average levels of homework, grade point average, and sports participation by actual work hours (among youth who are employed) as well as work hour preferences for work (among youth who are not employed) using cross-sectional data from the MTF. To assess work hour preferences, teenagers in the MTF were asked, “Think about the kinds of paid jobs that people your age usually have. If you could work just the number of hours that you wanted, how many hours per week would you prefer to work?” Nonworkers were divided by whether they wished to work intensively, moderately, or not at all. As shown in Figure 9.5, participation in homework and sports, as well as GPA, are remarkably similar for youth who actually spent long hours on the job and nonworking youth who merely wished they could spend long hours on the job (but for whatever reason did not). Actual moderate work shows positive associations with these school outcomes, but so do nonworking youth who desire limited hours of employment. Testifying to teenagers’ strong motivation to work, only 1 in 20 youth were not employed and did not desire to work (either moderately or intensively). Moreover, employed youth rarely wished they did not work.

The observed positive relation between intensive work and problem behaviors may also reflect the influence of

adolescents' prior orientations, motivations, behaviors, and background characteristics. Precocious development theory (Newcomb & Bentler, 1988), in particular, posits that adolescents who show little interest in school and exhibit problem behaviors (e.g., substance use, delinquency, school misconduct) are more likely to drop out of school, spend long hours on the job, leave the parental home, establish residential independence, and cohabit or marry, partly because these more "adult-like" role statuses offer fewer restrictions on their problem behaviors. Illicit drug use, in particular, is often discouraged by parents and teachers, so early drug users have a higher probability of selecting into "precocious" social environments that offer "self-sufficiency and independence," particularly acquiring a full-time job and moving out of the parental home (Newcomb & Bentler, 1988, p.169). Longitudinal research has shown that drug use subsequently increases for these precocious youth in early adulthood (Krohn, Lizotte, & Perez, 1997).

Other studies (Bachman & Schulenberg, 1993) have reported a similar relation between alcohol use and adolescent work hours. Binge drinking during high school is associated with a syndrome of adult-like behaviors such as spending long hours on the job, not participating in school-related activities, getting an inadequate amount of sleep, and eating a poor diet. Evidence from the YDS also suggests that ninth graders with higher rates of substance use, school-related deviance, and law violations worked more hours in subsequent years of high school (Mortimer, 2003; Staff & Uggen, 2003). Thus, the positive association between paid work and problem behaviors may arise from an endogenous or reciprocal process because prior engagement in these behaviors influences the decision to work and the amount of hours spent on the job.

Other theories suggest that intensive work roles in adolescence are a correlate, but not a cause, of problem behaviors in adolescence. According to problem behavior theory (Jessor & Jessor, 1977), youth who have a strong desire to act like an adult (i.e., are "transition prone") are more likely to engage in problem behaviors than youth who do not have this desire. Alcohol use, smoking, drug use, and sexual activity, in particular, are ways to claim this new adult status. Using a longitudinal sample of middle school students as well as college students from the early 1970s, the Jessors identified interrelations among marijuana use, sexual intercourse, drinking, heavy drinking, and general deviance. These behaviors were negatively correlated with conventional behaviors (e.g., school achievement and church attendance). Jessor and Jessor (1977) concluded that these

various transition behaviors represented a syndrome of adult-like activities that were often incompatible with more age-appropriate activities, like attending school. Getting a job, and spending long hours on the job, can also be a way to claim a more mature status for transition prone youth.

Prior involvement in delinquency and substance use may encourage early adult-like work patterns, but prior orientations toward work and school also may influence the motivation to work in adolescence. Once these differences are controlled, the effects of intensive work hours on substance use, delinquency, and school-related misconduct diminish to statistical nonsignificance (Apel et al., 2007). Youth who have less success in school and extracurricular activities are likely to invest themselves in paid work and to prefer work to school. Moreover, prior engagement in delinquency, such as drinking, having sex, using drugs, and misbehaving in school, may predispose some youth to enter work environments that offer fewer social constraints on these behaviors than do school and family (Newcomb & Bentler, 1988). This perspective contends that delinquency precedes involvement in work and any observed associations between paid work and deviance are spuriously related to preexisting differences between individuals. Evidence based on the annual MTF surveys suggests that an early desire for youth to work (measured before youth obtained jobs) predates both intensive work hours and problem behaviors in later adolescence (Bachman et al., 2003). Moreover, Staff, Osgood, et al. (2010) found similar levels of delinquency and substance use when youth were not working but wished they could work intensively and when they actually spent long hours on the job, even after controlling for time-stable sources of spuriousness.

In summary, paid work may have little association with short- and long-term achievement and social development during the transition to adulthood once preexisting and unobserved differences between students in their motivation, ability, and effort are taken into account. In the final section, we again highlight research that stresses the importance of selection into early work roles. However, this body of research suggests that paid work experiences *do* matter for achievement and adjustment, but these effects are conditioned by preexisting individual characteristics.

#### **Perspective 4. The Good and Bad Effects of Work Depend on the Worker**

As mentioned before, demographic background characteristics such as gender, ethnicity, and parent(s)' income and education predict whether teenagers work, what kinds

of jobs they hold, and how much they work. In particular, African American and Latino/a American teenagers are less likely to be employed than European American youth, but they average longer hours of employment during the school year when they are employed. Similarly, youth in low-SES households (socioeconomic, i.e., low education, low income, or both) are also less likely to be employed, but they, again, average more hours when they are employed than their more advantaged peers. These sociodemographic differences in work status and hours are evident even after controlling for prior achievements, orientations, and problem behaviors that select youth into work (Perspective 3).

The short- and long-term consequences of paid work may depend on the opportunities available to young people. As mentioned previously, poor youth are less likely to work than nonpoor youth. Poor youth who reside in poor neighborhoods are doubly disadvantaged in that they face a limited and often highly competitive job market (Entwisle et al., 2000; Newman, 1999), at least compared to youth who have more opportunities to find their way into the labor market. For disadvantaged youth in poor neighborhoods, just having a job might constitute a rare opportunity to earn some spending money and save for longer-term goals. Early work may be a positive experience for poor children and teenagers in low-income neighborhoods, instilling “work readiness” and positive work orientations. In contrast, youth in more prosperous neighborhoods find what was once called a “youth labor market” characterized by an abundance of low-level retail and service jobs (although it is important to note that these jobs are disappearing) as well as schools with numerous opportunities for extracurricular activities. The premature affluence (Bachman, 1983) associated with work for high-SES youth may intensify delinquency and substance use and thereby limit participation in the many school-related activities that are available. In addition, the abundance of jobs in more prosperous neighborhoods can sometimes foster more negative work attitudes and misbehaviors in young people, such as tardiness, absenteeism, and giving away of goods and services, because youth in these neighborhoods may find it easy to lose and then regain work. Thus, structural opportunities of young people may influence their involvement in paid jobs as well as both beneficial and harmful activities.

For youth from disadvantaged backgrounds, who generally have less connection to the educational system than their more advantaged peers (Kerckhoff, 2002), and who are more likely to select into intensive work roles in

adolescence (Mortimer et al., 2003), research suggests that the workplace may be an important venue for vocational development. For instance, among a sample of mostly lower SES youth in Baltimore, Entwisle et al. (2000) found that early work involvement increased the skill level of the job held in later adolescence. The authors speculated that early employment (e.g., during middle school) provided youth an alternative arena to develop their skills and increase the chances of future employment, especially if they had little interest in school. Consistent with this notion, teenagers in the YDS who engaged in more continuous and intensive employment during high school reported more work-related learning opportunities than did those who limited their hours (Mortimer, 2003). Because working is highly path-dependent, teens who are able to acquire jobs at one time are significantly more likely to be employed a year later (Sum et al., 2014), and to be reaping the potential benefits of those experiences.

Do the effects of work depend on the social background of the worker? In particular, long work hours may not be as harmful for those youth who come from more disadvantaged backgrounds. Compared to their more advantaged counterparts, low-SES youth may be working for different reasons (e.g., for family expenses or college) or be more likely to need to work more hours. Thus, low-SES youth may be able to avoid some of the problem behaviors associated with intensive work. Low-SES youth also have a harder time obtaining a job (due to the more competitive market), which means that this greater selectivity into employment might translate into a better job (e.g., more opportunities to work with adults, skill utilization, or vocational development) or a better worker (i.e., more serious about keeping job). For young, economically disadvantaged males, paid work actually increased their chances of high school completion (Entwisle, Alexander, & Olson, 2005). Farkas and colleagues (Farkas, Olsen, & Stromsdorfer, 1981; Farkas, Smith, & Stromsdorfer, 1983) revealed similar benefits of employment for the school enrollment of low-income youth. Lee and Staff (2007), using propensity score methods to control for observable differences between individuals, found that long hours on the job do not encourage high school dropout among youth who had especially high or low probabilities of intensive work. Thus, the effect of teenage work on school dropout is conditional on young people’s propensity to work long hours on the job. The differential effects of work hours extend beyond just achievement-related outcomes. Research by Johnson (2004) and Bachman, Staff, O’Malley, and

Freedman-Doan (2013) found that the effects of long work hours did not increase the alcohol and substance use of African American and Latino/a American youth.

Staff and Mortimer (2007) have suggested that employment patterns during the high school years can help disadvantaged youth establish strategies of time management that persist in young adulthood and facilitate higher educational attainment. Using data from the YDS, the authors found that youth from more advantaged backgrounds were likely to pursue a steady pattern of low-intensity and high-duration work during high school, followed by a similar pattern of part-time work combined with schooling in the years immediately following high school graduation. The inclusion of accumulated months of postsecondary “school and part-time work” mediated the benefits of steady high school work on subsequent receipt of a bachelor’s degree. By contrast, youth from disadvantaged backgrounds were likely to pursue more intensive work (high average work hours and high employment duration), followed by full-time work immediately after the scheduled date of high school graduation. More intensive workers had little likelihood of acquiring 4-year college degrees, and they were more likely to feel they were in “career” jobs during the years following high school (Mortimer, Vuolo, Staff, Wakefield, & Xie, 2008). However, when disadvantaged low-SES youth followed a steady work pattern during high school, their educational attainment and longer-term wages were especially enhanced (Staff & Mortimer, 2008).

In summary, each perspective that we have reviewed, positing a different relation between paid work and development, is supported by empirical research. Paid work can lead to adjustment and achievement problems, typically if the work is of high intensity and of poor quality. However, not all work is bad, and moderate work has been associated with well-rounded combinations of work, school, and family pursuits that benefit youth long term during the transition to adulthood. Further complicating the picture, *effects* of paid work are greatly diminished when selection issues are more fully addressed, such as prior achievement, motivation, and problem behaviors. Also, employment may matter for some youth and not for others, as prior orientations, leisure involvements, and demographic background features influence the decision to work and how much to work—as well as engagement in school and family—in adolescence. In the conclusion of this chapter, we return to some of these issues and suggest future research directions to assess the short- and longer-term consequences of adolescent paid work.

The research reviewed thus far is confined to studies of children and adolescents in the United States. We now turn to the literature on youth employment in an international context.

## CHILD AND ADOLESCENT EMPLOYMENT OUTSIDE OF THE UNITED STATES

Given manifest differences in the patterns, quality, and circumstances of youth employment even within a single country, the United States, it is likely that contextual variability across countries would render youth employment precursors and outcomes even more variable. Paid work during adolescence would likely be quite different in character and have distinct meanings across countries. For example, in nations like Germany, Austria, and Denmark, with strong “dual systems” of vocational training and classroom experience, learning in school and work environments is complementary and compatible by design, with the intention to foster human capital acquisition. In contrast, in the United States, there is little coordination between the workplace and the high school, except in specific circumstances (e.g., internships, job shadowing). One might expect the advantages of apprentice-type teen work would be much greater than teen “free market” labor force experience. In the developing world, child labor is more likely to take the form of agricultural work, work in extractive industries, or street trade, with little regulation, than in the developed economies. We therefore now turn to studies of adolescent work around the world.

### Worldwide Scope of Child Labor

Although there is some variation in the definition of child labor outside of the United States, the term is mostly understood in the field as conforming to the International Labour Organization’s (ILO) earlier definition of labor as “the production of economic goods and services,” which covers all market-oriented activities of children and excludes chores in the children’s own household or work activities tied to school (e.g., homework; participation in sports or academic clubs, etc.). The ILO recently revised its definition of child labor in order to encompass both economic activities and unpaid services like household chores (ILO, 2008). This way, a broader concept of children at work has been sought (Edmonds, 2008), one that represents all aspects of child labor in the world, including unpaid

market-oriented activities, exploitative work or jobs under hazardous conditions, household chores or babysitting family members, and other nonmarket activities, such as small repairs or caregiving for children, the elderly, or disabled (Bourdillon Levison, Myers, & White, 2010; Guarcello, Lyon, Rosati, & Valdivia, 2005).

Similar to what has been happening in the United States, a general decline in the prevalence of working children has occurred worldwide. For instance, by the beginning of the 21st century, the absolute number of children (ages 5 to 14) at work declined from 211 million in 2000 to 191 million in 2004, which represents a decrease from approximately 18% to 16% of all children in this age cohort (Castro, 2010; Hagemann, Diallo, Etienne, & Mehran, 2006; ILO, 2006). This overall decline in youth employment varies considerably by country, at least according to the UNICEF's fourth round of the Multiple Indicator Cluster Survey (MICS-4) ending in 2010. In Brazil, for instance, only 3% of children participated in the labor market, compared to 21% of children in the Dominican Republic and 34% in Peru. In the Asia and Pacific region, child employment ranged from 13% in Bangladesh to 34% in Nepal. The rates of youth employment showed the greatest variation in Africa. In Botswana, 9% of children worked, compared to 53% in Ethiopia and 57% in Guinea-Bissau. In fact, recent estimates by Diallo, Hagemann, Etienne, Gurbuzer, and Mehran (2010) show that Sub-Saharan Africa is the only region in the world to experience a slight increase in rates of children in employment in recent years, growing from approximately 26% in 2004 to 28% in 2008.<sup>4</sup>

An important trend reported by the ILO is the recent worldwide decline in the numbers of children employed in hazardous work, from around 6% (76 million) to 4% (53 million) of all children in the age cohort. Hazardous work refers to work that exposes children to physical, psychological, or sexual abuse, according to ILO's Convention 182 (ILO, 1999). Sub-Saharan Africa is the region with the highest percentage (approximately 13%) of children in this kind of work. The general decline in children working in hazardous jobs is due to many factors, such as the process of urbanization that reduces the proportion of children living in rural areas, the expansion of the educational system across the world, and overall improvements in households' living standards (Bourdillon et al., 2010).

<sup>4</sup>Sub-Saharan Africa is the region with the highest proportion of working children, whereas Asia and the Pacific is the region with the highest absolute numbers (96 million).

## Entering the Labor Force

As we reviewed earlier, children from disadvantaged backgrounds in the United States who have little interest or limited connection to school are most likely to invest their time in paid work. Research on child labor outside of the United States has devoted much attention to the role that poverty plays in children's entry and engagement with paid work (see, for instance, ILO, 1999, Convention No. 182). Worldwide, children are mostly likely to be found working when faced with family poverty, low-quality schools, and ineffective regulations that are unable to protect their health and well-being. Higher family income levels, higher quality of schools, and stable regulations are effective in keeping children and adolescents in school until at least the end of compulsory education.<sup>5</sup>

However, empirical evidence that child labor is always a symptom of extreme poverty is mixed. For instance, in a study of 14 countries in Latin America, Barros, Mendonça, and Velazco (1994) found that income differences accounted for less than 50% of the variation in children's labor force participation. Still, children's employment rates were lower in Brazilian metropolitan areas with lower poverty rates. In another study of Pakistani children, Bhalotra (2003b) found that poverty is related to a higher propensity to work for boys but not for girls. In studies of Ghana youth, Canagarajah and Coulombe (1997) and Boozer and Suri (2001) found that income differentials have little to do with the household decision on the allocation of children's time between school and work. Both studies argue that other family characteristics, beyond socioeconomic conditions, such as the parents' level of educational aspirations for their children, as well as the perception of the quality of the local school system, play an important role in the allocation of the children's work time.

While family poverty is certainly an important precursor of children's employment, especially in contexts where there is little institutional support for education or the regulation of child labor, cultural differences also play an important role in youth work. As Bourdillon et al. (2010) have argued, in some contexts employment is viewed as a natural part of childhood, even among children who are not poor. In India, for instance, children in lower castes or classes often

<sup>5</sup>The end of compulsory education occurs at the age of 15 in many countries. ILO Minimum Age Convention 138 establishes that 15 years old—14 in very poor countries—is the minimum age for admission to employment in developing countries (ILO, 1973).

have to work, whereas those who are from more advantaged backgrounds attend school. Children's agency is also found to be an important determinant of youth work in international research, just as it is in the United States. Children are able to understand the context around them and they engage in paid work not only to help to meet the family's needs, but because they enjoy earning their own income. Own earnings can, in turn, improve their status within the family and bring a sense of independence. Children and adolescents take pride in their contribution to their own and to their family's welfare (Bourdillon, 2006; Levison, 2000; Liebel, 2004; Woodhead, 2001).

### Types of Jobs

The type of work done by children in many developing countries is distinct from youth in the United States as well as many other countries in two important ways. First, a notable feature of children's employment in many developing economies is that only a small percentage work for pay outside their households (Bourdillon et al., 2010). Instead, they work mostly helping out with the family business, farm, and even inside the household, doing domestic chores. For instance, using data from UNICEF's MICS, Edmonds and Pavcnik (2005) showed that, among children in 36 developing countries, an average of 25% engaged in the labor market, but only around 2% worked for pay outside their households, and 65% performed domestic work. That means that the majority of children participating in the labor force in these countries are working for their own family, without pay, and helping out with the family business.

Second, compared to the United States and other developed countries, a higher proportion of working children in developing countries are engaged in hazardous work (Diallo et al., 2010). A subcategory of this group comprises the worst forms of child labor, including slavery, prostitution, drug trafficking, and participation in armed conflicts as child soldiers. Because these activities are illegal, it is very difficult to obtain reliable estimates of their prevalence (Hindman, 2009b). The International Program for the Elimination of Child Labor (IPEC, 2002) estimates that 1.8 million children are involved in sexual exploitation, 1.2 million in trafficking, 5.7 million in bonded labor, 600,000 in drug production and trafficking, and another 300,000 participate in armed conflicts. The total (9.6 million) accounts for roughly 7.5% of all hazardous workers and approximately 4% of all child workers around the world.

### Perspectives on Youth Work in an International Context

Earlier in this chapter we introduced four perspectives on child and adolescent work based on research in the United States. Consistent with Perspective 1, scholarship on child labor outside of the United States and especially in developing countries has mostly focused on the negative consequences of this activity—especially of hazardous work—for children in terms of their health, educational achievements, and long-term occupational attainments. However, some scholars have argued that the consequences of paid work are more complex and working can even be beneficial depending on the amount of time invested in paid work and the quality of these jobs (Perspective 2). Scholars using international data have also questioned whether the purported negative effects of child labor on development are spurious (Perspective 3) or depend on family background or reasons for employment (Perspective 4).

As discussed by Bourdillon (2006) and Hindman (2009a), much of the research and policymaking about child labor assumes that work will have negative consequences for children's lives in both the short and long term. Instead of working in a job, childhood is assumed to be a time of learning in school, spending time with family, and playing with friends. At the core of this perspective are assumptions that child labor reduces school attendance and performance and ultimately undermines longer-term educational attainment. Allais and Hagemann (2008), for example, used ILO's Statistical Information and Monitoring Programme on Child Labour (SIMPOC) data from 34 developing countries and found that the higher the incidence of child labor in a country, the lower the literacy rates and other educational outcomes. Ray and Lancaster (2005) analyzed the association between work and school attendance and performance in seven countries—Portugal, Namibia, Philippines, Sri Lanka, Cambodia, Panama, and Belize. They found that in six of the seven countries (not Sri Lanka), child labor was negatively associated with educational outcomes. Similarly, Cavalieri (2002) found that youth employment reduced the likelihood of completing each school level in Brazil.

Some scholars have questioned whether the negative relation between early employment and educational outcomes is spurious (Bhalotra, 2003a; Liebel, 2004), and instead reflects prior orientations, school-related behaviors, and socioeconomic advantages. Different methodological strategies have been used to address whether there is a causal relation between children's participation in the

labor market and educational attainment (Bourdillon et al., 2010; Ray & Lancaster, 2005). For instance, Boozer and Suri (2001) found child labor was negatively associated with school attendance in Ghana even after using rainfall variation and income fluctuations as instruments to help rule out potential unobserved spurious factors. In a similar vein, Goulart and Bedi (2008) used instrumental variable methods to understand the relation between youth work and education in Portugal, and their results indicated that participation in the labor market was associated with a reduction in school success. Beegle, Dehejia, and Gatti (2009) also employed instrumental variable methods to analyze tradeoffs between child labor and education in Vietnam and found that employment reduced educational attainment. However, Beegle et al. (2009) also found that youth work was positively associated with the likelihood of future employment, which could potentially offset the short-term negative effects of work on educational attainment.

Domestic work also can have an impact on children's time allocation and reduce time available to attend school, especially given its high prevalence among children in developing economies. Assaad, Levison, & Zibani (2010) used a probit model that allows for simultaneous determination of domestic work and school attendance among girls in Egypt and found that a high domestic workload reduced attendance rates. Similar findings linking children's domestic work and reduced educational attainment have been reported in Peru (Levison & Moe, 1998), Mexico (Levison, Moe, & Knaul, 2001), and China (Guarcello et al., 2005).

In addition to diminished schooling, scholars have expressed concern that working during childhood and adolescence can lead to physical injuries, exposure to toxic substances, psychological stress, and long-term health problems (Edmonds, 2008, 2010). Research has shown adults' self-reported health status in Brazil is worse among those who entered the labor market early (Kassouf, McKeel, & Mossialos, 2001). O'Donnell, Rosati, and Doorslaer (2005) and Beegle et al. (2009) reported a similar pattern in Vietnam. In Cambodia and Guatemala, however, Guarcello et al. (2005) found no clear relation between work and health, though their analyses were limited to nonmarket work activities.

These studies suggest that paid work in childhood and adolescence can hinder educational attainment and be harmful to health and wellbeing. Others have argued that rather than competing with schooling, paid work can be a natural part of children's development, helping them mature and gradually adapt to adult life. In this

perspective, the transition from school to work is not conceived as an abrupt transition but more as a continuum (Davidson, 2005), with "children gradually moving into the activities of adults as their competences develop and opportunities arise" (Bourdillon, 2006, p. 1202). Children and adolescents can benefit from early working experiences, acquiring skills and competences that will help them in future employment, and can even compensate for reductions in formal education. Early work, in appropriate conditions, can enhance children's self-confidence, sense of responsibility and independence (Bourdillon et al., 2010). As Bissel (2003) and Liebel (2004) pointed out, working children in developing countries are usually proud of their work and of the income they can bring to help support the family, boosting their confidence and even their status in the household. Work can be viewed as an important preparation for adult responsibilities.

Furthermore, as Edmonds (2008) has noted, it is hard to quantify the importance of children's work in the family economy, mainly because most working children do unpaid work within the family domain, whether it is business-related or domestic work. Studies that have focused on the income contribution of children found that, in Bolivia, they are responsible for approximately 13% of the household total income (Psacharopoulos, 1997), and, in Nepal, 11% of the total agriculture production (Menon, Pareli, & Rosati, 2005). In Brazil, Ilahi, Orazem, and Sedlacek (2005) found that working children contributed 17% of household income in urban areas and 22% in rural areas. Working children can provide help to the family economy in multiple ways (Levison, 2000). They not only can help to pay family bills and other household expenses, they can help to pay for their own educational expenses. Woodhead (2001) showed that working children in different parts of the world, such as Bangladesh, Ethiopia, the Philippines, El Salvador, Guatemala, and Nicaragua, were able to use part of their income to afford additional educational costs. A working child not only helps to support himself/herself and the family in general, but may also have a special impact on younger siblings (Bourdillon et al., 2010; Edmonds, 2008). Children's earnings and help with the family business allow them and, in several cases, their younger siblings, to attend school by paying for school tuition and fees, school clothes and supplies, and transportation. Skoufias (1994) found that the higher the income earned by the older sibling, the more time spent by younger siblings at school in India. A similar pattern was found for Brazil (Emerson & Souza, 2008), Nepal

(Edmonds, 2006b) and Paraguay (Patrinós & Psacharopoulos, 1995), where older siblings are more likely to work than the younger ones, and even help to afford the latter's school expenses.

These studies suggest that in many societies, paid work can be a natural part of childhood, either as part of the typical family survival strategy or simply as something sought by the children as a way to prove themselves as capable agents. Although full-time work and hazardous work conditions can pose health risks and hinder children's academic and social development, there is growing evidence that appropriate work activity is positively associated with children's educational and health outcomes, and even provides economic and social benefits for their families (Bourdillon, 2006; Boyden, Ling, & Myers, 1998; Levison, 2000; Liebel, 2004; Lieten, 2005; Woodhead, 2001). As noted earlier, in several cases, work, instead of hindering formal schooling, actually helps children to afford school tuition and fees and even supports younger siblings' expenses with school.

The conceptual differences between these perspectives are expressed in the terminology used to represent the study of children at work. The term "child labor" is widely employed by studies to represent work below the minimum legal age, implying that such work is intrinsically harmful to children. Critics argue that this concept, as used in most ILO statistics and other agencies' reports, does not allow a necessary differentiation between work that harms and work that benefits children (Lieten, 2006). In contrast, the term *child work* has been used, mainly by researchers, to better grasp the multiple dimensions and manifold consequences of children's labor force participation, sometimes harmful, but at other times beneficial. Besides, although no clear differences can be detected between the words *labor* and *work* in English grammar, in practice *labor* tends to represent paid employment and *work* represents both paid and unpaid employment (Bourdillon, 2006). Thus, considering that the majority of working children do not work for pay, the term *child work* appears to more accurately represent the work children do internationally.

Several governments around the world have created policies that aim to abolish child labor or establish minimum age requirements for youth employment with the hopes of increasing school attendance and improving academic performance. Among the most successful in this regard are the following programs: Oportunidade in Mexico, Bolsa-Familia in Brazil, and Food for Education in Bangladesh. However, policies addressing child work, especially in developing economies, must take into account

the importance of children's work for the family's survival strategies. If not, these policies could end up endangering children and the whole family, which could, in turn, lead to an increase in the intensity or danger of child work (Bourdillon et al., 2010; Edmonds & Pavcnik, 2005; Jafarey & Lahiri, 2002). Attempts to eliminate child labor, without appropriate consideration of its consequences for family welfare, can be especially harmful for many families in developing economies (Edmonds & Turk, 2004).

Furthermore, some scholars contend that the focus of policies governing child work should change from abolition and minimum age restrictions to the immediate conditions of work and the contexts in which work occurs. For instance, White (2009) argued that, instead of preventing children from working, interventions should protect them in ways that increase the likelihood that their work experiences will be beneficial. Attention should be directed to the quality of relationships at work, the avoidance of noxious and dangerous work, and guarantees that children's rights will be respected in terms of working conditions, hours, and salaries.

Further advances in this debate and, more generally, in knowledge about children's employment in developing countries depend, however, on improvements in methodological strategies. Snapshots and cross-sectional data sets, which are the most common data sources for studies in these countries, do not offer enough information to understand the multiple causes and consequences of children's work. An expansion of longitudinal studies in the developing world—like the Monitoring the Future study and the Youth Development Study (Mortimer, 2003) in the United States—could help to overcome this gap, offering insights on the role that work plays in children's developing life course (Bourdillon, 2006; Edmonds & Pavcnik, 2005).

## FUTURE RESEARCH

We see at least four promising areas of new research on youth employment.

### Future Direction 1. The Disappearance of Teenage Work in the United States

First, research is only starting to examine the consequences of the absence of work during adolescence. In previous generations in the United States, and up until very recently, it was normative for adolescents to work during the school year, and even more so during summers. In the Youth

Development Study (Mortimer, 2003), 93% of students in the 1991 high school graduating class reported that they had held employment at least some time during the 10th, 11th, and 12th grades while school was in session. Their parents also worked as teenagers, and believed that this experience contributed greatly to their own preparation for work and for adulthood in general. Despite warnings from some developmental psychologists (Greenberger & Steinberg, 1986), parents overwhelmingly approved of their children's employment (Phillips & Sandstrom, 1990). However, as we have documented from surveys of successive Monitoring the Future cohorts (Figure 9.2), teenage employment in the United States has been declining since the early 1980s. It has repeatedly fallen during economic recessions, without recovering thereafter. Sum et al. (2014) document plummeting teen employment rates from 2000 to 2011 in the 100 largest U.S. metropolitan areas. Since the beginning of the current Great Recession, the decline has been precipitous. The teen employment to population ratio among 16- and 17-year-olds is currently just 15%, the lowest level since the Bureau of Labor Statistics began collecting such data (Smith, 2011). Is the United States now witnessing the end of the teenage job?

We also observe a long-term historical decline in the variety of jobs typically filled by youth. Many of the jobs formerly held by teenagers are, for one reason or another, no longer available to them. As the farm sector has diminished, and many family farms have been replaced by "agribusiness" firms, a major source of employment for rural youth has eroded. The rise of "self-service" has virtually eliminated gas station attendants and many jobs in the retail sales sector (salesclerks) as consumers now perform these activities by themselves in brick-and-mortar stores or shop on the Internet. With the transformation and diminution of the clerical sector, fewer teenagers have opportunities to work as typists or secretaries. Other formerly "teenage jobs" have been taken over by older workers. For example, the newsboys or girls, who tossed papers onto doorsteps from their bikes, have been replaced by adults, who deliver newspapers door-to-door from their cars. Many retirees, in an attempt to supplement their fixed incomes, now perform jobs that teenagers used to fill, like the elderly who help food shoppers bag their groceries. Much of the decline in teen employment may be attributed to increasing competition between the young and old for jobs in general, which intensifies during recessionary periods (Smith, 2011). When given a choice, employers will often favor adults over teenagers, as teens are seen as less mature and less stable workers.

Still, some teenagers continue to find work. In addition to continuing to monitor trends in the availability and character of paid work, an important question for future researchers to address is whether the bases of selection to employment have changed. If teenagers are competing for a more concentrated and ever-diminishing number of job openings, employers may be much more selective, now and in the future, than in a prior era. Although the more advantaged youngsters have been more likely to be employed for some time, the likely accentuation of this trend may make it even more probable that in the future more disadvantaged youth, who appear to have the most to gain from employment, may be increasingly unable to find work. The development of human capital through paid work, the apparent strategy of the "most invested workers" (those who worked intensively throughout high school) in the Youth Development Study (Mortimer, 2003), who had little interest in school, is no longer a viable option for most teens. Those youth who followed this pattern moved quickly into adult-like "careers" after leaving high school (Mortimer, et al., 2008). Moreover, employers may increasingly avoid hiring youth who exhibit any sign of behavioral problems, thereby reducing the dangers of "precocious maturity" or "pseudomaturity" through paid work, but also lessening the exposure of such youth to an incentive structure that rewards more conforming behavior.

We know little about what it will mean for them if teenagers in the United States are no longer able to do paid work. Future research should continue to monitor adolescent time use. Are teens currently spending more time than their predecessors doing more housework, more schoolwork, or are they spending more time in more potentially harmful, discretionary activities, simply "hanging out" with their friends (in real life or online)? Clearly, these alternative pursuits have different appeal to distinct groups of teenagers, depending on their social backgrounds, ambitions, and resources.

Will teenagers increasingly seek volunteer positions, or unpaid internships, to obtain valuable work experience? Will their parents, recognizing the dearth of opportunities to gain work experience in the ways they themselves did, encourage their children to volunteer? Volunteering is, in many respects, similar to paid work, as teen volunteers work in organizations, operated by adults, which have similar routines and imperatives. Volunteers learn to take responsibility, be on time, and cooperate with others, lessons that may easily transfer to the work environment. Both students and their parents may see volunteering as even preferable to paid work. Youth volunteers may have

access to a broader range of organizations and exposure to adult workers in a wider variety of occupations that would typically occur in teen jobs. For example, teenage volunteers may be welcome in many service and nonprofit organizations. As volunteers, adolescents may also have more discretion in their employment than paid workers, allowing them to flexibly shift their hours and involvement altogether, as time demands wax and wane in their school and other activities.

### **Future Direction 2. The Influence of the Global Economic Recession on Worldwide Trends in Child and Adolescent Labor**

It is well established that economic shocks, at the macro- and micro levels, have negative effects on the household economy. These in turn can lead to an increase in the use of child work as a strategy to cope with the decline in family income. Studies of the household economy have shown that this pattern holds for Brazil (Duryea, Lam, & Levison, 2007), where the household head's unemployment led to an increased use of children's work. In Cambodia, Guarcello, Kovrova, and Rosati (2008) showed that shocks such as floods, drought, and, mainly, crop failure, preceded more intensive use of child work. In India, crop failure also impacted children's employment as well as school attendance (Jacoby & Skoufias, 2008). Guarcello, Meali, and Rosati (2010) found that both economic shocks and credit constraints pushed more families to send children to work in Guatemala. When family income increases and a household improves its overall living standards, a decline in the use of child labor follows. This trend is found in studies of Vietnam (Edmonds & Turk, 2004), South Africa (Edmonds, 2006a), Tanzania (Beegle, Dehejia, & Gatti, 2003), the Philippines (Yang, 2004), and in comparative studies of several developing countries (Edmonds, 2005; Edmonds & Pavcnik, 2005).

Predictions that the recent global economic recession would lead to an increase in child work across the world (Koseleci & Rosati, 2009; Mosel & Sarkar, 2009; UNICEF, 2009), however, have not yet been confirmed. For instance, Rosati and Lyon (2011) analyzed the impact of the 2008 global financial crisis on children and youth's employment in Latin America (Brazil, Ecuador, and El Salvador) and Indonesia. Although the evidence was somewhat mixed, none of these countries appeared to suffer major effects of the crisis on children's employment and schooling rates between 2007 and 2009. First, they found that, although Indonesia and El Salvador experienced rises in children's

employment, most of the working children were kept in school, not leading to a rise in school dropout rates. Brazil and Ecuador, in turn, experienced a slowing of the decline in children's employment rates, resulting in stability. Second, the only country where children's working hours rose in the period was El Salvador, while the others remained the same. Third, the share of children working in the agricultural sector rose in Ecuador and El Salvador, but fell in Brazil and remained stable in Indonesia. Fourth, working conditions for youth deteriorated in Latin America, where youth unemployment rates rose, but not in Indonesia. Though Rosati and Lyon (2011) concluded that the crisis had only a moderate effect on these countries' child employment conditions, they cautioned that it might be too early to truly understand the effects of the crisis on children's work and that we need more than descriptive evidence to support an accurate interpretation of links between broad changes in child labor, schooling, and the economy.

Evidence relating to unemployment among older youth seems to be clearer. The ILO's (2012) report on employment trends for youth showed that the recent global recession ended the steady decline in youth unemployment rates around the world. Currently, around 75 million youth are unemployed, which corresponds to 12.6% of the 15- to 24-year-old group. ILO projects that this rate will be kept at this level until 2016. In comparison to adults, youth workers are especially affected, with a youth-to-adult unemployment ratio of 2.8 in 2011. The highest unemployment rates in the developing world, in 2011, were found in North Africa (28%) and the Middle East (27%), and the lowest in East and South Asia (9%), Sub-Saharan Africa (11%), and Latin America and the Caribbean (14%).

Although both developed and developing countries have been affected, the ILO's report showed that the developed economies have been the most harshly affected by the great recession. The average youth unemployment rates in these countries rose from 12% in 2007 to 18.1% in 2011, the highest since the 1990s, and the projections suggest that this rate will not decline until 2016. Within this group, some countries were more affected than others. The countries where youth have been suffering the strongest negative impact, in terms of their unemployment rates, are in the European Union: Spain, with a rate of 46.4%; Croatia, with 35.8%; and Slovakia, with 33.6%. The United States was also highly affected, with an increase from 10% in 2006 to 19.6% in 2010 (U.S. Congress Joint Economic Committee, 2010). Though some studies have argued that there is scarce evidence on the strength of the link between

economic shocks and child work (Ferreira & Schady, 2008; Kane, 2009), more research is needed on the short- and longer-term effects of economic shocks, especially how the most recent economic recession has influenced worldwide trends in child and adolescent employment.

### **Future Direction 3. A Better Understanding of What Types of Work Are Beneficial or Detrimental for Which Types of Youth**

We have pointed out the many benefits of youth employment, as well as potential drawbacks. As this review makes clear, however, studying the consequences of employment for teenagers is a complicated endeavor. Benefits and costs of paid work depend on the degree of time investment in work and school activities, the types of jobs youth hold, the intrinsic and extrinsic qualities of their occupational experiences, and the characteristics of the children who work, including their resources and motivations. Because all of these factors are likely to change over time, understanding the significance of children's work for their development and attainment requires continued longitudinal monitoring. For example, with the general decline in youth employment, the work experiences and contexts available to youth who have paying jobs have contracted. Employment among youth is increasingly concentrated in the few remaining jobs available to them, particularly in the food service industry. Those teenagers who do find work are more likely than teen workers in past decades to be servers, cashiers, or perform other functions in restaurants. We need to know more about the consequences of this kind of work. Restaurant employment may be increasingly shunned by more advantaged youth seeking experiences that will enhance workplace learning, vocational growth, and service opportunities. Still, as Newman (1999) pointed out years ago, such jobs may continue to be sought after by minority and disadvantaged youth. Future research should pay greater attention to the characteristics of youth that moderate the effects of these and other paid work experiences.

Furthermore, if teens increasingly move toward unpaid work experiences, we will need to know more about whether volunteering has the same costs and benefits as paid work. There are reasons to believe that volunteering could be a more salutary experience, as it enables youth to work alongside adults and learn about workplace routines and responsibilities in an environment that emphasizes service to others. The problem of excessive hours of work would be reduced, given the lack of monetary incentive

and presuming little pressure from volunteer supervisors to work more than teens would like. To address the issue of costs and benefits, researchers need longitudinal studies that trace the nature of teen volunteering, whether, like paid work, volunteer tasks tend to become more time-consuming and complex as teens grow older. Future studies of volunteer work should monitor the wide variety of outcomes that have been linked to paid work (like school performance, problem behavior, work values, and the self-concept) so that it can be determined whether teen volunteer work is a positive or negative trend for their development.

Moreover, in view of the diminishing availability of paid work, researchers need to give greater attention to the variety of ways of obtaining work experience, their combinations and sequences, and their consequences for youth from different backgrounds. That is, some youth may go through adolescence with little or no paid or unpaid work experience; others may start off with volunteer jobs and then transition to paid work; a diminishing number will spend much of their adolescence in paid employment. What are the benefits, costs, and tradeoffs between these different strategies, and do these consequences differ for different types of youth? Highly advantaged teens might shift their activities toward more involvement in school clubs, sports, music, and other extracurricular activities, in comparison to previous generations of more affluent youth, with many positive outcomes for their development. For such youth, the lack of employment may have little observable cost, given their (usually) positive working role models at home and (usually) strong achievement orientations. The absence of paid work may have more adverse consequences for disadvantaged youth, who may be less motivated to undertake such alternative extracurricular pursuits, and may have fewer opportunities to do so. Some disadvantaged teens, like their counterparts in earlier eras, may become highly involved in family work, caring for younger siblings and performing household chores. For others, however, the absence of paid work may simply lead to more discretionary, unstructured time, and increase the attractiveness of illegal routes to monetary gain.

### **Future Direction 4. Thinking About Work and School in Tandem Rather Than School and Work in a Causal Sequence**

Theoretical models of the school-to-work transition often conceptualize it as a linear transition from school completion to work acquisition. As evident from decades of research, however, this transition is not so simple. As the

transition to adulthood has become prolonged and individualized (Shanahan, 2000), youth combine school and work for long periods of time. After high school, most youth in the United States enter some form of postsecondary education, usually combining their schooling with at least some paid work. Others leave school entirely and attempt to find paid work, only to return to school later seeking further educational credentials, again undertaking various combinations of school and work. As we have pointed out, researchers have given a great deal of attention to the educational costs of paid employment—whether working diminishes school performance or eventual educational attainment. We in the field need to know more about the diverse patterns of schooling and working while adolescents are still in high school as well as longer-term combinations of school and work after they embark on postsecondary education and work careers. We noted earlier that patterns of schooling and working established during high school tend to continue thereafter (Staff & Mortimer, 2007). For some youth this movement back and forth, even if punctuated by spells of “idleness” (involving neither activity), may be considered progressive and purposeful, fostering vocational development and educational attainment; for other youth the long transitional period may simply lengthen experiences of “floundering,” engendering little in the way of successful outcomes. Research on the patterns of schooling and working over a longer period of time, extending studies of “teenage employment,” may yield significant dividends in understanding the precursors of successful and unsuccessful outcomes (Vuolo, Mortimer, & Staff, 2014), including postsecondary educational degrees, income attainment (Staff & Mortimer, 2012), and the acquisition of high-quality adult work experiences.

It is important to recognize that structural variations in the school-to-work transition have important implications for the nature and consequences of adolescent work. In countries that utilize a dual system that combines part-time work experience with regular schooling (such as Germany, Austria, Denmark, and Switzerland), adolescents have available to them integrated educational and job training sequences, which lead directly to adult careers (Mortimer & Krueger, 2000). The institutionalized bridge from school to work makes it unnecessary for teenagers to construct their own work patterns, carving out their own combinations of school and work investments, as is the case in countries that place limited emphasis on vocational education in the secondary school system. In the United States, with a decentralized school system and only general educational credentials to rely on, many employers place

a premium on prior work experience, which youth must find for themselves. As a result, adolescents’ employment is entirely separate from their schooling, often viewed as deterring their educational progress, and seen as having little connection to their long-term occupations. Thus, teenagers in both contexts may work during adolescence, but their employment has very different meaning for the school-to-work transition and for the ensuing adult occupational career.

There is evidence, however, that such differences across countries may be narrowing. Mills and Blossfeld (2005) argued that recent structural changes have altered the transition from school to work in European countries, bringing more uncertainty about labor market placement, even when educational systems have high vocational specificity. Skrobanek, Reissig, and Gaupp (2009) showed that these structural processes have severely affected the German apprenticeship system and its usual ability to offer a quick integration into the labor market, diminishing opportunities for those with lower qualifications. A process of destandardization of the school-to-work transition is taking place, transforming the dual system into a multifaceted transitional system. These studies argue that, although the trends are still not very clear, important changes are under way and are going to transform the transition from school to work in highly stratified and vocationally specific systems.

In developing economies, researchers need to continue to examine the benefits and costs of paid and unpaid work as child labor diminishes, primary schooling becomes universal, and secondary schooling expands. An intriguing question is, as the worst forms of “child labor” are eliminated, whether “child work” will increasingly be substituted, offering a variety of work-related experiences that enable youth to develop a sense of competence, independence, and self-determination. With educational expansion, educational policy-makers have available to them alternative models of school-to-work transition from the developed world. Given favorable market conditions, youth in the developing world may increasingly combine schooling and working for long periods of time, like youth (especially in prior generations) in the United States. Alternatively, if such structural arrangements are constructed for them, they may, like their counterparts in Western European countries (such as Germany, Denmark, and Switzerland), enter a “dual system” of coordinated education and apprenticeship placements. Or, as child labor is eliminated, youth may increasingly move from school to work in a more distinct, sequential fashion.

Researchers need continued monitoring of the shifts from predominant “child labor” regimes to these various alternative forms, including their benefits and costs for different youth (rural and urban; affluent, middle-class, and poor) in distinct cultural environments.

## CONCLUSION

It is very difficult to understand children at work without considering how they got there, why they work, the nature of their work experiences, and how work fits into their current lives and long-term goals. Even when we limit our questions to one group (high school students in the contemporary United States), one dimension of paid employment (average hours of employment during the school year), and one outcome (grade point average), the evidence is mixed on whether and how work impacts school performance. Obviously, more research in both the developed and developing world will foster a better understanding of the complex interrelations between paid work, other types of work, and social development during the lengthening transition to adulthood.

assistance in gathering some of the literature for this chapter and Common Sense Media and the Henry J. Kaiser Family Foundation for use of tables and figures.

## OVERVIEW

Twenty-first-century environments are digital. Media become integrated into U.S. children's lives soon after birth, and media provide an ongoing backdrop for everyday living throughout development (Calvert & Valkenburg, 2013). Children use media in their homes, as they walk down the street, in restaurants, in planes, trains, and automobiles, in gyms, and even in schools except when the use of media is explicitly banned.

Media are integrated into children's everyday environments for two main reasons: because children choose to use them, known as *foreground* or *active exposure*, and because others are using media and children are inadvertently exposed, known as *background* or *passive exposure* (Huston, Wright, Rice, Kerkman, & St. Peters, 1990). Media experiences are beloved by many children, with entertainment and friends at their fingertips, making media a preferred foreground experience chosen by virtually all of them. They use media for many purposes, including observational learning of how to interact with others, social interactions with others through interfaces such as mobile phones, the Internet, and electronic gaming, or just to sit back and relax as they become immersed in the stories of others through televised programs, DVDs, and films. Media are informal teachers, providing a platform for children to explore and learn about a wide range of content, including educational lessons, violent behavior, and how to be a sexual person.

Media are also distractors, interrupting daily activities, disrupting concentration, and providing a constant stream of stimulation that is at times voluntarily chosen, and at times not. When involuntary exposure occurs, background media can be harmful to developmental outcomes (American Academy of Pediatrics, 2011). Foreground media exposure can also be harmful, such as children selecting violent television programs for viewing (Wilson, 2008).

This chapter explores media in its many forms, how it has evolved and is evolving, how media influence children's development, and how children influence media in its newer forms. The chapter begins with a discussion of the key theoretical perspectives from the disciplines of psychology and communications that have been brought to bear on media effects. Social cognitive theory and parasocial relationships frame the social relationships that influence children's behavior and learning through role models as well as through friendships that children develop with media characters (Bandura, 1986, 1997; Hoffner, 2008). Cognitive models that use scripts, schemas,

and stages are used to explain age-related differences in story comprehension as well as how the same cohort takes away entirely different media messages because of schematic processing (Calvert & Huston, 1987). The cultivation hypothesis examines how the kind of content available to children influences their beliefs about the world in which they live (Gerbner, 1972). Uses and gratification theory addresses why children view and use media: In the United States, it is mainly to fulfill their need for entertainment (Rubin, 2002). Arousal theory is considered in relation to aggressive and sexual content, in which desensitization dulls responses to real-life experiences (Zillmann, 1991). Psychoanalytic theory is used to discuss aggression, sexuality, and the development of identity (Erikson, 1963; Hall, 1999). Learning models emphasize reinforcement contingencies and classical conditioning principles (Miller, 2009).

The history of media is then considered. Although newer interactive media are rapidly entering children's lives, the colonization of children's leisure time through television viewing continues to play the dominant role in their daily experiences (Wartella & Robb, 2008). The vast penetration of electronic media into children's homes is the next topic, focusing on access to technology as well as use and exposure patterns, with the latter taking into account multitasking and the use of mobile technologies (Rideout, Foehr, & Roberts, 2010). Media diets and foreground and background exposure are considered.

The media environments of children are then discussed, initially focusing on content when available, then turning to evidence of effects on children and youth. The first focus is on the disappearance of quiet environments, as media have become an ever-present aspect of children's lives. The effects of noisy environments are considered in terms of declines in imaginative activities and creativity, disrupted sleeping patterns, and distractions that occur when multitasking. However, there are important exceptions to these negative influences. A media diet of prosocial television programming, for instance, can lead to enhanced imaginative play for young children, as well as higher levels of creativity when children become adolescents (D. R. Anderson, Huston, Schmitt, Linebarger, & Wright, 2001). Then the social nature of media environments is examined, including prosocial media and role models, parasocial relationships that children develop with media characters, and online social relationships that children engage in through social networks.

The mean and scary world follows, with descriptions of how media violence has aroused, desensitized, and

influenced the cognitive scripts and behaviors of children and adolescents in observational as well as interactive media. This scary media world is not just about violent content, but where children experience the supernatural, either by choice or by accident. The gendered world of media is discussed, which is a world that is still dominated by heterosexual European American men who are strong and powerful, supported by emotional women who define themselves by their physical appearance and are less often visible onscreen (Hust & Brown, 2008). Online experiences also provide opportunities for youth to express who they are, and they do so, often in sexual ways during the adolescent years when sexuality is becoming a key aspect of how youth define themselves (Subrahmanyam, Smahel, & Greenfield, 2006). Efforts to reduce youth exposure to sexually explicit online content are considered (Thornburgh & Lin, 2002), which have been complicated by peer-to-peer file sharing such as sexting, in which youth send nude or semi-nude pictures to one another (Lenhart, 2009).

The marketing of energy-dense, high-caloric foods to children is addressed in relation to the surge in the pediatric obesity rate (Institute of Medicine [IOM], 2006). The social marketing of healthier products to children, in part through popular media characters, is considered as one option to reduce the obesity crisis, as are interactive media, such as sensors that track energy expenditure and exergames that require gross motor movement for play (Calvert, Bond, & Staiano, 2014). Exposure to media portrayals of alcohol, tobacco, and drug influences on children's behavior is considered, particularly when attractive role models engage in these behaviors (Roberts & Christenson, 2000). Social policies are then addressed.

Conclusions are drawn about children's lives in the 21st century, where they are digital natives (Prensky, 2001), but soon will be displaced by the next generation of children whose lives will be embedded in the next generation of media. In the media area more so than any other, the only constant is rapid change.

## **THEORETICAL PERSPECTIVES ON MEDIA USE AND EFFECTS**

The study of children's media is multidisciplinary and interdisciplinary, spanning diverse fields including child psychology, child development, communications, health, medicine, and public policy. This diversity occurs, in part, because of the pervasive influence of media content and

media experiences on a broad range of topics and developmental outcomes. For this reason, the theories brought to bear on understanding the impact of media on children's development employ a range of different approaches. Theories of development that are grounded in psychology and theories of communication are the key approaches that have been used to describe and examine the influences of media on children and adolescents. Some of these theories, such as communication theories, psychoanalytic theory, and behaviorism, are less often used in contemporary developmental science, but they are useful for addressing core issues that are germane to the media area.

### **Social Cognitive Theory**

Social cognitive theory has played a central role in explicating the role of media on children's behavior (Bandura, 1986, 1997). Children learn behaviors through processes of observational learning, and later translate some of those actions into their own behavioral repertoire if there are sufficient motivational incentives to do so. The subprocesses of social cognitive theory involve attention to information, retention of that information through encoding and representational processes, production of that behavior, and motivation to do so which involves perceptions of rewards or punishments for acting on what one has observed. Self-efficacy, the perception that one can control the events around one, influences whether or not observers will act on an event that they have seen (Bandura, 1997).

Role models are central to Bandura's theoretical approach, with children who identify with certain media characters becoming more likely to imitate their actions. When undesirable behaviors are not punished or are even rewarded, disinhibition can occur, making it more likely that children will imitate antisocial behaviors (Bandura, 1986). Response facilitation occurs when children observe and then imitate models perform socially constructive, prosocial behaviors, some of which have previously been low in frequency (Bandura, 1986). Social cognitive theory is content neutral in predictions, and has been used to explain why and how children imitate a range of behaviors, including aggressive behavior, prosocial actions, gender-stereotypical or gender-counterstereotypical behaviors, and health-related behaviors.

### **Parasocial Relationships and Parasocial Interactions**

In the field of communications, parasocial relationships and parasocial interactions describe the kinds of

social experiences that children perceive that they have with media characters. Parasocial interactions originally described adults' relationships with televised newscasters who looked directly into the camera lens and spoke to the audience as if they were having a conversation (Horton & Wohl, 1956). Through these experiences, viewers came to trust certain newscasters and acted like they had a personal relationship with them (Horton & Wohl, 1956). Parasocial interaction and parasocial relationship were once considered the same phenomenon. Parasocial relationships now describe ongoing personal bonds with favorite characters, but parasocial interactions can take place one time (Schramm & Hartmann, 2008).

With a few notable exceptions (see Hoffner, 1996, 2008), research has examined adults' parasocial interactions and relationships with media characters rather than children's parasocial relationships and interactions. However, parasocial interaction techniques are often used in children's media with characters who directly address the child audience through the camera lens, talk to the child and pause for a reply, and then act as if they heard what the child said (Lauricella, Gola, & Calvert, 2011). In essence, characters act as if they are in an interaction with children in the viewing audience, and children, in turn, often reply to the characters through their own actions and words (D. R. Anderson et al., 2000), with those who respond to characters demonstrating better plot comprehension (Calvert, Strong, Jacobs, & Conger, 2007). Children also have favorite characters (Hoffner, 1996), and these personal relationships with media characters may indicate a parasocial relationship, which also predicts their learning (Calvert & Richards, 2014).

### Cognitive Approaches

Children's programs are presented through story or magazine formats (J. C. Wright et al., 1984). Mature plot comprehension involves separating the central, plot-relevant from the incidental, irrelevant program content, ordering the central content into a story scheme, and drawing inferences about characters' motives and integrating the cause-event sequences that organize the story (W. A. Collins, Wellman, Keniston, & Westby, 1978). Prior to Ages 9 and 10, children have difficulty in understanding implicit program information, such as character motives and feelings (W. A. Collins et al., 1978).

Because children must understand motives and intent to comprehend television stories (W. A. Collins et al.,

1978) and advertisements (Calvert, 2008a), cognitive theories are often used to examine the impact of media on children's learning and social behavior. The theories of Piaget (1954), Vygotsky (1962, 1978), and various information-processing approaches have been used to examine children's comprehension of televised narratives, their social behavior, and their comprehension of commercial intent (i.e., that advertisements are designed to persuade consumers to buy products), which is often blurred by marketing practices (Calvert, 2008a; Kunkel & Castonguay, 2012).

The visual and verbal ways that content is presented can be linked to developmental differences in how children think in iconic or symbolic modes (Calvert, 2005). Modes of thought have been used to understand plot comprehension, as are scaffolds provided by parents or other adults, such as teachers, to help children reach just beyond their current level of comprehension to advance their understanding of program-related content (Vygotsky, 1962, 1978). Cognitive developmental approaches have also been used to understand gender constancy in relation to children's selective attention and memory of program-related material (e.g., Luecke-Aleksa, Anderson, Collins, & Schmitt, 1995). In information-processing theory, viewers' schemas guide children's selective attention and understanding of content.

### The Cultivation Hypothesis

Because content influences the impact that media has on children and adolescents, content analyses, in which the kind of onscreen information is analyzed, have been conducted in numerous areas, including media aggression, prosocial behavior, gender-stereotyped behaviors, health-related behaviors, and sexuality (Calvert & Wilson, 2008). Gerbner (1972) argued that media content depicts the power structure and symbolic relationships among people in a social system, as reflected in his Violence Index that tracked the amount of violent content in television programs. For instance, female characters, particularly women of color, are often symbolically annihilated on television, appearing much less frequently than male characters do, which reflects their trivialization and lack of power in U.S. culture (Tuchman, 1979).

In Gerbner's cultivation hypothesis, media exposure can promote certain beliefs and expectations. For instance, repeated exposure to violent content can lead to *mainstreaming*, which leads to the construction of a shared

vision of reality as a violent place because so much of the content is violent (Gerbner, Gross, Morgan, & Signorielli, 1994). Exposure to content can also *resonate* with viewers' own experiences if what they view is consistent with something that has happened to them (e.g., being mugged in real life could resonate with seeing depictions of muggings onscreen; Gerbner et al., 1994). The Internet allows underrepresented youth to create their own shared realities, as when sexual minorities present themselves and find support from others through blogs in the form of online personal diaries (Huffaker & Calvert, 2005).

### Uses and Gratification Theory

Uses and gratification theory explains why we use media. In this approach, children select certain media content and experiences (the uses) to fulfill certain emotional and social needs (the gratifications; Rubin, 1994). Three main motivations to use media have emerged: for diversion and escape, for personal identity construction or social utility (such as strengthening contact with others), and to gain information, such as social information about others (Rubin, 2002). Selective exposure to media, then, depends on the needs of the users.

### Arousal Theory

Arousal theory involves physiological responses in relation to real or imagined events (Calvert, 1999). Autonomic arousal, the typical focus in media studies of emotion, has been measured physiologically with heart rate and skin conductance (Zillmann, 1982) as well as by facial expressions (Cantor & Hoffner, 1990). With increased exposure, habituation occurs and desensitization takes place. As a consequence, the content must become more extreme to create the original arousal level, although arousal can return to its former level after sufficient time passes and disinhabituation occurs (Zillmann, 1982). Arousal has no predetermined direction for outlets, instead being triggered by immediate environmental influences (Zillmann, 1982).

Arousal theory can also be linked to uses and gratification theory and to children's selective exposure decisions. That is, media can be used to regulate arousal levels. Those who are bored may search for content that stimulates them, whereas those who are anxious may search for content that relaxes them. For instance, children can regulate their own arousal levels by choosing whether or not to view scary and aggressive content.

### Psychoanalytic Theory

Freud proposed that humans are by nature aggressive and sexual, which represents the destructive and libido instincts, respectively (Hall, 1999). To release pent up drives, energy is released through various mechanisms, such as catharsis, in which a fantasy experience can substitute for a real experience (Hall, 1999). Theoretically, viewing or playing with aggressive content can drain off aggressive impulses in a way that is not harmful to others. When studying media, most social scientists have used Freud's approach to psychoanalytic theory.

Within psychoanalytic theory, an overlooked variation of Freud's ideas is Jung's articulation of archetypes as an explanation for interest in media portrayals, such as violence. Archetypes are prototypical experiences of humans represented in media by symbols such as the hero, the villain, the wise old man, the mother, the father, the child, the shadow (generally representing the dark side of human nature), the sun, and a wolf howling at the moon (Hall & Nordby, 1999). When applied to media, the archetype of the hero represents the fight for good over evil against the villain, including the hero's struggle to stay just when engaging in behaviors that can take a person to the dark side of the emotions, such as feelings of anger and revenge (Calvert, Kondla, Ertel, & Meisel, 2001).

Another variation of psychoanalytic theory developed by Erikson (1963) adds psychosocial to psychosexual stages. Identity formation is central to this paradigm, as are other developmental tasks experienced by children at different points in their development (Erikson, 1963). Online experiences can be a resource for youth to construct their identities (Calvert, 2002; Subrahmanyam et al., 2006).

### Behaviorism and Classical Conditioning

Although not used as much in contemporary developmental research, media influences continue to examine rewards and punishments. That which is reinforced tends to recur, and behaviors that are punished tend to decrease. The mere exposure effect, based on classical conditioning principles, is an example of how repeatedly exposing viewers to content can lead to positive feelings about it (Auty & Lewis, 2004). Marketing often uses behavioral conditioning principles by, for example, pairing branded media characters with foods or by placing products (i.e., product placement) in films or electronic games that they want children to purchase and consume (Auty & Lewis, 2004; Calvert, 2008a). The consumer, in this instance,

is being exposed to a subliminal message, and hence, may select that food because of associations with positive experiences, such as playing a game (Calvert, 2008a).

### Summary

Theories based in psychology and in communications have been used to explain why children use media, how they learn from media, and how they feel and act after media exposure. In cognitive theories, such as those put forth in schema theories and cognitive developmental theories, cognition organizes experience and behaviors (Huston, 1983). By contrast, in theories that come from a learning tradition, such as behaviorism and social cognitive theory, behavior occurs mainly due to reinforcement contingencies in the environment (Huston, 1983). Bandura (1986, 1997) did include cognitive mechanisms in his approach, including attention, retention, and self efficacy, but developmental changes in thought, such as those advanced by Piaget (1954), are absent from his approach. Parasocial relationships and parasocial interactions expand Bandura's ideas to social relationships with media characters as perceived friends, not just as role models (Calvert & Richards, 2014).

## THE HISTORY AND EVOLUTION OF MEDIA PLATFORMS

From birth onward, children's lives are embedded in a complex web of media that pervade their daily existence (Common Sense Media, 2011, 2013; Rideout et al., 2010). According to Wartella and Robb (2008), extensive electronic media experience marked a major change in the lives of children over the past century. In 1934, adolescents spent an average of *10 hours each week* with media. They now spend *more than 10 hours each day* with media when multitasking is included (Rideout et al., 2010; Wartella & Robb, 2008).

Face-to-face interactions in indoor and outdoor settings were normative at the beginning of the 20th century, with book reading as the main medium available for children to use. The electronic media of films and radio became popular in theaters and homes by the 1930s with radio becoming an option in cars. No environmental media influence, however, has been or has remained as powerful as television, which colonized children's leisure time as it entered children's homes during the 1950s (Wartella & Robb, 2008).

Television has been conceptualized as the electronic hearth of the home (Tichi, 1991), with parents and their children originally viewing together in their family or living rooms because they only had one television set. After World War II, recreational media moved from the public space of theaters to television sets inside the home, with penetration rates reaching 66% of U.S. homes between 1948 and 1955, and almost 90% by 1960 (Spigel, 1992). The popularity of viewing television programs has not diminished, even as newer interactive media appeared (Rideout et al., 2010), but children now view television programs online as well as on traditional television screens (Rideout et al., 2010).

Electronic video games became popular in the 1970s with personal computers becoming a common feature in homes during the 1980s. Children initially played video games on consoles and personal computers that were rather large, with later devices becoming smaller with options such as Gameboys. As the Internet moved into homes in the 1980s and 1990s, online experiences became an increasingly common activity for youth (Pempek, Yermolayeva, & Calvert, 2009). As the 20th century moved to a close, changes in Internet speed and emerging interfaces such as social networks led to a shift from online interactions with strangers to interactions with friends, particularly for adolescents who as a group tend to be early adopters of newer technologies (Pempek et al., 2009). Gaming became an online experience that continued to include strangers who were linked across the world in competitive experiences, such as massive multiplayer online role playing games (Tarpley, 2012). Sensor-based systems that originally involved hand-held devices, such as the controllers held to play games (Staiano & Calvert, 2011a), can track a person's movement and embed them onscreen as avatars that represent the player without any external device. These trends reflect an electronic hearth that is no longer a one-way experience that can now situate children within onscreen experiences.

The penetration of mobile technologies, such as musical devices, electronic tablets, and mobile phones, allows youth to be connected to media and to move seamlessly across them 24/7. Mobile technologies are a gateway to a vast array of information. With the computer as the hub of the wheel, the media environments of children are now integrated, providing multiple functions to youth as they use their mobile phones to listen to music, text or call one another, watch an online television program or film, or play an online game or mobile app.

Underlying this playful online experience is a business that is directed at profit making, which places children in a highly sophisticated commercial culture throughout their lives (Montgomery, 2012). Tracking software follows many of the keystrokes and activities of users, leading to a vast and detailed knowledge base for marketers to influence consumer attitudes and behaviors, which raises serious privacy issues (Montgomery, 2012).

Although the technologies are changing quickly, the developmental needs of children, such as friendship creation, identity formation, and emotional regulation, have remained constant (Calvert & Wartella, 2014). Indeed, children use media as a space in which they acquire information that addresses developmental needs, such as their sexual identity (Subrahmanyam et al., 2006). Developmental and communication theories which could account for media effects emerged and advanced during the same time frame that media were evolving, lending themselves to ongoing inquiries about how media influences children.

## THE ECOLOGY OF THE DIGITAL WORLD

Children's worlds are increasingly electronic and digital where information is accessed, delivered, and distributed by screen media rather than by traditional hard or soft cover books. Presumably, the impact of media depends on media access and exposure. Access is relatively straightforward: A child or the family has the technology, and children can use it. But what exactly is media exposure? Definitional and measurement issues create challenges in answering the latter question.

### Media Access

Numerous surveys have taken place in the United States over the past two decades to measure media access. These include Kaiser Family Foundation surveys with nationally representative samples conducted on 8- to 18-year-olds, which were published in 1999, 2005, and 2010, as well as younger children who were 0 to 6, published in 2003 and 2006, and then followed up on by Common Sense Media in 2011 and 2013.

The 2013 survey of U.S. parents of 0- to 8-year-olds ( $N = 1,463$ ) by Common Sense Media documented the extensive penetration of screen media in young children's homes. As seen in Table 10.1, 96% of these children's homes had a television set, 76% had a computer (69%

**TABLE 10.1 Media Present in 0- to 8-Year-Old U.S. Children's Homes**

	Among all children 0 to 8, percentage with each item in the home
TV	96%
Cable or satellite TV	70%
DVD player	78%
DVR	28%
Computer	76%
High-speed Internet	69%
Video game console	63%
Handheld video game player	35%
Smartphone	63%
Video iPod or similar device	27%
Kindle, Nook, or similar e-reader	21%
iPad or similar tablet device	40%

Source: Common Sense Media (2013), a nonpartisan nonprofit organization ([www.commonsense.org](http://www.commonsense.org)).

of which had high-speed Internet access), and 63% had a video game player. Television sets often had cable or satellite access, a DVD player, or a digital video recorder. Thirty-six percent of these children had their own television set in their bedrooms, 22% had a DVD or VCR player, 9% had a video game player, and 3% had a computer. A major change in access to mobile devices occurred in children's homes between 2011 and 2013. Overall, young children's mobile media access doubled from 2011 to 2013, and mobile media use tripled for young children during that time frame. In 2013, smartphones were available in 63% of homes compared to 41% in 2011, e-readers (like the Kindle and Nook) were found in 21% of homes compared to just 9% in 2011, and tablets (such as iPads) were found in 40% of homes compared to just 8% in 2011. Seven percent of 0- to 8-year-olds had their own tablet in 2013. Consistent with these findings, Wartella, Rideout, Lauricella, and Connell (2013) found that mobile devices were becoming prevalent in a nationally representative sample of low-income families with children under the age of 8 during 2012; specifically, 55% of these families had smartphones, though only 18% had tablets.

For U.S. children who were ages 8 to 18, the penetration rates of media in children's homes, particularly interactive and mobile media, were much higher than those of younger children. In a survey of 8- to 18-year-old U.S. children ( $N = 2,002$ ) conducted by Rideout et al. (2010), 99% of these children lived in homes with a television set (84% with cable or satellite options). The typical U.S. home for older children had 3.8 television sets, 2.8 DVD or VCR players, 1 digital video recording device, 2.3 video game

**Figure 10.1** Increases in mobile media access over time.

consoles, 2.5 radios, 2.2 CD players, and 2 computers. With few exceptions, more and more media entered 8- to 18-year-old U.S. children's bedrooms between 1999 and 2010, which enabled youth to exercise considerable control over their own media preferences and media exposure.

Mobile phones are mini computers, linking children to communication options as well as virtually any kind of information throughout the Internet, anytime and anywhere that the signal will travel uninterrupted. As seen in Figure 10.1, a major increase occurred from 2005 and 2010 in youth access to mobile media, including iPod/MP3 players, mobile phones, and laptops. Mobile phones became increasingly popular for all age groups, with older children owning these devices more than younger ones. Portable CD/tape players declined over time, perhaps because iPods and MP3 became music players, and music has again migrated, now to smartphones.

### Defining Media Exposure

Children's exposure to video content includes a mixture of foreground and background content. Just because a television set is "on" does not mean that children are paying attention to the content. In fact, very little relation was found in homes between children looking at a screen and being in the room with an operating television set, in part because exposure was occurring in the backdrop of family activities, such as playing or even sleeping (D. R. Anderson, Field, Collins, Lorch, & Nathan, 1985).

For foreground exposure, eyes on screen may be the most valid measure. Even so, one can be looking at a screen and not really paying attention (Calvert, 1999). Doing another activity during viewing may also indicate that television viewing is a foreground or a background activity, as children may still be responsive to the audio

track in both instances. That is, they may intentionally look back at the screen when they think that something interesting is about to happen, or they may automatically look back at the screen when a primitive attentional orienting response is elicited, such as a loud onscreen noise (Calvert, Huston, Watkins, & Wright, 1982). Foreground exposure is more likely to be age-appropriate than is background exposure, but background exposure also affects developmental outcomes (D. R. Anderson & Pempek, 2005). For instance, background media exposure disrupts children's play, a contributor to early cognitive development (Schmidt, Pempek, Kirkorian, Lund, & Anderson, 2008).

A *media diet*, consisting of the overall amount (quantity) and the kind of exposure (quality), is another consideration in defining media exposure (D. R. Anderson & Hansen, 2009). The quantity of media exposure can be correlated with certain developmental outcomes simply because that kind of content is more available. For instance, most television programs contain violent content (Wilson, 2008), and hence overall television exposure may be correlated with aggressive outcomes. The kind of media exposure, such as exposure to aggressive or prosocial material, is useful for assessing specific media effects (D. R. Anderson et al., 2001).

Exposure is somewhat easier to assess for interactive than for observational media because children are typically doing some kind of physical behavior, such as touching the screen or moving content around. However, trends for multitasking that emerged in the Kaiser Family Foundation (Rideout et al., 2010; Roberts, Foehr, & Rideout, 2005) data for 8- to 18-year-olds as well as in the Common Sense Media (2011) data for 0- to 8-year-old children added yet another layer of difficulty to defining media exposure. When they are multitasking, youth may have a primary and a secondary media activity, such as writing a blog

and listening to music. This kind of exposure is not unlike foreground and background exposure to television or other kinds of video content. *Total media use* was defined by how much time was spent with media, whereas *total media exposure* added extra time to that total when more than one medium was used simultaneously due to multitasking (Roberts et al., 2005).

### Measuring Media Use and Exposure

Seven main methodological approaches have been used to measure media use and exposure (D. R. Anderson & Hanson, 2009; Vandewater & Lee, 2009). *Global time estimates* ask parents, children, or both to estimate overall exposure to various media (e.g., “How many hours did you (or your child) watch television yesterday?”). Diaries include *time-use diaries*, such as the Child Development Supplement (CDS) of the Panel Study of Income Dynamics (PSID), which asks parents of younger children or older children themselves to track and write down all of their media experiences over a period of time (Vandewater & Lee, 2009). *Media diaries* use various approaches such as having parents write down the specific television program a child is viewing in say, 15-minute intervals (e.g., D. R. Anderson et al., 1985). *Direct observations* of behaviors using video equipment are another option, but the cost is prohibitive (D. R. Anderson et al., 1985). *In experience sampling*, youth can carry an electronic device and be randomly contacted at periodic intervals to inquire about what they are doing at that specific moment, but it disrupts participants’ ongoing behaviors (Csikszentmihalyi & Kubey, 1981). *Electronic monitors*, such as the Nielsen People Meter, can track who is viewing a specific television program although this kind of methodology is invasive. Similarly, *tracking software* is very accurate and can identify exactly where specific users have gone online (Vandewater & Lee, 2009), but privacy issues are raised (Thornburgh & Lin, 2002).

Although diaries are one of the most accurate measures (D. R. Anderson et al., 1985), the cost effectiveness of global time estimates have made them a method of choice. Indeed, the most comprehensive data on U.S. children’s media use and exposure patterns over the past decade have come from nationally representative cross-sectional surveys using global time estimates initially conducted by the Kaiser Family Foundation (Rideout et al., 2010; Rideout & Hamel, 2006; Rideout, Vandewater, & Wartella, 2003; Roberts et al., 2005; Roberts, Foehr, Rideout, & Brodie, 1999) and now Common Sense Media (2011, 2013). These

surveys examined three different cohorts broken into two different age groups: 0- to 6-year-olds (and later 0- to 8-year-olds), and 8- to 18-year-olds. Because these are major sources of ongoing information about children and youth media use and exposure patterns, this age breakout and their survey measure will be used to organize the area of media use and exposure patterns.

### Media Use for 0- to 8-Year-Old Children

In the 2013 Common Sense Media survey of 0- to 8-year-old U.S. children’s media use patterns, children spent 2 hours, 43 minutes on a typical day with screen media, music, and reading. Exposure to screen media far surpassed music and reading exposure. Specifically, children spent 1 hour, 55 minutes per day using some kind of screen media, but only 28 minutes reading or being read to, and 20 minutes listening to music. Within screen media, watching television and DVDs dominated young children’s time, with interactive media use lagging behind.

When age comparisons were conducted, developmental differences were found for exposure to screen media. As seen in Table 10.2, infants spent an average of about one hour with screen media each day, which increased to just

**TABLE 10.2 Average Amount of Time Spent With Media by Age Among 0- to 8-Year-Old U.S. Children on a Typical Day**

under 2 hours daily for 2- to 4-year-olds, and almost 2½ hours daily for 5- to 8-year-olds. Reading or being read to also increased significantly from the first year of life to Ages 5 to 8 ( $M = 19$  minutes versus 32 minutes, respectively); those who were Ages 2 to 4 ( $M = 29$  minutes) were not significantly different from the younger or the older age groups. Notice that the overall amount of screen time is higher than time spent reading at all ages, even though the early years are important for the development of language and reading skills. The one area of media exposure that decreased significantly after Age 1 was listening to music.

The Common Sense Media (2011) survey also found that parents reported that 16% of 0- to 8-year-olds were multitasking some or most of the time, with the highest rates for 5- to 8-year-old children, 23% of whom multitasked some or most of the time. Approximately twice as many African American (22%) and Latino/a American (21%) than European American (11%) 0- to 8-year-old children multitasked some or most of the time.

Earlier reports from the Kaiser Family Foundation (Rideout et al., 2003; Rideout & Hamel, 2006) found that parents generally had favorable beliefs about the *kind* of media content that their young children used. For instance, 66% of parents reported that they had observed their young children imitating prosocial behaviors, particularly after viewing children's educational television programs. By contrast, only 23% of parents observed their young children imitating aggressive behavior, which was reported more for sons than daughters. Older children imitated content more than younger children did.

Parents also perceived different media differently. In particular, Rideout and Hamel (2006) found that 69% of parents believed that computers helped their children, and 38% of parents viewed television favorably, but only 17% perceived video games favorably. By contrast, only 8% of parents thought that computers hurt their young children compared to 31% who viewed television negatively, and 49% who perceived video games negatively. These differences in attitudes toward technologies may well signify content as well as interactivity differences that their children are experiencing when using these media (Calvert, 2006).

### Media Use and Exposure for 8- to 18-Year-Old Children

For youth who were 8 to 18 years of age, the daily *total media use* averaged 7 hours, 38 minutes (Rideout et al., 2010), more than double that of younger children. When the time spent multitasking was considered separately, *total media exposure* escalated to an average of 10 hours, 45 minutes for older children. Television viewing was by far the most used medium, followed by music, and video games, with print and film being the least used media. Although mobile phone use was an emerging trend, only listening to music, playing games, or watching videos was counted toward media exposure to keep the 2010 report consistent with prior reports. That left out texting and talking on mobile phones as part of the media exposure total, which is a major omission given that 8- to 18-year-olds spent an average of 1 hour, 35 minutes per day texting, and an additional 33 minutes per day talking on mobile phones (Rideout et al., 2010).

**Figure 10.2** Media use and exposure by age.

Source: *The Media Family: Electronic Media in the Lives of Infants, Toddlers, Preschoolers and Their Parents*, by V. Rideout, U. Foehr, and D. Roberts, 2010, Menlo Park, CA: Kaiser Family Foundation. Reprinted with permission.

Age differences in total media exposure during the 2010 media study significantly favored older over younger youth. As seen in Figure 10.2, daily *total media exposure* was about 12 hours daily for 11- to 14-year-olds, 11½ hours for 15- to 18-year-olds, and “only” about 8 hours per day for 8- to 10-year-olds. Note that these figures are *per day*. The *total media use* figures were close to 9 hours per day for 11- to 14-year-olds, about 8 hours per day for 15- to 18-year-olds, and about 5½ hours per day for 8- to 10-year-olds. All age groups spent more time watching television content than any other media activity, though television viewing moved to additional platforms, such as computers and mobile phones. Reading print media was actually more prevalent among younger 8- to 10-year-old children than for 15- to 18-year-old youth, a finding that has striking ramifications for literacy skills in the United States.

In the 2010 media survey, boys’ *total daily media exposure* was about 11 hours per day compared to about 10 hours for girls (Rideout et al., 2010). The gender difference was mainly attributable to boys investing more time in gaming on video game consoles or computers than girls did. Girls, by contrast, spent more time with music, print media, and online social networks than boys did. The 2010 gender differences in exposure to music and playing console video games are consistent with prior 2005 patterns (Roberts et al., 2005). In 2010, however, girls spent almost one hour more texting and talking on mobile phones than boys did, which was not counted in total media exposure time (Rideout et al., 2010). Had these figures been included, there would probably have been no gender difference in overall media exposure in 2010.

During the earlier 2005 media survey, increases in *total media exposure* were fueled mainly by multitasking. The authors speculated that 6½ hours of daily *total media use* was the peak of what was possible (Roberts et al., 2005). The mobile media that entered children’s worlds after that second report, however, proved them to be incorrect, with *total media use* increasing to about 7½ hours per day. As electronic media continued to gain more ground in children’s *total media use*, reading print media lost ground when compared to the earlier survey (Rideout et al., 2010; Roberts et al., 2005).

African American and Latino/a American youth have more media exposure than European American youth. *Total media exposure* was approximately 13 hours per day for African American and Latino/a American youth, but “only” about 8½ hours per day for their European American peers. That is a daily *total media exposure*

increase of almost 4 hours for African American children, about 4¾ hours for Latino/a American children, and about 1½ hours for European American children between 1999 and 2010 (Rideout et al., 2010). Between 2005 and 2010, significant increases were found favoring Latino/a American and African American youth in exposure to music and video game play, and television exposure favoring Latino/a American over African American and European American youth (though African American youth still consumed the most television content at almost 6 hours per day). Ethnic differences in media use patterns were robust, even with numerous statistical controls (Rideout et al., 2010). Differences also appeared in 2010 for using mobile phones to talk, favoring both African American and Latino/a American over European American youth, and in texting, favoring African American over European American youth. By contrast, European American youth read more books than African American or Latino/a American youth did.

Consistent with the Kaiser Family Foundation survey data, diary data from the Panel study of Income Dynamics revealed that African American children spent more time watching television and playing video games than European American or Latino/a American children did. By contrast, European American children viewed more educational television programs than their African American peers, and European American children played more educational computer games than either African American or Latino/a American children (Bickham et al., 2003).

Because electronic media permeated older youths’ homes, their experiences were often oriented around media. In 2009, 64% of youth reported that the television set was typically on during meals and 45% of the time when no one was viewing. Only 26% of U.S. 8- to 18-year-olds reported any rules about the music they listened to, only 30% had any rules about the video games they played, 46% had rules about what *kind of program* they could view on television (as compared to 28% who reported rules about *how much* television content they could view), and 52% had rules about what they could do on a computer (Rideout et al., 2010). Daily total media exposure in homes with no rules was higher (almost 13 hours) than in homes with some media rules (almost 10 hours). Few ethnic differences existed in how much time children were allowed to spend with media, but European American children generally had more rules about content than did their African American or Latino/a American peers did.

Taken together, the data suggest that media provide a backdrop in which most U.S. children develop, much of

which is unregulated by their parents. Ethnic minorities are extremely heavy users of electronic media, outpacing their European American peers in adopting and in using all media except for reading books for pleasure and watching educational television programs. The implication is that European American more so than African American and Latino/a American children live in homes that support educational media, a pattern that reinforces an ongoing digital divide in the quality of home media environments. Television viewing, nonetheless, remains the most common experience for U.S. children of all ages, suggesting an ongoing and sustained interest in watching the lives and the stories of others.

### THE DISAPPEARANCE OF QUIET ENVIRONMENTS

Overall, the picture that emerges from children's media access, usage, and exposure patterns is an environment characterized by considerable noise and potential distractions. This noise comes not just from the media that children and youth select, but also from ambient noise that is part of the everyday environment. This noisy world can disrupt children's play and creativity (Schmidt et al., 2008; Valkenburg & Calvert, 2012), their sleep (Thompson & Christakis, 2005), and their concentration (Christakis, Zimmerman, DiGiuseppe, & McCarty, 2004).

### Media, Imaginative Play, Creativity, and Daydreaming

Imagination contributes to positive developmental outcomes, including higher levels of empathy, perspective taking, happiness, and flexibility (D. G. Singer & Singer, 1990). Imagination can be conceptualized as children's imaginative play (also pretend or fantasy play), creative imagination (i.e., creativity), and fantasies. In imaginative play, children transcend the immediate environment and act "as if" they are experiencing another perceptual reality (van der Voort & Valkenburg, 1994). For instance, a child may engage in role-play activities or pretend to be someone else (James & McCain, 1982). Creative imagination can be defined "as the capacity to generate many different novel or unusual ideas" (Valkenburg & Calvert, 2012, p. 158), or as divergent processing (D. G. Singer & Singer, 2005). Involvement in the arts is one area that is used to measure creative imagination (D. R. Anderson et al., 2001), as are tasks that require the generation of numerous novel responses (Valkenburg & van der Voort, 1994). Daydreaming involves the suspension of physical activity while one

engages in internal, mental fantasies (Valkenburg & van der Voort, 1995).

A quiet environment is a necessary ingredient for creative imagination to develop as it provides a space to think, to reflect, and to pause during and after busy days (D. G. Singer & Singer, 2005). These kinds of spaces are generally inconsistent with television viewing and more readily found when reading books, thereby increasing the probability of disrupting imaginative play and creativity as electronic media exposure increases (D. G. Singer & Singer, 2005). One can also consider a media diet, in which the quantity of exposure is examined separately from the quality of exposure (D. R. Anderson & Hanson, 2009). Thus, exposure to certain kinds of media and media content could cultivate imagination and creativity.

Two overarching hypotheses have been used to examine the role of media in imaginative play, creativity, and fantasy. These are the *stimulation hypothesis*, in which exposure to media is predicted to increase imagination, and the *reduction hypothesis*, in which exposure to media is predicted to disrupt imagination (Valkenburg & van der Voort, 1994; van der Voort & Valkenburg, 1994).

### The Stimulation Hypothesis

In the stimulation hypothesis, media environments provide the raw content that children can subsequently use in their play, their creative tasks, and their internal fantasies (Valkenburg & Calvert, 2012). Most studies on this topic have examined television exposure, which is a limitation of the database, because interactive media are more likely to require children to generate a product than observational media are (Calvert & Valkenburg, 2013). When the quantity of television exposure is examined, the data suggest that children incorporate the content that they view into their fantasy play and their creative products, but the data do not indicate that children are any more imaginative in their play (Shmukler, 1981) or make creative products due to television exposure (e.g., J. L. Singer, Singer, & Rapaczynski, 1984).

A more positive picture emerges for the role of media on imagination when the *quality* of the content that children view is considered. More specifically, educational and prosocial programs that are designed to cultivate creativity and imaginative play, such as *Mister Rogers' Neighborhood* and *Dora the Explorer*, generally do so (Calvert et al., 2007; Friedrich-Cofer, Huston-Stein, McBride-Kipnis, Susman, & Clewett, 1979). Environmental supports, such as having children play about the content, are especially likely to yield beneficial outcomes for imaginative play

(e.g., Friedrich & Stein, 1975). Longitudinal research also finds more creative activities during adolescence for those who viewed more versus less imaginative television programming, such as *Mister Rogers' Neighborhood*, during early childhood, even after including numerous statistical controls (D. R. Anderson et al., 2001).

Exposure to imaginative role models, as predicted by social cognitive theory, is one reason that imaginative play and creativity may increase after exposure to television programs such as *Mister Rogers' Neighborhood*, because Fred Rogers modeled imaginative activities (Valkenburg & Calvert, 2012). The slow pacing and pauses built into some children's programs, which allow time for reflection and interaction, are other possible reasons that certain kinds of media content may promote imaginative play and creativity (Calvert & Valkenburg, 2013).

Lean forward media can also increase imaginative play, particularly with friends. When 10- to 12-year-old children were participating in computer-generated interactions, in this case within a visual and textual multiuser domain (MUD), they sometimes engaged in role playing experiences, such as pretending to shoot imaginary balls at a basketball net, or pretending as if they were drowning at a beach (Calvert, Mahler, Zehnder, Jenkins, & Lee, 2003). Children engaged in role-play activities twice as often when they knew the peer in the MUD than when the peer was a stranger (55% versus 27%, respectively; Calvert, Strouse, Strong, Huffaker, & Lai, 2009).

Youth can also create content on sites that provide opportunities to do so. Scratch, a relatively simple programming language created at MIT, allows children to create their work on their own computer and then post their program in a shared online space. Children who created programs in Scratch also engaged in remixing, in which they build on the products that others have created. In one qualitative study, Brennan, Monroy-Hernandez, and Resnik (2010) described a girl who followed another girl's stories about a hero named Jodie that she had created and represented in words and still-frame visual depictions. As the reader became increasingly interested in the stories, she imagined visual moving images. She contacted the author online and asked if she would like a collaborator who could animate the stories. Hence, the animated stories of the superhero Jodie came to life in 10 episodes through a collaborative team effort. Describing these kinds of collaborative experiences could be informative about how creative group work will take place in the 21st century, as major scientific advances are often now the output of teams of scholars rather than the output of a single individual.

Creative innovation also occurs in the online interactions of youth as they develop and use new language systems in which abbreviated codes represent words, such as *brb* (for be right back) and *lilas* (for love you like a sister) (Calvert, Mahler, et al., 2003; Greenfield & Subrahmanyam, 2003). Coded language, also called Netpeak, includes iconic images called emoticons to express feelings, such as a smiley face 😊, or :- ) when text based, to represent happiness, or a frowning face ☹, or >:( when text based, to represent anger (Huffaker & Calvert, 2005).

Daydreaming is more likely to be stimulated than disrupted by television viewing (Valkenburg & van der Voort, 1994). The kind of content that is part of a child's media diet also plays a role in daydreams. For instance, Dutch children who viewed more aggressive television programs reported the most aggressive, heroic content, whereas those who viewed nonviolent children's programs reported more positive content in their daydreams (Valkenburg & van der Voort, 1995).

### ***The Reduction Hypothesis***

According to van der Voort and Valkenburg (1994), television viewing can reduce imaginative play due to *displacement* (viewing television takes time away from participating in imaginative activities), *passivity* (television viewing makes children lazy processors, which is the antithesis of the active involvement required for imaginative activities), *rapid pacing* (television images come and go so quickly that there is no time to reflect, a key component of imaginative activities), *arousal* (television viewing overstimulates children, and hence they become hyperactive and impulsive rather than reflective, which is required for imaginative activities), and *anxiety* (television viewing frightens children, thereby disrupting imaginative activities). The data mainly support *displacement* as the reason that television viewing disrupts imaginative play (van der Voort & Valkenburg, 1994). For example, children shifted about an hour and a half per day of playing to viewing when television was first introduced in the United States (Maccoby, 1951), and children played less when television was introduced in their towns when compared to other towns where children still only had radios (Schramm, Lyle, & Parker, 1961). However, play time increased when television was initially introduced in Australia (Murray & Kippax, 1978) so not all research finds displacement. Background television exposure also decreased the amount of time that 12-, 24-, and 36-month-olds spent playing, partly because looking at the television screen disrupted play (Schmidt et al., 2008).

For creative imagination, Valkenburg and van der Voort (1994) argued that the evidence supported the reduction hypothesis via *visualization* (the ready-made images of television productions disrupt children from making their own images), *arousal* (the rapid pacing in television programming increases impulsiveness and restlessness, thereby disrupting imaginative activities), and *displacement* (television viewing displaces other activities, including imaginative ones). In support of the visualization hypothesis, children typically generated more novel story endings when they listened to radio stories than when they watched stories on television (Greenfield, Farrar, & Beagles-Roos, 1986; Valkenburg & Beentjes, 1997). The arousal hypothesis has not been directly tested, but the foundation of this argument is consistent with the reduction hypothesis. Specifically, viewing violent television programs creates more arousal (Zillmann, 1991), intolerance for delays (Friedrich & Stein, 1973), and restlessness (Singer et al., 1984). The displacement hypothesis has also received support: The longer television was available in a Canadian town, the more creative imagination scores declined (L. F. Harrison & Williams, 1986).

The visualization, passivity, and rapid pacing hypotheses were used to examine potential reduction effects for daydreaming as a function of television exposure. These hypotheses were not supported by empirical studies (Valkenburg & van der Voort, 1994).

### Summary

The extant data suggest that heavy television viewing typically reduces imaginative play and creativity. Television viewing can displace imaginative play, and there is some support for visualization, arousal, and displacement effects for creativity. However, the kind of content viewed also makes a difference, with imaginative programs leading to imaginative play in the short term, and creativity in the long term. Moreover, emerging qualitative data suggest that using interactive media to make content can lead to creative activities. Daydreaming in the form of internally generated fantasies is positively influenced by television viewing, with the kind of content viewed becoming integrated into children's fantasies, but little is known about the role of newer interactive media and daydreaming. The loss of quiet environments *per se* has not been studied as a potential explanation for the reduction hypothesis, even though quiet, reflective time has been proposed as a necessary ingredient for imaginative activities (D. G. Singer & Singer, 2005).

### Media and Sleep Patterns

Sleep disturbances, in the form of later bedtimes, nightmares, and tiredness from lack of sleep, are linked to media use. Paradoxically, many youth use some type of media as sleep aids to help them go to sleep. Approximately 37% of Flemish adolescents reported that they watched television programs to go to sleep, 22% played computer games, 60% listened to music, and 55% read books (Eggermont & Van den Bulck, 2006). Adolescents who relied on television programs, computer games, and music as sleep aids slept less well and reported being more tired than those who read books (Eggermont & Van den Bulck, 2006).

Using time-use diaries from the Child Development Supplement of the Panel Study of Income Dynamics, Adam, Snell, and Pendry (2007) found that 5.5- to 11.9-year-old U.S. children who watched more television on weekdays had fewer total hours of sleep, although the effect was small. During the weekend, television viewing and playing computer or video games predicted less sleep for younger children as well as older adolescents because of later bedtimes. African American and Latino/a American children slept less than their European American peers did during the weekend, in part due to watching television programs and playing computer and video games (Adam et al., 2007).

One problem in sleep disorders is going to sleep (Mindell, Moline, Zendell, Brown, & Fry, 1994). Exposure to light can alter circadian rhythm cycles that influence when one is awake and when one is asleep (Lewy, Sack, Miller, & Hoban, 1997). In an experimental study comparing young Japanese male adults who were exposed to computer screens that varied in light levels (high or low) and cognitive demand levels (high or low), the cognitive demand, not the brightness of the computer screen, impacted sleep cycles. In particular, delayed sleep latency occurred during the high-cognitive-demand task due to increased heart rates and reported decreases in sleepiness (Higuchi, Motohashi, Liu, & Maeda, 2005), which is consistent with arousal theory. The total amount of REM sleep, which involves dreaming, also decreased during high over low cognitive demands, but again was not influenced by onscreen light levels (Higuchi et al., 2005). These findings suggest that engaging tasks may disrupt sleep onset. The sample for this study was small, and hence, light cannot be ruled out as a distractor when going to sleep.

The noise that comes from audio tracks has not been examined, even though Japanese adolescents reported

falling asleep more quickly when they were in quiet rather than noisy rooms (Alexandru et al., 2006). Loud noises, which periodically occur in television programs and video games, elicit primitive attentional orienting responses to video screens from children who are Ages 4 through 10 (Calvert et al., 1982; Calvert & Gersh, 1987; Calvert & Scott, 1989). The implication is that children who go to sleep with television programs playing in the background may have difficulty staying asleep due to changes in the audio track.

Another potential noise disruption during sleep is a text or a call on a mobile phone. Van den Bulck (2007) found that Finnish adolescents who reported sending or receiving texts on their mobile phones after the lights were out were more likely to report being tired a year later. Although many of these texts were exchanged soon after bedtime, almost one fifth of these youth reported sending or receiving texts at all hours of the night. One possible explanation is that these sleep disruptions could be caused by sounds on mobile phones that alert youth that a text is arriving, thereby interrupting their sleep cycles.

Media diets have also been linked to sleep disturbances. For example, Paaoven, Pennonen, Roine, Valkonen, and Lahikainen (2006) found that Finnish 5- and 6-year-old children who were passively exposed more rather than less often to adult-oriented television programs had more problems with transitions between being awake and asleep as well as more overall sleep problems, even after controlling for socioeconomic status, family conflicts, family income, and the father's work schedule. Consistent with these findings, the kind of program is associated with sleep problems. For instance, exposure to an adult-oriented police series was linked to disorders involving transitions between being asleep and awake. By contrast, links between the quantity of active exposure to child-directed programs and sleep disorders were not significant after controlling for other background variables (Paaoven et al., 2006). Viewing scary content is also linked to sleep problems, as is having a television set in children's bedrooms (Cantor, Byrne, Moyer-Guse, & Riddle, 2010). In short, passive exposure to adult-oriented programs is detrimental to children's sleep as is exposure to scary content, but active exposure to child-oriented programs is not.

Taken together, the data indicate that youth who have electronic media at their fingertips, particularly in their bedrooms throughout the night, sleep less well and have more problems going to sleep and waking up than their peers who read before going to sleep. These problems come from

engagement with media content, self-inflicted interruptions in their own sleep cycles when they interact with their peers on devices such as mobile phones, and possibly changes in light or audio levels. Virtually all of the data, however, are correlational.

It seems likely that children's use of electronic media may exacerbate the problems associated with going to and staying asleep, but a potential third factor may underlie this relation: Some youth have difficulties going to sleep in the first place, and hence, elect to use media. Adolescents across numerous cultures report going to bed later as they get older (Crowley, Acebo, & Carskadon, 2007). Their choice to use media at bedtime as a sleep aid may create a self-defeating cycle where youth are more likely to stay awake very late and to sleep poorly because electronic media disrupts rather than aids them in obtaining a restful night of sleep.

Reading a book at bedtime is linked to better sleep, yet if that book is sufficiently engaging, reading could potentially keep youth awake into the wee hours of the morning as well. Those who think too much when going to bed may find some level of distraction useful, with reading a calm or boring book or white noise from another electronic medium providing a pathway to falling asleep. Little empirical work has been directed at this approach.

### Media and Concentration

Multitasking can occur when a child is using various windows within a medium (e.g., listening to music while searching the Internet), with multiple media at a time (e.g., watching television while texting on a mobile phone), or across various media and nonmedia activities (e.g., driving a car while listening to a radio or while texting on a mobile phone). Switching back and forth between tasks can disrupt concentration and even compromise safety. For instance, texting while driving is a problem behavior for adolescents because visual and motor attention are needed both to drive and to text, thereby competing for attentional focus (Halsey, 2012). See Anderson and Kirkorian, Chapter 22, this *Handbook*, Volume 2, for a discussion of media and multitasking.

## THE SOCIAL NATURE OF MEDIA ENVIRONMENTS: ELECTRONIC FRIENDS AND COMMUNICATIONS

Media have always been rooted in social relationships. Book, radio, film, and televised stories communicate

fictional as well as factual stories through oral, written, and visual forms. These stories provide readers, listeners, and viewers with the option to drop into the lives of others, to learn about the everyday social experiences that comprise daily life as well as potential ways to deal with the inevitable conflicts that occur in human interactions.

Mediated communication has also become a norm for social interactions, with social networks like Facebook attracting millions of users who communicate with one another online (Pempek et al., 2009). Although phone conversations have been popular among adolescents for decades, mobile technologies now add opportunities for youth to interact socially with one another through texting and to connect to one another through online interfaces, such as social networking sites. These technological changes make face-to-face interactions less prominent in everyday experiences, supplementing them, or in some cases even displacing them, with mediated communications (Calvert & Wartella, 2014). In addition to the actual people in children's daily worlds, social relationships include parasocial relationships in which children treat media characters as friends, role models that are depicted in programming, and electronic interfaces in which youth link up with their friends as well as with strangers (Calvert, 2013).

### **Prosocial Media: "It's a Beautiful Day in the Neighborhood"**

Prosocial media involves demonstrating or eliciting socially constructive behaviors (Calvert, 1999), as when Fred Rogers sang about and shared many beautiful days in his neighborhood with his young viewers. The range of behaviors that researchers have included as prosocial, however, has varied considerably (Friedrich-Cofer et al., 1979; Hearold, 1986; Mares & Woodard, 2005). Prosocial behaviors are defined here as socially constructive behaviors, such as positive social interaction skills and altruism, but other definitions will be included when relevant. Most prosocial television content is presented via stories (Calvert & Kotler, 2003).

### **Prosocial Content**

Prosocial content became prevalent during the 1970s due to pressure on broadcasters to decrease the amount of violent content (Calvert, 1999). In a comparison of the content on children's programs broadcast on CBS, ABC, and NBC to those on PBS, altruism was the most frequently portrayed prosocial behavior, occurring more often in programs

broadcast by PBS than by the commercial stations ( $M = 9.73$  versus 6.81 acts per half hour; Poulos, Harvey, & Liebert, 1976). Content analyses documented particularly high levels of prosocial content for *Mister Rogers' Neighborhood*, which contained 95% positive reinforcement versus 5% punishment (Coates & Pusser, 1975).

When deregulation of children's programs occurred in the 1980s, prosocial content waned, only to be followed by a reappearance in frequency during the 1990s with the passage of the Children's Television Act (CTA), which required broadcasters to provide educational and informational television content for children (Calvert, 2008b). The Federal Communications Commission (1991), the government agency tasked with enforcing the CTA, defined educational television very broadly, including any kind of content that can advance children's cognitive, informational, or socioemotional needs. When this definition was combined with the FCC implementation of the 3-hour rule, which required each commercial broadcaster to provide a minimum of 3 hours of educational and informational programming per week, prosocial television programs received a boost.

In a sample of television programs that broadcasters designated as educational and informational (E/I) to meet the requirements of the Children's Television Act, Jordan, Schmitt, and Woodard (2001) found that 51% of the programs involved prosocial content about social and emotional lessons. Prosocial lessons included appreciation of self for 0- to 4-year-olds, interpersonal (e.g., cooperation) and intrapersonal lessons (e.g., self-esteem) for 5- to 11-year-olds, and more mature prosocial topics like dating and sexual harassment for 12- to 16-year-olds. The educational strength of these programs was high for 33% of the programs, moderate for 46% of them, and minimal for 21% of them (Jordan et al., 2001).

In 2008, Wilson, Kunkel, and Drogos conducted a content analysis of educational/informational (E/I) television programs using the system previously developed by Jordan et al. (2001). Their report, titled "Educationally/Insufficient," found that the television programs being broadcast for children had become weaker when compared to the earlier analysis (i.e., Jordan et al., 2001). Only 13% of the programs were rated as highly educational, 63% were rated as moderately educational, and 23% were rated as minimally educational. Broadcasters again presented prosocial content to fulfill their public obligation. Almost three-quarters of all episodes in their sample contained a social or emotional lesson, focusing on positive social interactions (26%), self-esteem (18%), self-restraint (12%),

altruism (8%), emotional skills (7%), and acceptance of others (2%) (Wilson et al., 2008).

### ***Influences of Prosocial Media on Children's Learning and Behavior***

The early research about the impact of prosocial television often used Bandura's social cognitive theory, predicting that prosocial behaviors are acquired through observational learning just as aggressive behaviors are. In a classic study that examined children's performance of prosocial behaviors, Stein and Friedrich (1972) compared 3- to 5-year-old children's behaviors before and after 9 weeks of exposure to prosocial *Mister Rogers' Neighborhood* episodes, aggressive Superman and Batman cartoons, or to nature films that had neutral content. Children who viewed episodes of *Mister Rogers' Neighborhood* persisted longer at tasks, followed rules better, and tolerated delays better than the other two groups. Those from low- but not high-socioeconomic backgrounds also increased in positive interpersonal behaviors, including cooperation, nurturance, and labeling their feelings. First grade children who viewed a prosocial *Lassie* episode in which a boy rescued Lassie's puppy also pushed buttons to help dogs who were barking in a kennel more often than children who viewed a *Lassie* episode with neutral content where the boy character took a violin lesson or an episode of the *Brady Bunch* in which there was a seesaw competition (Sprafkin, Liebert, & Poulos, 1975).

Although everyone loves good stories, their meaning can be elusive. Young children are deficient in processing character emotions and motives, key skills for mature story comprehension (W. A. Collins et al., 1978). In particular, 3- to 5-year-olds had difficulty remembering the emotions of television characters at the end of the story (Hayes & Casey, 1992), and 8-year-olds judged character actions, goals, and successful outcomes as equally important in understanding a simple textual narrative story, whereas 11-year-old preadolescents judged the main character's goals and outcomes as more important than the character actions (Van den Broek, 1989). Even adolescents struggle with plot comprehension when viewing a complex film, with those who are more versus less empathic with media characters demonstrating more identification with characters, better plot comprehension, and stronger feelings about the characters (Calvert, Strouse, & Murray, 2006).

Environmental aids, such as role playing and verbal labeling, that are provided by adult experimenters can assist early learning. Girls' learning of prosocial themes increased when an adult provided verbal labels of the

program content, and boys' prosocial behaviors increased when an adult provided supplemental role-playing activities with puppets to support the program content (Friedrich & Stein, 1975). Verbal labels delivered by an adult who viewed with children also increased young children's understanding of prosocial program themes (Watkins, Calvert, Huston-Stein, & Wright, 1980) as did advance organizers and intraprogram synopses of central prosocial program content that were embedded in the program (Calvert, Huston, & Wright, 1987; Neuman, Burden, & Holden, 1990). Formal production features like action (i.e., movement) can also improve children's story comprehension by providing a visual code that children can use to supplement more abstract linguistic content (Calvert et al., 1982).

To examine the effectiveness of the programs created to meet the requirements of the Children's Television Act (CTA) on children's learning, Calvert and Kotler (2003) conducted a short-term longitudinal examination of second- to sixth-grade children's learning from their favorite programs, which compared commercial broadcasters, who were required to comply with the CTA, to cable and public broadcasters' offerings who had no such requirement. Prosocial programs were the overwhelming favorites of children. Children, particularly girls, reported many lessons after viewing prosocial programs, including caring about others, helping, honesty, loyalty, persistence, and social interaction skills such as being a good friend. Children learned equally well from their favorite commercial or non-commercial educational television programs, but did not learn as much from their favorite programs that were strictly designed for entertainment. Overall, these findings indicated that children derive measureable benefits from viewing prosocial programs that are part of media-related policies designed to improve children's television programming.

Meta-analyses reveal positive effects after viewing prosocial programs. For example, a meta-analysis of 230 studies conducted by Hearold (1986) indicated strong and enduring effects of viewing prosocial content ( $r = .34$ ). Similarly, a meta-analysis of 34 studies that focused on interpersonal interactions found an overall effect size of  $r = .27$  after exposure to prosocial content, with the effects increasing from Age 3 to their peak at Age 7 (Mares & Woodard, 2005).

In contrast to prosocial television programs, studies about gaming experiences that are designed to promote prosocial behavior are relatively rare. One three-pronged study of youth from varying nations, conducted by Gentile

et al. (2009), is an exception. In a longitudinal examination of Japanese 5th (mean age = 10.9 years), 8th (mean age = 13.6 years), and 11th graders (mean age = 16.6 years), exposure to prosocial video games led to increases in prosocial behavior approximately 3 months later. Similarly, a cross-sectional study demonstrated that children who were in secondary school in Singapore (mean age = 13.0 years) who played more prosocial video games were more likely to help, cooperate, share, and demonstrate empathy. Consistent with these findings, an experimental study found that U.S. college students (mean age = 19.2 years) were more likely to help their partner after playing a prosocial than a neutral or a violent video game (Gentile et al., 2009). These findings suggest that there is promise in having children play prosocial video games to promote prosocial behavior.

In summary, prosocial programs can provide valuable life lessons about positive interpersonal and intrapersonal skills, many of which can be translated into behavior. Plot comprehension is important for children to learn prosocial lessons, particularly because many plots with positive outcomes often include conflict before the prosocial resolution occurs (Lovelace & Huston, 1983). Young children often benefit from environmental support from adults in the viewing environment or that are built into the actual program when their understanding of the program is unclear.

### Parasocial Relationships With Media Characters

In the current transmedia environment in which characters traverse multiple offline and online experiences, children and youth have numerous opportunities to create mediated friendships with characters (Calvert & Richards, 2014). Favorite characters are invited into children's homes through television and computer programs as well as through children's play with toys (Bond & Calvert, 2014). Moreover, media characters are almost always available for children as playmates in their homes, even when their real-life peers are not. Popular media characters are also a part of the marketing experiences that target numerous products at children (IOM, 2006). Through these ongoing and sustained experiences, children sometimes form parasocial relationships, particularly with their favorite media characters, which can fill some of children's social and informational needs (Hoffner, 2008).

Little research has been conducted on parasocial relationships during the childhood years, instead relying on the importance of adult role models (Bandura, 1986; Friedrich & Stein, 1973). However, role models involve vertical

relationships rather than the horizontal relationships that characterize childhood friendships (Calvert & Richards, 2014). Bond and Calvert (2014) found that parents reported three major components of children's parasocial relationships: *character personification* (e.g., child trusts character; treats character as friend; thinks character has thoughts and emotions); *attachment* (e.g., character makes child feel safe, character's voice soothes child); and *social realism* (e.g., child thinks character is real). Some parasocial relationships emerge because the character directly addresses the audience in a pseudo parasocial interaction (Bond & Calvert, 2014), but parasocial relationships can also emerge when children view characters as they interact with one another onscreen, an observational learning outcome (Calvert, Richards, & Kent, 2014).

Meaningful social relationships with media characters may foster early learning by serving as social partners (Richert, Robb, & Smith, 2011). For instance, 18-month-olds who nurtured a plush puppet version of a character during play over a 3-month period subsequently learned more from a task presented onscreen by that character (Gola, Richards, Lauricella, & Calvert, 2013). Similarly, toddlers who played with and nurtured a personalized interactive character (i.e., programmed to have the same favorite color, foods, etc., as the child) learned more from a subsequent screen-based task than a control group did, but toddlers who had a nonpersonalized interactive character did not (Calvert, Richards, et al., 2014). Taken together, these results suggest that toddlers who treat characters as persons and who nurture them, a behavioral indicator of a parasocial relationship (Gola et al., 2013), subsequently learn more from those characters.

Although characters can become early teachers of children through the social relationships that children form with them, very few apps take advantage of this relationship. To address the role of media characters in toddlers' learning from touch screen devices, Richards and Calvert (2013) developed an experimental app to compare 32-month-olds' belief in the credibility of the familiar *Sesame Street* Elmo character to the unfamiliar Taiwanese DoDo character. The app varied the accuracy of the character's labels of familiar and unfamiliar foods, and then presented novel foods with made-up labels. Children were more likely to choose the previously accurate character for unfamiliar fruits, regardless of prior familiarity with the character. These findings suggest a more advanced style of determining credibility when toddlers use interactive touch screens, as 3-year-olds chose a familiar over an unfamiliar teacher's labels for novel objects portrayed on video, even when the familiar,

trusted teacher had previously labeled the familiar objects incorrectly (P. Harris & Corriveau, 2011).

### Social Media: Being and Staying Connected

The developmental needs of children and adolescents include learning how to interact with peers, make friends, and develop a mature identity (Subrahmanyam et al., 2006). These kinds of developmental advancements require peer interactions, which were initially limited in online experiences because early interactive media platforms only allowed asynchronous communications, such as email, or synchronous communications that were predominantly with strangers, such as chat room experiences (Calvert & Wartella, 2014). Innovative applications and faster Internet speeds enabled the emergence of social networking sites that connected youth with their friends and families rather than with strangers. Social networking sites include MySpace, Facetime, Friendster, Twitter, and Facebook.

Early Internet users visited chat rooms and multiuser domains (which are spaces in which youth can interact in a flexible form or in a game-like fashion that was originally built on a board game) where they assumed personae in which they took on names and identities (Turkle, 1995). Although the flexibility to be anyone that they desired was often embraced by many adults (Turkle, 1995), youth generally communicated who they were online in ways that had been historically important identity markers in offline experiences (Calvert, 2002). For instance, 55% of adolescents disclosed their own age, sex, and location in response to the chat room query *a/s/l*, i.e., age/sex/location (Subrahmanyam et al., 2006), and often included their ethnicity as well (Tynes, Reynolds, & Greenfield, 2004). Rather than creating a gender- and color-blind society, the Internet became yet another forum in which these same identifiers were typically disclosed (Calvert, 2002).

The early relationships that youth developed with others that they met online were also characterized by weak ties rather than strong ties. Specifically, users who met other people online spent less time together, relationships were more superficial, and less closeness was felt toward them when compared to those who were known through face-to-face interactions, in part because online youth were interacting with strangers rather than with people whom they knew offline (Subrahmanyam, Greenfield, Kraut, & Gross, 2003).

As digital natives, adolescents were among the first to embrace social media to communicate with their friends (Pempek et al., 2009). Eighty percent of U.S. adolescents

use at least one social media platform (Lenhart et al., 2011). College students often reported hundreds of friends on their Facebook profiles, and they reported spending most of their time communicating with those friends, particularly those from their high school years who did not attend their current college, thereby addressing the important developmental need of adolescents for friendship formation and maintenance (Pempek et al., 2009).

Twitter is a social networking site that allows users to microblog. Microblogging occurs when users post brief text updates about the events that are happening in their everyday lives, what they are experiencing, and how they are feeling (McFedries, 2007). On Twitter, each entry is limited to 140 characters of text, including emoticons to express their feelings through pictorial icons in their posts. Users of Twitter have the ability to interact with one another by mentioning others in their updates or by reposting original posts from their friends' Twitter feeds. Users can also follow others' tweets, such as those posted by celebrities. By microblogging, youth can communicate and share content quickly in a world that increasingly requires their attention to be divided across multiple tasks. Nearly 20% of adolescents reported regular use of Twitter, double the number of adolescents using Twitter just 2 years earlier (Lenhart et al., 2011). Individuals who interacted with others on Twitter often knew each other offline or had very similar interests (Java, Song, Finin, & Tseng, 2007). Online interaction with real-life friends via social media venues like Twitter can strengthen perceptions of friendship and lead to higher levels of emotional well-being among adolescents (Valkenburg & Peter, 2007).

Social networks have focused mainly on adolescents, but a report by the Joan Ganz Cooney Center (Grimes & Fields, 2012) examined children's use of what they labeled as social networking forums, an expansion of the traditional definition of social networking sites to include virtual worlds and game spaces where millions of children are interacting with one another. To do so, they examined key characteristics of social networking sites and then applied them to children's online activities.

Grimes and Fields (2012) found that children's social networking sites *support communications among participants* by chat bubbles or whispering, as previously done in chat rooms when youth moved from a public forum to a one-on-one instant messaging interaction (Subrahmanyam et al., 2006). Social networking sites have users develop *personal profiles* in which they describe themselves, which tend to be consistent with the real self (Pempek et al., 2009). Children create representations of themselves on children's

sites, such as avatars and virtual pets and dolls. Social networking sites allow users to *leave residues of their online presence in relation to other users on the site*, such as posts, friend lists, and belonging to specific groups. Finally, social networking sites have *hierarchies of access*, such as age restrictions to join Facebook (Grimes & Fields, 2012). This approach to social networking captures the kinds of activities that children are more likely to do with one another online, as children play together more than they post written comments or videos. Research about how younger children interact with one another on these sites is notably absent and needed (Grimes & Fields, 2012).

### THE MEAN AND SCARY WORLD: MEDIA VIOLENCE AND SCARY CONTENT

When rampage killings take place that bear striking similarity to children's media experiences, such as two male adolescents repeatedly playing the videogame *Doom* before attacking their teachers and fellow students, the public and policymakers inevitably ask if media exposure played some role in these deadly execution style killings. Gerbner, Gross, Signorielli, and Morgan (1986) argued that heavy exposure to television content cultivated a view that the world was a mean and scary place due to the amount of violence in programs. Cultivation effects could take place when children are exposed to other kinds of violent media, such as the news. In addition to the scary aspects of violent content, children are exposed to other kinds of scary content, such as supernatural events (Cantor, 2012). Exposure occurs because children select these kinds of experiences, or are exposed to them by another person.

#### Media Violence

Children look up to certain people, including media personalities, adopting the behaviors of social models through observational learning (Bandura, 1986). Because of social concerns about the impact of violent content on children's aggression, researchers have systematically tracked the amount of violent content (e.g., Gerbner, 1972; Gerbner, Gross, Morgan, & Signorielli, 1980; Wilson et al., 2002) and conducted systematic studies about the role of violent content on children's antisocial behavior (C. Anderson, Gentile, & Buckley, 2007; Bandura, 1965; Stein & Friedrich, 1972). Social cognitive theory, arousal theory, psychoanalytic theory, cultivation, and script theories have also been used to frame media violence effects.

#### Violent Content

The selection of one operational definition for violent acts depicted on television has been challenging, with the inclusion of intent used in some definitions, but not in others (see Wilson, 2008). The National Television Violence (NTV) study defined violence as acts or threats of physical force intended to harm other animate beings (Wilson et al., 1997).

In the NTV study, violent content in television programs broadcast on commercial stations, independent stations, PBS, and basic and premium cable were analyzed. From 1994 to 1997, 60% of television programs contained violent content, with PBS having the lowest and premium cable having the highest rates of violence (Wilson et al., 1997, 1998). Sixty-nine percent of children's programs in the sample contained violence, compared to 57% of nonchildren's programs (Wilson et al., 2002). In the NTV study, 90% of films broadcast on television contained violent content (Smith et al., 1998). By contrast, only 15% of music videos contained intentional physical aggression, but only the visual, not the musical track with lyrics, was examined for aggressive content (Smith & Boyson, 2002).

Violent content is also heavily concentrated in video games. Using content analyses, 98% of video games with a Teen (T) rating that entered the market place in 2001 and 64% of video games with an Everyone (E) rating that entered the market place between 1985 and 2000 contained violent content (Haninger & Thompson, 2004; Thompson & Haninger, 2001). Sixty-eight percent of the most popular video games in 1999 contained violent content (Smith et al., 2003). Overall, the data indicate the heavy use of violence in children's media.

#### The Influence of Violent Content on Learning and Social Behavior

Given the pervasive use of violent content in media, concerns have been raised for decades about how media violence impacts children's aggressive behavior. Experimental studies demonstrated aggressive outcomes after children observed violent actions in films or in television programs (Bandura, 1965; Wilson, 2008). Although questions have been raised about the impact of televised violence in field studies (Freedman, 1984), one of the more influential field studies of televised violence demonstrated aggressive outcomes for young children who were initially above the median in aggressive behaviors (Friedrich & Stein, 1973). Seven meta-analyses also indicated that viewing high concentrations of televised violence contributes to children's antisocial behavior, with effect sizes ranging

from .11 to .31 (median value = .20; Comstock, 2008). Risk factors for aggression included antisocial behavior, disruptive disorder behaviors, poor social relationships, poor psychological well-being, and parents who treated their children in a rigid or indifferent style (Comstock, 2008).

Scholars often point to psychoanalytic theory as the reason that the media industry believes that violent content is harmless (Bushman & Huesmann, 2012). In Freud's version of psychoanalytic theory, people are innately aggressive, and viewing violent content or playing violent video games is predicted to harmlessly drain off those natural tendencies through catharsis (Wilson, 2008). Research demonstrates, however, that viewers become more aroused and more, not less, likely to imitate and enact aggressive actions after exposure to violent content (Calvert, 1999). Jung's ideas of archetypal images, including the hero who is aggressive and prosocial for a just cause, are often used in television and film scripts, as the hero has been a compelling person and character throughout time (Calvert et al., 2001), but studies on this approach are virtually nonexistent.

A challenge in showing heroic portrayals to young children is that they view the world as good or bad, not nuanced, and their plot comprehension is often poor so they do not understand the character's motives (Calvert, 1999; Gunter, 2008). For instance, older boys were more likely to choose helpful than hurtful behavioral options when they understood an episode of a simple cartoon, *Superfriends*, that was presented with a mixed prosocial and aggressive message, but the opposite pattern occurred for younger boys (Liss, Reinhardt, & Fredriksen, 1983). Consistent with these findings, adolescents from the United States and Taiwan who demonstrated poor plot comprehension of a film were more likely to identify with the villain (Calvert, Murray, & Conger, 2004). These findings suggest that improving children's and adolescents' plot comprehension is important for moderating the impact of filmed or televised aggression on their role model choices and their aggressive conduct.

As lean forward media became more standard in homes, children became participants in, not just observers of, violent actions (Calvert & Tan, 1994). Meta-analyses revealed that playing violent video games increased children's aggressive actions, ideation, and feelings and physiological arousal while reducing empathy as well as prosocial actions (C. Anderson et al., 2010). These effects occurred for people in Eastern as well as Western cultures, females as well as males, and in experimental studies

for all forms of aggression (C. Anderson et al., 2010). Other meta-analyses, however, have demonstrated minimal effect sizes once controlling for publication bias, in which studies with nonsignificant findings are not published (e.g., Ferguson, 2007).

The Proteus effect describes how individuals are affected by their digital self-representation (Yee & Bailenson, 2007). In a virtual environment, for instance, those who were assigned to be more attractive avatars were more likely to move closer to another's avatar and to reveal more information about themselves than those who were assigned to be an unattractive avatar; similarly, those who were assigned to have taller avatars viewed themselves as more self-confident than those who were assigned to have shorter avatars (Yee & Bailenson, 2007). Building on the research about the Proteus effect, Pena, Hancock, and Merola (2009) primed aggression by having players' avatars wear either black or white cloaks in a virtual world. Those whose avatars wore black coats reported more aggressive attitudes and intentions about their behaviors than those who wore white cloaks (Pena et al., 2009). Playing aggressive video games with a personalized avatar rather than a nonpersonalized avatar also resulted in increased aggressive behavior and arousal by players (Fischer, Kastenmuller, & Greitemeyer, 2010).

Interactive media have made it possible for youth to engage in cyberbullying (Dake, Price, & Maziarz, 2012; Dilberto & Matthey, 2009). Bullying has been defined as repeated, intentional aggressive acts toward another person (Agatston, Kowalski, & Limber, 2007). Cyberbullying involves the same behaviors, but takes place electronically rather than in person. In a survey of young adolescents ( $N = 3,767$ ), 11% reported being a cyber victim, 4% reported being a cyberbully, and 7% reported being both a cyberbully and a cyber victim (Kowalski & Limber, 2007). In a survey of a nationally representative sample of adolescents ( $N = 7,182$ ), Wang, Iannotti, and Nansel (2009) found that approximately 14% of these youth reported being bullied electronically in the previous 2 months. Boys were more often cyberbullies, and girls were often cyber victims. African American youth were more likely to be cyberbullies than cyber victims. Adolescents who reported strong parental support were less likely to be cyberbullies or cyber victims, but having a large number of friends was not a protective factor, as is the case for traditional bullying (Wang et al., 2009).

In summary, exposure to media violence can increase aggressive and antisocial behaviors due to arousal, social learning, priming of aggressive responses, and

the development of aggressive scripts and schemas. Little evidence supports the idea of catharsis. Plot comprehension also influences outcomes, thereby making younger children who have poorer plot comprehension skills at risk for antisocial outcomes after viewing aggressive content (Calvert, 1999). Although there is some disagreement about the evidence (e.g., Ferguson, 2007; Freedman, 1984), viewing or interacting with televised violence has been treated as a risk factor for childhood and adolescent aggressive behavior (Wilson, 2008).

### Children's Fright Reactions to Scary Media Content

Viewing things that go bump in the night appeal to many children, in part because they enter the realm of fantasy and find the content arousing and entertaining (Zuckermann, 1979). For younger children, however, the lines between what is real and pretend can be tenuous (Valkenburg & Buizen, 2008), and exposure to scary fictional and real events can have enduring effects (Cantor, 2012; Riddle, Cantor, Byrne, & Moyer-Guse, 2012).

The literature in this area is based mainly on parent and child surveys, and on retrospective, autobiographical self-reports, as researchers have been reluctant to show scary content to children in experimental studies for ethical reasons (Cantor et al., 2010). According to Cantor et al. (2010), 76% of 5- through 12-year-old children reported being frightened after exposure to media content, mainly by movies.

Three different reasons have been used to describe exposure to scary television and film content: Children actively select scary content, which would be foreground, intentional exposure; because friends, peers, or other family members select scary content, and children just happen to be there, a background exposure effect; and because children just stumble across scary content and watch it. Children reported the most fright when they did not select the content for themselves, instead watching because someone else had selected the program (Cantor, 2012).

Why do children choose to expose themselves to scary media content when it can frighten them? According to Zuckermann (1979), sensation seeking is a main reason for selective exposure as children seek an optimal level of arousal, and scary content is arousing. Cantor and Reilly (1982) found that 80% of adolescents reported that they liked scary media either somewhat or a lot, and boys reported that they liked scary content more than girls did. Seventy-six percent of adolescents reported that they watched scary television content sometimes or

often, and 55% reported that they viewed scary movies frequently. Nonetheless, younger adolescents reported that they avoided exposure to scary content more than older adolescents did, and girls reported avoiding scary content more than boys did. Overall, then, there is an audience for scary content, although some children prefer not to view it, and 32% of this sample reported regret for having watched certain scary programs (Cantor & Reilly, 1982).

The kind of program content that children reported being frightened by varies with developmental skills, with children's abilities to separate fantasy and reality playing an important role (Cantor & Hoffner, 1990). Consistent with cognitive developmental theories, such as those advanced by Piaget (1954), parents reported that their children who were under Age 8 were most frightened by content based on the physical appearance of characters, such as viewing depictions of monsters or creatures (Cantor & Sparks, 1984). By contrast, parents reported that their adolescents were more frightened than their younger children were of content that required abstract, conceptual processing, such as movies about a nuclear war (Cantor, Wilson, & Hoffner, 1986). Depictions of supernatural events frighten both children and adults, perhaps because even some adults remain somewhat unsure about whether or not these events could actually happen (Cantor, 2006). Children with the most severe fright reactions to fictional portrayals had a television set in their bedroom (Cantor et al., 2010), suggesting minimal parental supervision (Cantor, 2012).

Riddle et al. (2012) found that approximately 35% of a sample of U.S. 5- to 12-year-olds was frightened by the news, with natural disasters, kidnappings, wars, and burglaries being mentioned the most. Unlike exposure to fictional media events, having a television set in one's bedroom did not predict the likelihood of being frightened by a news depiction for younger or older children, nor did restrictive rules by parents prevent their children's exposure to scary news events, perhaps because this exposure was accidental (Riddle et al., 2012).

The aftermath of viewing extremely scary content ranges from short-term fears to enduring anxiety and fright. Sleep disturbances, such as being afraid to go to sleep or having bad dreams, have been reported after exposure to scary media content (Cantor, 2012; Wilson, 2008). Children have also reported physical problems such as stomachaches or headaches as well as anxiety (Cantor et al., 2010). Lingering fears were reported by approximately 25% of those who had viewed a program that really frightened them (Harrison & Cantor, 1999), such as fears

of swimming after viewing the film *Jaws*, in which a great white shark attacked swimmers at ocean beaches (Cantor et al., 2010).

Although some parents restrict their child's viewing of scary content (Riddle et al., 2012), many parents underestimate how frightened their child is after viewing scary content (Cantor & Reilly, 1982). Strategies for fear reduction vary by age. For young children, behavioral strategies such as holding onto another person or covering or hiding one's eyes behind a pillow are often effective in reducing their fright (Cantor, 2012; K. Harrison & Cantor, 1999; Wilson, 1989). By contrast, older more than younger children cope with scary content by using cognitive strategies, such as telling themselves that the content is not real (K. Harrison & Cantor, 1999). Parents and older siblings also use cognitive and behavioral strategies for younger children in the family who are scared (Cantor & Wilson, 1984; Wilson & Weiss, 1993).

Girls in the United States and Holland reported being more frightened by television content than boys did (Cantor, 2012; Valkenburg, Cantor, & Peeters, 2000; Walma van der Molen & Bushman, 2008). Girls used behavioral approaches for fear reduction more than boys did, but both boys and girls reported the use of cognitive strategies to reduce fear (Valkenburg et al., 2000). The effectiveness of reassuring language depends on children's verbal skills. For instance, children were told that most snakes were not poisonous after exposure to a video excerpt from *Raiders of the Lost Ark* where the protagonists were trapped in a snake pit (Wilson & Cantor, 1987). However, younger children were more likely to focus on the word *poisonous* than on the phrase *not poisonous* (Wilson & Cantor, 1987).

In summary, exposure, particularly inadvertent exposure, to scary stories depicted in media can frighten children. Media content frightens youth of all ages, although the kind of media content that is scariest varies by age. Coping with fear by the youngest viewers involves behavioral strategies whereas cognitive strategies are most effective for older viewers. However, actual events, as portrayed in the news, are not fictional events, and hence, are frightening to children who view events that they cannot control.

Arousal theory provides the best explanation for why children expose themselves intentionally to scary events, some of which have enduring effects on their sleep patterns as well as their everyday behaviors where they avoid certain activities. The findings suggest that media portrayals can lead to phobias when a child is unable to cope with

the content that they have viewed. Research on the effects of books and computer games on fear responses have not been studied, and are an important avenue of future research (Valkenburg & Buijzen, 2008).

## MEDIA, GENDER, AND SEXUALITY

Gender is a multidimensional construct that is a central organizer of human experience (Huston, 1983), in part because gender serves as an organizer of children's identities (Erikson, 1963; Kohlberg, 1966). U.S. media, particularly television portrayals, depict a highly gender-stereotyped reality that is rooted in culture but that also reinforces and exaggerates traditional gender values (Calvert & Huston, 1987; Signorielli, 2012). Gendered beliefs are also used by youth to choose what to view and what they do online (Subrahmanyam et al., 2006).

With the onset of puberty during the preadolescent and adolescent years, changes come in identity as an increased interest takes place in defining oneself as a sexual person (Erikson, 1963). In addition to parents and schools, informal teachers about sex can be abundantly found in media, including both traditional observational media as well as newer interactive interfaces. Media with sexual content is presented in two basic ways: embedded in stories that contain both sexual and nonsexual images and content, and as sexually explicit content that is presented by itself (Wright, Malamuth, & Donnerstein, 2012). In the new online environments in which children and youth move fluidly, youth now generate sexual content and share it in their communications and in peer-to-peer file sharing programs (Lenhart, 2009).

### Gender-Stereotyped Content

The content of media can be examined as *who counts*, in terms of quantity of depictions, and *who matters*, in terms of the quality of the images and roles (Calvert, 1999). Women lag behind men in both categories in television programs. In 2010, women comprised 50.8% and men comprised 49.2% of the U.S. population (U.S. Census, 2011). Although a longitudinal content analysis of the number of male and female characters in television programs demonstrated significant increases in the number of females over the past several decades, from 24% in 1967 to 41% in 2009, men still outnumbered women as television characters in television programs compared to their actual

representation in the U.S. population, and men continued to have more prestigious occupations than women did (Signorielli, 2012). The value of women often comes from their physical appearance rather than their occupation. Content analyses documented that women in popular films were younger than their male counterparts (Lauzen & Dozier, 1999), and women in television depictions were likely to have thin and attractive bodies (Fouts & Burggraf, 2000). Overall, the media depicts men as strong, serious, powerful, and heterosexual, and women as passive and emotional (Hust & Brown, 2008).

Children's programs were especially likely to portray characters in gender-stereotyped ways, where females were emotional and romantic (Calvert & Huston, 1987; Signorielli, 2012), and males were muscular and powerful superheroes (Baker & Raney, 2007). Even female characters who were superheroes were still physically attractive and emotional (Baker & Raney, 2007). Content analyses of children's educational and informational television programs found no differences in the number of male and female characters, but male characters engaged in a wider range of roles than female characters did, and no programs had a female lead character (Barner, 1999). Taken together, the findings suggest that children encounter a world of television that adheres to traditional gendered stereotypes.

### **Influences of Media on Gender-Related Processing and Outcomes**

Gender schema theory, social cognitive theory, and cognitive developmental theory are the main theoretical approaches that have been used to understand how gender influences children's selective attention, learning, and behaviors after exposure to, or interaction with, media. In gender schema theory, children develop learned expectations that guide perception, memory, and inference, including gender stereotypes (Calvert & Huston, 1987). Because gender is such an important organizer of identity (Martin & Halverson, 1981), children and youth search for content that can guide their constructions of self. These experiences include exposure to role models that can be viewed on television and in films as well as gendered interactions and peer feedback that take place in online experiences. Cognitive developmental theory examines age-related changes in children's understanding of gender, primarily through gender constancy where children come to understand that their biological sex will never change, which then influences their selective attention to social

models (Huston, 1983). Social cognitive theory focuses on the gendered roles that children observe, which they can then imitate (Huston, 1983).

Consistent with gender schema theory, children seek out television content that matches their gender roles. Boys, for instance, were more likely to view cartoons and action-oriented programs in their homes (Huston et al., 1990), whereas girls were more likely to view programs that focused on social and emotional themes (Calvert & Kotler, 2003). Boys who had attained gender constancy were also more likely to view television programs at home that featured male television characters and that involved sports or action adventure content (Luecke-Aleksa et al., 1995). Gender constant boys were preferentially attentive to boys on screen when compared to gender preconstant boys, whereas girls were equally attentive to both male and female characters, regardless of gender constancy attainment (Luecke-Aleksa et al., 1995). Latino/a American 4-year-old boys, who theoretically should not yet be gender constant, were also less likely to identify with the Latino/a American girl character Dora than were European American boys and all girls (Calvert et al., 2007).

Information that is consistent with gender schemas is recalled accurately, but gender schemas can distort memory of televised content so that it is consistent with expectations (Calvert & Huston, 1987). For instance, when children viewed a televised depiction of a female doctor and a male nurse, they remembered the opposite occupational roles for the characters, except for those who had met an actual male nurse (Cordua, McGraw, & Drabman, 1979). Although all 8- and 9-year-old children remembered content that was relevant to gender roles, those who were highly gender-stereotyped remembered less nontraditional role information than those who were less gender stereotyped (List, Collins, & Westby, 1983). Consistent with these findings, grade-school aged children who were heavy versus light television viewers were more likely to believe that gender stereotypical household chores were performed either by men or women (Signorielli & Lears, 1992). Overall, these findings indicate that memory of gender-stereotypical information is generally quite good, but that children who hold and act in more gender stereotypical ways do not remember counter-stereotypical portrayals as well as children who are less gender stereotyped do.

When second- through sixth-grade school children wrote online reports about their favorite educational television program, their reports contained more male than female characters, more male than female pronouns, and

more masculine than feminine behaviors (Calvert, Kotler, Zehnder, & Shockey, 2003). Girls and boys were equally likely to report male characters in their reports, but girls had more female characters in their reports than boys did. Although girls (69%) were more likely than boys (21%) to write about the heroic actions portrayed in the cartoon *The Wild Thornberrys*, which featured a female lead, reports about this program still contained the most language about heroic actions, a traditionally masculine activity (Calvert, Kotler, et al., 2003).

Consistent with social cognitive theory, children also select same-sex role models more so than opposite-sex role models. For instance, when children were asked which media character they would like to be like, boys chose only male characters and girls chose female characters two thirds of the time (Miller & Reeves, 1976). Consistent with these findings, 3-year-old children who were heavy television viewers selected more gender-stereotypical occupations for their futures than light television viewers did (Beuf, 1974). When media presentations of non-traditional roles for women increased, preadolescent girls developed more interest in the occupations that were frequently portrayed except for girls who continued to view programs that had women in more stereotypical professions (Wroblewski & Huston, 1987). These studies suggest that gendered role models and depictions influence children's decisions about whom they want to be like and what kinds of behaviors they are likely to exhibit.

Children bring who they are to online activities, which influences the kinds of behaviors that they do. Two studies described preadolescent children's online interactions when in the same multiuser domain (MUD) on two occasions, which varied whether the pairs knew one another or not (Calvert, Mahler, et al., 2003, Calvert et al., 2009). Boy pairs moved across different scenes and played with one another, and girl pairs chatted with one another through the dialogue box, regardless of whether they knew one another. When paired with an opposite sex peer that they did not know, boys and girls altered their interactions, with boys writing more and playing less, and girls writing less and moving more (Calvert, Mahler, et al., 2003). However, mixed pair interactions were more strained when the pair knew one another, with boys trying to play games with the girls, and girls trying to talk to the boys through the chat function. These problems occurred, in part, due to different gendered communication and interaction styles (Calvert et al., 2009).

Turkle (1997) found that gender bending, in which players present themselves as the opposite biological sex when

they are online, was common among adult players who frequent MUDS. In contrast to Turkle's findings, surveys of users who role-played in the MUD LambdaMOO found that 50% of players reported the use of only one identity when online, and of those who reported multiple identities, 75% used only one of those identities over a 2-week time frame (Schiano & White, 1998). Similarly, the evidence on gender bending for children and adolescents is weak. For instance, preadolescents overwhelmingly selected an avatar that matched their own biological sex and selected a gendered name for their avatar (Calvert, Mahler, et al., 2003; Calvert et al., 2009). Even when engaging in gender bending, girls continued to chat and boys continued to play (Calvert et al., 2009). Gender-typed names were also found in studies of adolescent youth who were interacting in chat rooms (Subrahmanyam et al., 2006).

Consistent with these findings, Gross (2004) found that approximately 10% of U.S. adolescents reported gender bending as a prank, to preserve their privacy, or to gain access to online sites with age restrictions, and they were more likely to gender bend when with others than when alone. Approximately 10% of Dutch preadolescents and adolescents also reported gender bending when online (Valkenburg, Schouten, & Peter, 2005). It appears, then, that most preadolescent and adolescent online users present themselves and act as one person, perhaps because they stay close to the actual parameters that define who they are during that developmental time frame.

Electronic gaming is a highly gendered activity, with males playing more so than females during childhood and adolescence. Yee (2006) conducted a survey of 30,000 users of Massively Multiuser Online Role Playing Games (MMORPGs), which are online worlds that persist independently of specific users. These sites typically contained mostly violent content in the past, but now provide a range of activities for users. In this 3-year study, Yee found that approximately 85% of the users were male. About 25% of the sample was adolescents, and approximately 97% of the users who were under Age 18 were males. Adolescent males tended to use the game for their own personal gain, and also reported that the friendships that they had within the game were as important as those in their offline experiences. Females who played on these sites were older, typically were introduced to them by a romantic partner, and used the game to build supportive social networks as well as to escape. Nearly half of the study participants reported that they were addicted to the MMORPG world, spending an average of 22 hours a week in these online spaces, with 61% of the sample reporting

that they had spent as many as 10 hours of continuous time at their specific MMORPG.

In summary, observational and interactive media typically present content that is gender-stereotyped, and if not stereotyped, children often use media in ways that are gender-stereotyped. Specifically, children select content that fits their own gender-related beliefs, they tend to remember content that is consistent with traditional gender stereotypes well though children who hold more nontraditional beliefs also remember nonstereotypical content, and they play in gender-stereotyped ways when using interactive media. The data suggest that media serve as a reflection of our broader culture, and that children act accordingly.

### Sexual Content

*Embedded* sexual content is often found in televised or film stories. Kunkel, Eyal, Finnerty, Biely, and Donnerstein (2005) conducted a content analysis of the sexual content broadcast on television programs on 10 channels (four commercial stations, one independent station, one public broadcasting station, and four cable stations), excluding children's programs, the news, and sports programs. Sex was defined as depictions and/or talk about sexuality or sexual behavior. Seventy percent of the programs in the sample contained sexual content. Talking about sex occurred more often than sexual behavior did (68% versus 35%, respectively), but explicit sexual presentations were rarely shown. The percentage of programs containing sexual content also increased significantly over time from 56% in 1998, to 64% in 2002, to 70% in 2005. The content that is popular with adolescents rarely included any information about risk factors for being sexually active or how to protect oneself from sexually transmitted diseases or unwanted pregnancies by acting in a sexually responsible way.

Sexual relationships in television programming typically occurred between unmarried partners in ways that were highly gender stereotyped (Kunkel et al., 2005). For instance, men were depicted as wanting sex for recreational reasons, and women were presented as searchers of love and intimacy in enduring relationships where they were the gatekeepers for sexual activity (Hust & Brown, 2008). Heterosexuality was the norm, with limited presentations of gay, lesbian, or transsexual individuals; when portrayals of sexual minorities did occur, they typically did not involve any kind of sexual interactions on broadcast television programs (Hust & Brown, 2008).

Content analyses have not been conducted on online content. Even so, just about any kind of sexual content can be found online, including sadomasochism and rape (Thornburgh & Lin, 2002).

### Influences of Sexual Content on Children

Most of the data about how sexual content influences youth are surveys or reports about accidental exposure because it is illegal to show sexually explicit content to minors in the United States as well as in many other countries. Most of the experimental evidence about how sexual content affects youth comes from college students' exposure to *embedded* sexual content in television programs and films. Theoretically, exposure to sexual content can affect youth through processes such as the construction of sexual scripts, arousal, desensitization, and imitation.

#### Stories With Embedded Sexual Content

Youth exposure to sexual content has always been a controversial topic in the U.S. (Jowett, Jarvie, & Fuller, 1996), yet adolescents are likely to select television programs with sexual material as their favorites (Kunkel et al., 2005). As exposure increases, the evidence supports desensitization and/or disinhibition to sexual content as well as the emergence of scripts about sexual behaviors. For example, youth who viewed more television content that involved sex between unmarried partners (Bryant & Rockwell, 1994) and who listened to more music videos demonstrated more acceptance of premarital sex (Greeson & Williams, 1987).

While the direction of the relation is unclear, those who viewed more versus less programs with sexual content also engaged in more sexual activity, and they had more negative views about being a virgin (Brown & Newcomer, 1991). Longitudinal research linked more frequent exposure to televised sexual content to sexual activity within the next year for 12-to 17-year-olds (Collins et al., 2004), and within the next 2 years for 12- to 14-year-olds who had a heavy diet of sexual content via television, movies, music, and magazines, even after controlling for a number of other variables (Brown et al., 2006). Parents who talked to their children about television content had children who were less likely to engage in sexual activity than those whose parents did not talk to them (Peterson, Moore, & Furstenberg, 1991), perhaps because family communication patterns influence how children view sexual activity.

### *Sexually Explicit Content*

Both experimental and correlational studies demonstrate that males have more sexually aggressive attitudes toward females after exposure to pornography (Wright et al., 2012). The males who are most influenced by these portrayals are predisposed to sexual aggression, and violent content is often mixed with pornographic content (Wright et al., 2012). Longitudinal studies found that Dutch youth who exposed themselves more often to sexually explicit content had more uncertainty about their sexuality, more positive attitudes about casual sex, and were more likely to perceive women as sex objects (Peter & Valkenburg, 2008, 2009).

In an ethnographic study of online teen chat room discussions among anonymous users, Subrahmanyam et al. (2006) found that sexualized nicknames (e.g., RomancBab4U), an expression of identity, were found for approximately 20% of participants. Sexual themes occurred in about 5% of utterances, or at a rate of about one utterance per minute. Those who presented themselves as male engaged in more explicit sexual utterances whereas those who presented themselves as females engaged in more implicit sexual utterances. Although this was a teen chat room, participants reported that their ages ranged from 10 to 24 years, with more explicit and obscene comments made by those who reported being 18 to 24 than those who reported being 10 to 17 years of age. Those who were in a chat room monitored by an adult made fewer explicit sexual or obscene comments than those in an unmonitored chat room, but younger females were also more likely to participate in the monitored rather than the unmonitored chat room (Subrahmanyam et al., 2006), suggesting that girls are more likely to select a protected space from boys when online. Pairing off strategies, in which participants engaged in cyber pick ups by making a sexualized advance with a request to leave a public conversation for a private one, also occur online, which often result in a sexually intimate verbal exchange called “tiny sex” between the pair (Turkle, 1997).

Faster Internet speeds allowed visual as well as verbal communications about sex. *Sexing* involves sending or receiving nude or seminude photos or sexually explicit messages through mobile phones or the Internet in emails or social networking sites (Dake et al., 2012). Sexing takes place in three main ways: between romantic couples; distribution of pictures with others outside of a couple’s relationship, which sometimes takes place after an argument between the couple; and between two people in which

at least one person is hoping for a sexual relationship to develop (Lenhart, 2009).

About 4% of 12- to 17-year-old youth reported that they sent and 15% reported receiving a sexually explicit picture on their mobile phones, with older youth reporting more sexting than younger ones (Lenhart, 2009). The National Campaign to Prevent Teen and Unplanned Pregnancies (2010) found that 51% of 13- to 19-year-old girls felt pressured by boys, but only 18% of adolescent boys felt pressured by girls, to send sexts of themselves. Sexing is also associated with risky behaviors, such as more unprotected sexual intercourse, substance abuse, and emotional issues, such as attempted suicide or forced intercourse (Dake et al., 2012).

In summary, access to sexual content is widely available, particularly online where content and activities are less regulated. Adolescents often seek out sexual content, some of which is generated and is distributed by them. These experiences influence adolescents’ beliefs and feelings about sexuality and can put them at risk in their sexual interactions with others.

### **FROM OUTDOOR TO INDOOR ENVIRONMENTS: THE OBESITY EPIDEMIC**

Within the United States, overweight and obesity rates tripled over the past three decades to 21% of 2- to 5-year-olds, 36% of 6- to 11-year-olds, and 34% of 12- to 19-year-olds, with rates particularly high among Latino/a American boys and African American girls (IOM, 2006; U.S. Centers for Disease Control and Prevention, 2012). Increases in overweight and obesity issues are associated with health-related problems, including Type 2 diabetes, heart disease, stroke, and cancer (IOM, 2006), which forecasts long-term health issues for children throughout their lives.

The everyday environments of children are saturated with exposure to unhealthy foods, delivered in part through media (IOM, 2006, 2012). Television advertising reaches millions of children daily, and 1.2 million children visit food websites each month (J. Harris, Speers, Schwartz, & Brownell, 2012). In 2009, food marketers spent \$1.79 billion to market to children Ages 2 to 17, a 19.5% drop, adjusted for inflation, from 2006 marketing expenditures (FTC, 2012a). This cost is lower, in part, because marketers decreased their television advertising buys by 19.5% while expanding their marketing presence by 50% in newer media, such as the Internet, mobile phones, and viral

marketing (FTC, 2012a). Online marketing costs less than television advertising does, thereby making it more cost effective (Calvert, 2008a).

Energy balance involves taking in the same number of calories as those that are expended to maintain the same weight (Calvert, Bond, et al., 2014). One risk factor for obesity involves increased exposure and subsequent intake of high caloric foods that are low in nutritional value, much of which is marketed at children through television advertising (IOM, 2006). Another risk factor involves decreased physical activity because of a shift from outdoor activities to sedentary indoor media activities (Calvert, Bond, et al., 2014). These two pathways to obesity are not mutually exclusive, as the shift to indoor activities also increases the probability that youth will be exposed to television advertisements.

### The Content of Food and Beverage Advertisements

Using the U.S. Department of Health and Human Services formula in which foods are classified as Whoa (to be consumed only once in a while or for a special occasion; e.g., sweetened breakfast cereals), Slow (of moderate nutritional value to be consumed sometimes; e.g., sports drinks), and Go (to be consumed anytime; e.g., apples), Kunkel, McKinley, and Wright (2009) evaluated the foods and beverages in television advertising on 139 children's programs that were broadcast on CBS, NBC, ABC, CW, FOX, Nickelodeon, and Cartoon Network. Results indicated that the Whoa category of foods was far more prevalent (68.5%) than either the Slow (31%), or Go (<1%) categories. The use of popular, licensed characters to advertise to children, such as SpongeBob from *SpongeBob SquarePants*, also doubled from 2005 to 2009 (Kunkel et al., 2009). Content analyses of children's favorite websites and food websites documented extensive marketing of unhealthy foods to children, including the use of advergames (i.e., games that are intended to advertise) to attract children (Alvy & Calvert, 2008; J. Harris et al., 2012; Weber, Story, & Harnack, 2006).

### Energy Intake: Media Influences on Children's Diets and Health Outcomes

In a comprehensive analysis of studies conducted on the foods and beverages that are marketed to children and youth, which primarily involved television advertising, researchers found that advertising influenced children's

food and beverage preferences, their immediate dietary consumption patterns, and was associated with long-term obesity problems (IOM, 2006). A causal connection between television advertising and obesity could not be drawn because ethical issues prevent experimental studies from being conducted that would deliberately make children overweight or obese. Therefore, the data were correlational. Even so, the data were consistent with the hypothesis that exposure to television advertising is one cause of overweight and obesity problems for children (IOM, 2006). Another review of the literature conducted in the United Kingdom reached a similar conclusion, linking children's exposure to television food advertising to pediatric obesity and overweight issues (see Hastings et al., 2003).

Not surprisingly, studies of online marketing yield similar findings to those reported in television advertising. For instance, 6-year-old children had more difficulty in discriminating advertisements depicted in simulated web pages than 10-year-old children did (Moondore, Blades, Oates, & Blumberg, 2009), just as they have problems in identifying television advertisements from the program content (Calvert, 1999). Similarly, 7- to 12-year-old children, particularly those who reported playing advergames in the past, were more likely to consume snacks of poor nutritional quality after playing advergames that promoted unhealthy foods, but ate more fruits and vegetables if they played an advergame that promoted consumption of healthy foods (J. Harris et al., 2012). Consistent with these findings, 9- and 10-year-old, low-income African American children were more likely to select and consume healthier snacks after playing an advergame in which their Pacman character was rewarded (gained points) for consuming healthier products and punished (lost points) for consuming unhealthy products when compared to peers who played the same advergame with the opposite reinforcement contingencies (Pempek & Calvert, 2009). The findings suggest that children select and consume nutritional or nonnutritional products that are marketed to them via advergames through the simple behavioral principles of vicarious rewards and punishments to their character, yet marketers overwhelmingly promote unhealthy foods online (Calvert, 2008a).

Motivational variables provide a window into how youth use technologies in ways that can lead to positive dietary behaviors. Those who eat breakfast have healthier diets and healthier weights than those who skip breakfast (Sjoberg, Hallberg, Hoglund, & Hulthen, 2003). To improve breakfast consumption, Byrne et al. (2012)

provided motivational incentives to children to eat breakfast through feedback given through children's virtual pets, who were accessed via mobile phones. When children received both positive and negative feedback from their virtual pet, they were twice as likely to eat breakfast as those who received only positive feedback from their pet or those who had no pet at all. In other words, a combination of positive and negative consequences provided maximum feedback and benefit to the child.

### Media-Related Caloric Expenditure

Energy expenditure comes from two main sources: (1) exercise activity thermogenesis, which is typically attributed to healthy lifestyles as it involves daily exercise; and (2) nonexercise activity thermogenesis, or NEAT, which is the most variable form of activity and a likely contributor to the obesity crisis, as obese youth sit about 2½ hours more per day than lean youth sit (Levine, Eberhardt, & Jensen, 1999; Levine, Vander, Hill, & Klesges, 2006). In obesity prevention, every step counts, from running to walking to get a glass of water (Fujiki, Kazakos, Puri, Buddhharaju, & Pavlidis, 2008; Levine, Baukol, & Pavlidis, 1999).

Theoretically, media use may lead to overweight and obesity issues by *displacing* more active nonmedia experiences with sedentary behaviors. Small or negligible correlations were found, however, between children's television viewing and video game play in relation to their physical activity as nonactive indoor activities, such as board games, were displaced (Vandewater, Bickham, & Lee, 2006). Nor are all media experiences sedentary. Lean-forward media, including mobile media as well as exergames, can provide opportunities for youth to get moving and to track their own energy expenditure through sensor-based technologies (Staiano & Calvert, 2011a, 2011b). Although simply keeping track of an activity yields a change toward positive, recommended choices and action (Kopp, 1988; Nelson, 1977), NEAT is particularly difficult to track. Small, unobtrusive sensor-based devices that sync wirelessly via bluetooth to mobile devices can monitor the number of calories expended during exercise, providing individualized feedback about users' everyday activities without the burden of self-report. This individualized, tailored feedback is far more effective for behavior change than nontailored alternatives (Vandelanotte & De Bourdeaudhuij, 2003). Sensor-based capabilities include monitoring for goal setting and game-like elements, including social play.

The term *self-monitoring* refers to activity tracking, often in conjunction with goal setting, for health-related behavior change. An example is a pedometer that can track every step taken. When linked with software, data gathered by sensors can be displayed graphically, charting energy expenditure over time (Consolvo, Klasnja, McDonald, & Landay, 2009; Staiano & Calvert, 2011a). However, self-monitoring alone does not produce long-term, sustainable change, in part due to boredom with receiving only raw feedback (Y. Lin & Landay, 2008).

Electronic games, on the other hand, can be extremely engaging (Lieberman, 2006), particularly when combined with social feedback from one's peers (Staiano, Abraham, & Calvert, 2013). Competition can increase motivation to play sensor-based games (Fujiki et al., 2008; Toscos, Faber, An, & Gandhi, 2006), particularly when compared to solitary play (J. Lin, Mamykina, Lindtner, Delajoux, & Strub, 2006). When compared to a nonplaying control group, however, cooperative exergame play at school was effective in producing actual weight loss in a low-income African American sample of obese and overweight adolescents, but competitive exergame play was not (Staiano et al., 2013), and motivation to play was also higher for the cooperative than the competitive exergame group (Staiano, Abraham, & Calvert, 2012). Because the competitive mobile game studies did not examine weight loss, it appears that cooperation may be a more viable approach for getting children to invest in game play that can lead to long-term physical benefits. However, not all exergame studies obtain weight loss, particularly when conducted for short periods of time at home (Baranowski et al., 2012; Maloney et al., 2012), suggesting the importance of lengthy treatments and social interactions with peers, particularly in school settings.

### Summary

In summary, the kind of media diet that children have is linked to the obesity crisis. Specifically, exposure to food advertising for high caloric, low nutrient foods is associated with overweight and obesity issues more so than the total amount of exposure to media. In addition, activity displacement appears to involve similar kinds of experiences (e.g., watching television rather than playing a video game) rather than television viewing displacing high-energy expenditure sports activities that are played outdoors. Exergames and virtual play with mobile phone games in which children have to move can lead to caloric expenditure and even weight loss, particularly when cooperation is involved. However, mobile phones are not

allowed in many school systems, and exergame play does not always lead to weight loss.

### **RISKY MEDIA ENVIRONMENTS: ALCOHOL, TOBACCO, AND ILLEGAL DRUGS**

Alcohol, tobacco, and drugs are portrayed and used in varying degrees by artists across diverse kinds of media (Borzekowski & Strasburger, 2008). While regulation of substance use occurs during advertising on television, the stories themselves often embed characters engaging in the use of alcohol and tobacco, thereby providing ample opportunities for youth to observe and potentially imitate behaviors that can be risky for them.

#### **The Content: Exposure to Risky Behaviors**

Both tobacco and alcoholic beverage consumption is prevalent in most media and is generally treated favorably in media depictions (Borzekowski & Strasburger, 2008), with popular media characters involved in drinking alcohol and smoking tobacco. Consequently, role models are being presented who act in ways that could be harmful to child and adolescent health outcomes. Although illicit drug use is presented in movies, it is less likely to be presented in television programs, and when it is, illicit drug use is generally presented unfavorably, which could potentially discourage participation in illegal drug use (Roberts & Christenson, 2000). Video games rarely portray any kind of substance abuse (Haninger & Thompson, 2004). Nevertheless, media role models are plentiful for children to observe and potentially to imitate for all three classes of substance abuse.

#### **Influences of Exposure to Alcohol, Tobacco, and Illegal Drugs on Children**

According to Heatherton and Sargent (2009), adolescents who view movies with characters who smoke are 3 times as likely to try smoking. These conclusions are based on numerous large-scale surveys that use multiple statistical controls, some with longitudinal follow-ups. Both the onset of smoking tobacco (Hanewinkel & Sargent, 2008; Sargent et al., 2001; Sargent et al., 2005) and drinking alcohol (Hanewinkel & Sargent, 2009; Sargent, Wills, Stoolmiller, Gibson, & Gibbons, 2006) increased for U.S. and German youth who had viewed film portrayals where these behaviors had been modeled. Parents who monitored their 9- to 12-year-old children's viewing of movies with

a restricted (R) rating were less likely to try smoking cigarettes or drinking alcohol than those whose parents did not monitor them, suggesting protective factors when parents limit their children's exposure to media content that demonstrates risky behaviors (Dalton et al., 2006).

Adolescents' attitudes about smoking tobacco are influenced by whether their favorite stars smoke (Heatherton & Sargent, 2009). In one longitudinal study (Distefan, Pierce, & Gilpin, 2004), 12- to 15-year-old adolescents who had never smoked named their favorite movie stars. A sample of movies for a 3-year period was also examined for the smoking behaviors of their top 10 favorite stars, tallied separately for boys and girls. One third of the sample group who selected a star who smoked in the movies became smokers, an outcome that was stronger for adolescent girls than for adolescent boys. African American girls were less likely to name a favorite movie star that smoked than were other youth, and content analyses documented that the favorite actors of African Americans girls generally did not smoke onscreen. These findings can be interpreted within social cognitive theory, as role models are more likely to be imitated (Bandura, 1986).

In a survey of marijuana and alcohol use among high school students ( $N = 1,211$ ) from blue-collar neighborhoods, Primack, Kraemer, Fine, and Dalton (2009) found that those who listened to more music were more likely to smoke marijuana, while those who attended more movies were more likely to drink alcoholic beverages. By contrast, those who read more books or played more video games were less likely to smoke marijuana or drink alcohol. The authors speculated that video game or book reading may remove youth from situations that lead to drug and alcohol abuse or reduce their exposure to other media that portray substance abuse.

In summary, the research consistently links exposure to media depictions of alcohol and tobacco with the onset of drinking and smoking among adolescent youth. The results are consistent with decreased inhibitions to smoke and to imitation of role models, as would be predicted by social cognitive theory. Although a variety of statistical controls are used in analyses, the major weakness in this literature is that the studies are correlational in design, thereby limiting inferences about causality. However, experimental studies are not possible because of ethical issues.

### **MEDIA POLICY**

Numerous professional organizations and government entities, including the U.S. Congress, have advanced and

implemented media policies. Most policies involve ways to address the influences of exposure that is deemed to be harmful to children, such as sex and violence. The First Amendment, guaranteeing freedom of speech, is integral to how U.S. policies are created and implemented (Calvert, 1999).

### Early Media Exposure

The American Academy of Pediatrics (AAP) has advanced policies to prevent or reduce children's exposure to media. In particular, parents are discouraged from letting their children be exposed to screen media prior to Age 2 (AAP, 1999, 2011), to limit screen exposure to no more than 2 hours per day for children over Age 2 (AAP, 2001a), and to have no television sets in children's bedrooms (AAP, 1999, 2001a, 2011). The AAP (2011) also recommended that pediatricians encourage parents to read to their toddlers to promote literacy and cognitive skills. These recommendations were designed to prevent excessive exposure to violence, to improve sleep, and to improve cognitive skills (Evans Schmidt, Bickham, Branner, & Rich, 2008). Such policies make clear that the AAP favors traditional over screen-based learning.

### The V-Chip

The Federal Communications Commission (FCC) has set forth policies to assist parents in controlling the kind of content that their children view. One involves the V-Chip, which is a computer chip installed in television sets that have picture screens 13 inches or larger. Television program ratings, which came into being as a result of the Telecommunications Act of 1996 (Iannotta, 2008), are used to program the V-Chip to block content. One set of television program ratings is based on content: *S* represents sexual content, *D* represents suggestive dialogue, *L* represents profane language, *V* represents violence, and *FV* represents Fantasy Violence, although very few parents use the V-Chip because it is difficult to program (Jordan, 2003).

### Media Violence

The American Psychological Association (1996, 2005) recommended a reduction in violent television and videogame content and the use of technologies, such as the V-Chip, that would enable viewers (or their parents) to control or

eliminate youth exposure to media violence. The American Academy of Pediatrics (2001b) targeted media violence presented via television, movies, video games, and music as a risk factor to children's health and argued for a change in children's media environments. Their recommendations included what is being broadcast, parental supervision of children's media exposure, and children's participation in media literacy programs. To reduce the impact of violent content on children's behaviors, the American Academy of Child and Adolescent Psychiatry (2002) recommended that parents reduce their children's exposure to television, consider removing a television set from their children's bedrooms, and refuse to let their children view violent television programs.

### Regulating Sexual Content

The FCC regulates commercial television programs with sexual content and pay services like dialing for pornography, but the FCC has limited jurisdiction over cable programs, as cable operates over private, not public, airwaves (FCC, 2000; Iannotta, 2008). In addition, any regulation of sexual content presented on the Internet is difficult, if not impossible, to enforce due to the international reach of the content provided online (Thornburgh & Lin, 2002).

A National Academies committee led by Thornburg and Lin (2002) presented a range of technological tools, legal approaches, and social and educational strategies that could be implemented to protect children and youth from sexually explicit online content. At a technological level, *filters* that prevent access and *surveillance* software that tracks behavior were recommended as ways to prevent minors from accessing sexually explicit online content. At a legal level, the committee recommended that child pornography laws continue to be aggressively prosecuted and that law enforcement officials systematically enforce existing obscenity laws, which were not being prosecuted on a frequent basis at the time of the report. Educational and social strategies, such as school media literacy programs were recommended, as children's education was deemed essential to instill ethics of responsible choice and to teach children to use technological tools to implement those choices.

One issue that arose during the National Academies committee's report involved the distribution of materials through peer-to-peer file sharing, in which one minor sent a sexually explicit picture to another (Thornburgh & Lin, 2002). This area was viewed as one that would be particularly difficult to address, which indeed has occurred

with online activities such as sexting. Although no federal laws apply to sexting behaviors among minors (Dilberto & Matthey, 2009), state laws have been used to prosecute minors who sext (Dake et al., 2012). Because sexting is technically the production and distribution of child pornography (Lenhart, 2009), minors who are found guilty of sexting have been subject to possible prison sentences or being registered as a sex offender (Dake et al., 2012). The American Psychological Association (2008) recommended that steps be taken to prevent the sexualization of girls, and teaching girls to value themselves for who they are rather than how they look. The sexualization of girls creates an environment that is conducive to activities like sexting (Dake et al., 2012).

Internet applications like Snapchat now reduce the possibility of distributing sexting materials past the intended recipient. Snapchat allows images to be transmitted for 10 seconds or less, as determined by the sender, after which the message is destroyed. This peer-to-peer file sharing application enables youth to transmit sexts to one another with less fear of prosecution or loss of control of the distribution of the images. Nonetheless, the onscreen images can be captured if the recipient is quick, in which case the sender is immediately notified (<http://www.snapchat.com/#What-is-snapchat>).

### **The Commercialization of Childhood**

U.S. children live in a highly commercialized environment. The American Psychological Association, the American Medical Association, and the American Academy of Pediatrics have called for the elimination of, or restrictions in, advertisements directed at children under Age 8, as they are deceptive and unfair (Evans Schmidt et al., 2008). These kinds of advertising restrictions have already occurred in other countries such as Australia, Canada, Great Britain, and Sweden (American Psychological Association, 2004). The use of media characters in children's marketing has also been controversial, such as when the characters become part of product-based programs or program-length commercials, in which the intent of the program is to sell toys (Federal Communications Commission, 1974). There have been similar arguments to restrict or eliminate the use of media characters beyond the screen for commercial purposes (Linn, 2004), but policies have not been put into place, in part because toy revenue pays for the creation of programs in the United States (Cahn, Kaligan, & Lyon, 2008) and because of the First Amendment. Youth also create and post online videos about their favorite

products on websites like youtube.com, transforming them into active consumers who generate advertising content (Montgomery, 2012).

### ***Tobacco and Alcohol Advertising***

Efforts to restrict television tobacco advertising have been effective. In 1971, The FCC banned tobacco advertisements from television because of potential health hazards (Aufderheide, 1990). The American Medical Association recommended a ban on all tobacco advertising, as tobacco advertisements are still available in other media, such as magazines and online venues (Evans Schmidt et al., 2008). Advertisements for hard liquor also disappeared from television commercials due to a voluntary agreement with the liquor industry, although beer commercials are still abundant, particularly during sports programs (Evans Schmidt et al., 2008). Smokers and drinkers continue to appear in television programs, perhaps creating an even more effective approach for marketing than traditional advertising, as popular characters are smoking and drinking, and these behaviors are not being labeled as potentially dangerous.

### ***Food Marketing***

The products advertised to children have been linked to pediatric health issues, specifically becoming overweight and obese. Based on an evidentiary review of the literature, an Institute of Medicine (2006) committee made ten recommendations, such as food marketers should use their resources to market healthy foods and beverages to children and youth. Dr. J. Michael McGinnis (2008), who chaired the 2006 IOM committee, testified before Congress, finding little progress in the implementation of the ten recommendations. The lack of progress was occurring not just on the industry side, but also on the government end.

### ***Privacy***

The tracking of online youth has been an ongoing privacy concern, as numerous companies track what children are doing online, and use targeted marketing in which online advertisements appear based on the specific interests and preferences of their participants. The 1998 Children's Online Privacy Protection Act (COPPA) gave the Federal Trade Commission (FTC), who regulates interstate commerce in the United States, the authority to create rules that would restrict commercial websites from collecting personally identifying information about minors who are under the age of 13 (Montgomery, 2012). The FTC updated the COPPA policy with amendments that make companies

seek parental permission to capture children's pictures, videos, and geographical location, which are now possible through social networking sites, and added mobile phones, tablets, and online games to the media that had to follow the rules (FTC, 2012b).

### Driving Hazards

In 2012, 39 U.S. states had laws prohibiting texting while driving, and 10 states banned handheld mobile phone use while driving (Governors Highway Safety Association, 2012). With car crashes as the leading cause of adolescent death, a 2012 television media campaign also created the catchy phrase of a "designated texter" to keep the driver focused on the task of driving the car (Halsey, 2012).

### The Children's Television Act

The Children's Television Act is consistent with policies made by health organizations to improve children's well-being through legislation that supports high quality children's television programs (Evans Schmidt et al., 2008). The AAP advises parents to show only educational television programs, which includes prosocial programs (Evans Schmidt et al., 2008). With changes in television to the digital spectrum, the FCC retained the original requirements of the CTA, but created additional guidelines for multicasting, advertising, and website labeling (Calvert, 2008b; Hill-Scott, 2012). In particular, not more than 50% of the E/I programs broadcast can be repeated during a given week on a particular channel, children's websites must be intended for noncommercial use and the primary website content must be related to the program, and the rules of character use and selling by the program host were updated (Hill-Scott, 2012).

## CONCLUSIONS

Electronic media have been with us for less than a century, but in that short window of time they have become integrated into the fabric of our children's lives. While some parents fear that digital media will be detrimental to their children's development, others fear their children will be left behind without it. Perhaps there is a measure of truth in both visions.

Electronic media are ubiquitous, and they are here to stay. Media range in size from very, very large home

theaters to very small, mobile smartphones that connect children to each other and to the world around them. Wearable devices, such as smart watches, are now beginning to enter the marketplace (though the character Dick Tracy wore one many, many years ago).

The content is not changing, nor are the developmental issues that children face, but increasingly media are seamlessly integrated across both real and virtual life experiences. For example, children can look out of their Google glasses that allow a window into an electronic web of information, which is enmeshed within their current individualized environment. Alternatively, children's images, actions, and settings can now be embedded in some of the apps and video games that they play. What will reality mean for children as the lines between face-to-face and virtual experiences are increasingly blurred?

Media researchers are challenged to keep pace with this rapidly shifting array of platforms, allowing various affordances to content access, creation, and distribution, and to respond to requests about policy issues. Early development already occurs in a context in which media characters traverse time and space, from the screen to the toy store to the grocery store. Older children increasingly control their own media environments, with relatively little regulation by their parents. In the midst of these changes, some things remain constant. Observational media will ever be a part of our children's lives. Children like to watch, and the stories of others fascinate them. To what extent will children be able to enter those stories in the future, creating their own plots and representing their unique life stories? Who will our children's friends be? For example, what will a social relationship mean as intelligent agents and robots look and increasingly act more as human beings who are children's special friends, able to respond to each one in highly personal ways? Will children prefer these virtual friends to their more difficult real-life ones? Will children forsake their privacy for the ease of gaining quick access to products that they like? Will privacy even be possible in the future, as tracking software increasingly follows children everywhere they go?

With the exception of the Children's Television Act, rarely do policies take advantage of the enormous potential of media to promote constructive behaviors, such as altruism. Instead, most policies focus on problematic issues, such as reducing children's exposure to sex, violence, and advertising, with some policies recommending restricted access to any kind of electronic media. Ideally, media policy should follow research, not precede it. Yet urgent social issues sometimes drive quick policy decisions

instead of policies emerging after a careful, deliberative research process. Even when media policies are grounded in research, the First Amendment prevents many of them from having the kind of teeth in the United States that would be required to make a meaningful difference.

As our media landscape rapidly changes, one thing is certain: Media platforms will continue to evolve. As digital natives, children accept these changes as inevitable (Prensky, 2001), ever willing to explore and to help develop the newest digital innovation. Each successive generation now leaves a unique digital footprint behind them. The question for us is whether we have the vision to leave a digital footprint worthy of our children's futures.

## INTRODUCTION

Children's development does not occur in isolation. Children grow up in families with cultural backgrounds and beliefs, and in families with varying financial resources

---

Velma McBride Murry's involvement was supported by funding from the Lois Autrey Betts Chair in Education and Human Development. Special thanks to Na Liu and Jonathan Whichard for their assistance.

and social capital. They reside in communities and neighborhoods that are homogeneous or diverse, with varying levels of resources and risks. A full understanding of development cannot be gained without careful consideration of the processes through which context and development are co-constructed. This chapter synthesizes theory and research that explain how context influences children's development. Specific consideration is given to mechanisms through which social position (race/ethnicity) and social stratification (income level or poverty) are

associated with fundamental processes in development. We begin by summarizing theoretical frameworks and describing models that guided our review.

### **Linking Contextual Theories and Developmental Models to Study of Child Development**

After decades of developmental theory grounded in mechanistic and organismic worldviews that minimized or ignored the contextual influences on development (Lerner, 1986; Parke, 2004), Bronfenbrenner's ecological theory (1974, 1977, 1986) advanced the inclusion of context in the study of human development. This model contends that human life is inextricably linked with and infused into multiple interlocking contextual systems. Thus, individuals' capacities and developmental outcomes are products of the dynamic relational interactions that occur within these systems. To further explicate how developmental systems influence development, Bronfenbrenner and Morris (1998) synthesized and expanded the original ecological model and included biology, culture, and chronological/historical time as dynamic features of the human development system—thus evolved the bioecological model of human development. In this model individuals are characterized as active agents in their environment with capacities to influence, as well as be influenced through social interactions that are embedded in their context. Social interactions, therefore, are the processes that “make human beings human” (Bronfenbrenner, 2005). Applying the conceptualization of human development to child, one would focus on processes through which an individual's developmental systems and dynamic interactions with others, promote or inhibit mental health, literacy, intellectual growth, educational attainment and other dimensions of development (Bronfenbrenner, 1979; Bronfenbrenner & Morris, 2006).

Later advancement in the scholarship of human development and systems theories sought to explain the contributions of social relationships and human dynamic systems to human development over the life span (Lerner, 2002; Overton, 1998). This advancement highlighted the processes through which relational interactions facilitate developmental changes. Relational processes are characterized as reciprocal, mutually influential interactions that occur among an individual's biological, psychological, and proximal social relational level systems (e.g., parent-child, siblings, and peers). Developmental systems not only are influenced by social relations but are also influenced by multiple systems that are structurally and functionally integrated and embedded in history and sociocultural systems,

including educational, public policy, governmental, and economic systems. Variability in an individual's development is attributed to human interactions in her/his environmental settings (Spencer, 2006). As active agents, humans have the capacity to engage in behaviors to shape social interactions and change the directional influence of environmental settings in ways that affect subsequent development (Lerner, 1982). Thus, developmental change is produced and is a product of linkages among a child, her/his family, community, and society; any change in one system spills over to affect changes in other ecological contextual systems (Lerner, 1986; Lerner, Peterson, & Brooks-Gunn, 1991). For some, the nature of individual-context relations is met with numerous environmental, social, political, and economic challenges that influence the course of their growth and development. This circumstance is of particular importance in understanding the developmental trajectories of racial and ethnic minority children, and of children growing up in poverty or isolated rural communities. Development for these children, for example, is more likely to be influenced by their social positions and social stratification than for children growing up in other contexts.

Another contribution of the developmental relational system theory is its ability to explain how race, ethnicity, gender, sexual orientation, and national and cultural settings influence the course of development (Castellino, Lerner, Lerner, & von Eye, 1998). As Lerner (1998) notes, human response to “diversity is the exemplar of the presence of relative plasticity in development” (p. 904). Differential responses to challenging environment and the feedback that humans receive have significant effects on positive and negative developmental change. The fact that diversity is included as a core component of ongoing interactions between people and their multiple embedded contexts further suggests how significant the contribution of social position and social stratification is for the developmental trajectories of some groups of children growing up in the United States. This proposition has been posited by García Coll et al. (1996). Their model demonstrates how critical aspects of some children's environment are profoundly influenced by racism, prejudice, discrimination, oppression, and segregation. García Coll (1996) and colleagues urge scholars studying child development to consider ways in which developmental outcomes are influenced by social stratification and its derivatives. Specifically, race, ethnicity, and social class are core rather than peripheral contextual processes in the development of children who are marginalized because of social position and social stratification. Further, when these constructs are

omitted from developmental theories and research, their beneficial impact on youth in more advantaged contexts are missed. Contexts provide both synergies of advantage and disadvantage. The primary purpose of this chapter is to draw attention to and integrate knowledge on contextual factors for a more holistic understanding of normative development. We focused on the following two questions: (1) How have researchers studied the development of marginalized children? (2) To what extent have social positions and social stratification been conceptualized as fundamental to developmental systems of marginalized children?

### Organization and Scope of Chapter

This chapter synthesizes extant studies that have examined ways in which race/ethnicity, socioeconomic status, geographic residence, immigration status, and family formation status (e.g., transracial adoption) are associated with both normative (e.g., social emotional well-being, academic aspiration, prosocial friendships) and nonnormative (e.g., externalizing behaviors, high risk behaviors, school dropout) child development. It identifies methodological and theoretical strengths and weaknesses of extant studies and provides recommendations to advance future studies of child development in diverse contexts.

Before beginning our analysis of the extant literature, we clarify major concepts and terminology. Specifically, we provide an analysis and clarity regarding race and ethnicity, as these two concepts have been used in the field of human development in studies examining the role of diversity in child development. Following this discussion, we provide an overview of the changing demographics of families and children in the United States. Finally, we synthesize extant studies of child development based on social positions and social stratification. To the extent possible, we identify ways in which these factors are interlocked with contextual processes to explain individual differences in mental health, literacy, intellectual growth, educational attainment, and other dimensions of development (Bronfenbrenner, 1977; Bronfenbrenner & Morris, 2006).

### IMPLICATION OF RACE AND ETHNICITY IN STUDIES OF CHILD DEVELOPMENT

The term *race* is often used to group people based on presumed genetic, biological, or physical similarities (S. Graham, Taylor, & Ho, 2009). Genetically, humans

are 99% identical and the use of the term *race* to categorize groups of individuals is not scientifically supported (Bonham, Warshauer-Baker, & Collins, 2005). There are, however, variations in DNA mapping that can be used to determine the extent to which individuals have ancestors who are African, European, East Asian, Native American, or from the Pacific Islands. This information is only beneficial in identifying groups of individuals if certain sampling criteria are met, such as homogeneity of people from the geographic location and geographic homogeneity of the individual (Rich, Burchard, Ziv, & Tang, 2002; Rosenberg et al., 2002). Despite the controversy and ambiguity that definitions of race evoke, the use of biological definitions and society's construction of the meaning of race based on boundaries between racial groups remains.

Generally, ethnicity is used to reflect the heterogeneity within cultural groups. For example, in the United States, ethnicity is used to describe Latino/a Americans who represent many races and are therefore distinguished by ethnicity (e.g., Puerto Rican, Dominican, Columbian), which is an accurate representation of this subpopulation. While the United States Census Bureau (2010) recognizes the ethnic background of Latin/Hispanic Americans, it does not recognize the ethnic backgrounds of other racial groups, such as Black/African Americans or Asian Americans. For these groups, the word *ethnicity* is often used as a euphemism for *race* when referring to non-Latino/a Americans. This conceptualization is largely incorrect. Individuals from the African diaspora include many ethnic backgrounds (African American, Haitian, African, etc.). Further, Asian Americans, as an ethnic minority group, are quite heterogeneous with over 20 subgroups (Chinese, Japanese, Filipino, Korean, etc.)—each with unique linguistic, cultural, and sociodemographic backgrounds, as well as immigration histories in the United States (Sue & Morishima, 1982). Because research scholars often ignore ethnicity within race for Asians (e.g., Chinese Americans), African (e.g., Caribbean Americans), and European Americans (e.g., Irish Americans), this incorrect perspective impedes the study of important contextual variations in children's development and socialization.

While the fields of sociology, anthropology, psychology, demography, and human development are replete with discussions about the complexities associated with conceptualizing and operationalizing race and ethnicity, studies of children of color historically presumed that it is possible to capture the experiences of these children in collective categories of non-European American individuals residing in the United States. We acknowledge that using

both ethnicity and racial group membership in broad labels dilute and obscure moderating effects of national origin, immigration history, religion, and traditions on normative and maladaptive development (Lin & Kelsey, 2000; Mio, Trimble, Arredondo, Cheatham, & Sue, 1999). We also recognize that visible phenotype characteristics, often driven by race and ethnicity, along with social economic status, inform and influence the experiences of children, families, and communities of color. The legacy of racial discrimination remains because biologically driven phenotypic characteristics continue to elicit unique experiences for the majority of children of color. For example, African Americans and Latino/a Americans are more likely to be profiled based on phenotypic characteristics, subjected to race-ethnic related negative reactions from European Americans, and exposed to parenting processes uniquely designed to teach them how to cope with demands of a society that devalues their heritage, race, and culture (Coard, Wallace, Stevenson, & Brotman, 2004; McAdoo, 1992; Murry, Berkel, Brody, Gerrard, & Gibbons, 2007). The social, economic, political, and environmental realities of these children suggest the need for careful consideration of ways in which being a member of a *minority racial group*, or being a *child of color*, influences development apart from and in addition to the cultural implication of their ethnicity (Harrison & Thomas, 2009).

In addition to addressing in this chapter race-related consequences for child development, we also consider ways in which classism fosters specific ecological circumstances that explain child development (Evans, Fuller-Rowell, & Doan, 2012). In sum, given the implications of physical characteristics, language, and immigration status for subpopulations of individuals residing in the United States, we are of the opinion that there is a need to maintain distinct conceptualization of race and ethnicity. These labels shape and influence ecological systems and context relations of children in certain social positions (Hill, 2006; Hill, Murry, & Anderson, 2005). Whereas these issues have been apparent for understanding development of ethnic minority children, they are increasingly deemed more normative as the United States population becomes more diverse and the field of human development becomes more globalized.

## DIVERSITY EXPLOSION: DEMOGRAPHIC SHIFTS IN THE UNITED STATES

Highly noted in the United States at the dawn of the new millennium is “an explosion of diversity” in every state

across the United States (Fry & Passel, 2009). Given these demographic changes in U.S. society, Prewitt (2013) recommends the elimination of the term *race* because the diversity explosion in United States has facilitated an emergence of a *hybrid America* that includes peoples of many nationalities, ethnicities, and cultures (Prewitt, 2013). Several patterns have been associated with the drastic population shift. The number of immigrants in the United States reached a record 40 million in 2010. Consequently, based on the census count, one out of every three Americans is a person of color (U.S. Census Bureau, 2010).

Dramatic changes in fertility patterns in the United States have also been associated with the majority/minority population shift (Passel, Livingston, & Cohn, 2012). Prior to 2000, non-Latino/a American European Americans (i.e., non-Hispanic Whites) accounted for nearly 66% of all births; followed by African Americans, representing 17% and Latino/a American representing approximately 15% of all births in the United States. By 2008, non-Latino/a American European American births dropped to approximately half of all births, with concomitant increases observed in the number of births to Latina American mothers, accounting for 26% of all births, compared to 16% of births to African American mothers (Hamilton, Martin, & Ventura, 2011). Further, since 2009, childbirths have been higher among Latina American mothers than European Americans and African Americans, averaging 2.99 versus 1.87 and 2.3, respectively.

## Projected Population Shifts

Dramatic demographic shifts in the United States have resulted in a booming population of youth in, what has been characterized as the “vanguard of America’s new racial and ethnic diversity” (K. M. Johnson & Lichter, 2010, p. 151). The number of minority children in the United States increased by 15.5% between 2000 and 2008. Of the 73.9 million children in the United States, Latino/a Americans accounted for 3.9 million, an 80% increase from 2000 to 2008. The largest minority group in the United States is Latino/a American, a position historically held by African Americans (U.S. Census, 2010). Demographers contend that if the shrinking population patterns of non-Latino/a European Americans in this country continue, by the middle of this century, non-Hispanic European Americans will cease to be a majority population in the United States (Lichter, Parisi, Taquino, & Grice, 2010). These changing demographics of U.S. society shape, challenge, and complicate the lives of children and families that have been

traditionally marginalized (Hernandez & Cervantes, 2011). The rapid increase in ethnic diversity is not represented across the range of sociodemographic backgrounds. There is a growing economic divide that is confounded with racial/ethnic diversity.

### Social Stratification

In addition to ethnic or racial background, social stratification drives opportunities and developmental outcomes for children. The patterns and pathways of impacts of social stratification across socioeconomic status (SES), geographic residence, and rural/urban context are well documented (García Coll et al., 1996). Further, their impacts are not equally felt across racial and ethnic background. There are additive and multiplicative impacts of race, ethnicity, poverty, and wealth on the life chances of children. Each is described below.

### Socioeconomic Status

A well-documented phenomenon is that on most social indicators, children of color fare less well than their non-Latino/a American European American counterparts (Duncan, Magnuson, and Votruba-Drzal, Chapter 14, this *Handbook*, this volume). Among children of color, 16.4 million are poor and of those, 7.4 million are growing up in extreme, concentrated, persistent poverty (U.S. Census Bureau, 2010). Unprecedented levels of income and wealth inequality create challenges that take a toll on the families and their children. African American and Latino/a American children are more likely to be raised in families with incomes less than half the poverty threshold than non-minority children who are poor (Child Trends Data Bank, 2014). Low-income children live in noisier, more crowded, and low-quality housing than do their middle-income counterparts, and experience more psychosocial stressors, such as elevated family turmoil, greater child-family separation, and higher levels of violence (Brooks-Gunn & Duncan, 1997; Evans & English, 2002; McLoyd, 1998). Moreover, children of color are coming of age during a period of equity disparities in a society with heightened intolerance for diversity, increasing the likelihood of exposure to discrimination (Cauce, Cruz, Corona, & Conger, 2011). The combination of racism, classism, and geographic isolation will greatly affect their development.

### Geographic Residence

Research on poverty and child development, with few exceptions (Brody et al., 2005; Burchinal, Vernon-Feagans,

& Cox, 2008; Murry, Berkel, Brody, Miller, & Chen, 2009), has been limited by focusing primarily on urban youth. The need to consider how poverty impacts rural children is of great concern because poverty is becoming less geographically concentrated in inner city neighborhoods (Jargowsky & Yang, 2006; Kingsley & Pettis, 2003). Concentrated poverty in rural America is more extreme than what is observed in urban areas. Population trend data shows that rural children of color are not only more likely to be poor but are also more likely to be living in situations characterized as persistent, “deep poverty.” Rural environments often lack structural resources that are often available to families in urban settings (Proctor & Dalaker, 2003). Consequently, family members of rural children must deal with a restricted range of employment, great distances to businesses and services, limited public transportation, and lack of recreational facilities for children (Murry et al., 2009). In addition, families living in rural environments have fewer educational opportunities than do their urban counterparts (Fan & Chen, 1999; Witherspoon & Ennett, 2011), and most jobs available to rural African Americans are labor intensive and pay low wages (Brody et al., 2005). The strain of such demanding work depletes families’ time and energy resources; this, in turn, can occasion psychological distress that may compromise parenting (Brody & Flor, 1997).

### Changing Faces of Poverty and Rurality

The faces of children in rural poverty are different from their urban counterparts. One stark difference between rural and urban poor children is that rural poor children are more likely to be European American. More than half of all poor rural children are non-Latino/a American European American compared to approximately 25% of poor urban non-Latino/a American European American children (Lichter, Qian, & Crowley, 2005). While poverty has similarly devastating consequences for rural European American children’s development (Ali, McWhirter, & Chronister, 2005; Blum et al., 2000), European American children are seldom included in discussion linking poverty to developmental outcomes in children. Reasons for this omission may be attributed to the fact that terms such as *low-income*, *poverty*, and *rurality* have been, historically, used interchangeably with *race* and *ethnicity*. We include in our systematic review the few available studies on the social stratification and developmental outcomes of European American youth in a later section of our chapter.

While a major proportion of rural children are non-Latino/a American European American, the double

burden of disadvantage is more likely to be experienced by racial/ethnic families residing in rural communities (U.S. Census Bureau, 2005). In the next section, we continue our analysis of relevant theories and models that expand on our previous discussion and summarize extant studies that have examined the contributions individual-contexts on the developmental processes of children of color, those who are poor, and those residing in low-resource rural communities. Our analyses include studies that have considered both proximal and distal relational developmental systems that forecast both normative and nonnormative development of children in diverse context.

### PROTECTIVE NATURE OF CHILDREARING PRACTICES OF PARENTS OF DIVERSE CHILDREN

Whereas enculturation, acculturation, and ethnic socialization are nearly singularly applied to children and families of color, immigrant groups, and cultural minority groups, *all* children experience enculturation. Enculturation is developing competency in an identity with one's culture of origin (Gonzales, Knight, Morgan-Lopez, Saenz, & Sirotli, 2002). It is the normative socialization process through which children become functional members of their society (Farver, Xu, Bhadha, Narang, & Lieber, 2007), the manner through which individuals learn the beliefs and practices of the culture in which they live and become an accepted and contributing member of the cultural group (Arnett, 1995; Gauvin & Parke, 2010). Children are born with the potential to fit into any culture and with the hope of seamlessly fitting into the culture in which they are embedded. In fact, human development itself is, in part, the process of learning and internalizing the ways of being, interacting, and knowing that an individual is represented in one's culture (Gauvin & Parke, 2010)—that is, socialization. Children's learning is driven in large part by a desire to fit into, function within, and feel comfortable within one's cultural setting (Fuller & García Coll, 2010; Lopez, Correa-Chavez, Rogoff, & Gutierrez, 2010). When children are studied only in one cultural context, some culturally embedded aspects of development and family dynamics are assumed to be "natural" or "universal." It is only when human development and family processes are studied in diverse contexts that true culturally embedded aspects emerge (Cole, 1996). Still, universal aspects of child development, including language, communication,

and the primacy of social relations, are the foundations upon which cultural competency and human development are established.

### Balancing Universal and Cultural-Specific Parenting

Parents and other family members are the primary sources of socialization and the filters through which messages of larger culture are affirmed, challenged, and interpreted. The essential goals of parenting include helping children internalize the values and behavioral standards of the family and the broader culture, equipping youth to become product members of a defined society or group, developing emotional well-being and emotional security (Hill, 2009). General tools or dimensions of parenting include behavioral control or demandingness, warmth, and responsiveness (Baumrind, 1971; Maccoby & Martin, 1983). However, the parenting styles that emerged from Baumrind's, as well as Maccoby and Martin's work (e.g., authoritative, authoritarian, and permissive) do not fully generalize beyond families from European American, middle-class backgrounds on which the research was originally based (Brody & Flor, 1998; Chao, 1994; E. Kim, Cain, & McCubbin, 2006; Mason, Walker-Barnes, Tu, Simons, & Martinez-Arrue, 2004). Although parents utilize a constellation of warmth, control, and responsiveness, one's cultural context defines the desired outcomes, standards, or goals that parents wish to develop. The appropriateness of particular parenting strategies, how parenting practices cohere, children's interpretations and reactions to said practices, and the effectiveness of parenting practices all play into a child's cultural context (Hill, 2006, 2009; Okagaki & Divecha, 1993).

Although cultural socialization is universal, it takes on a unique function for racial and ethnic minorities, as well as for immigrant youth and families, because the youth must be socialized into their ethnic or natal culture, into the dominant culture, and into an understanding and resolution of inconsistencies and conflicting viewpoints across cultures (Boykin, 1986; Farver et al., 2007; Knight et al., 2011). While parents struggle in adapting to two cultures themselves, they are also providing their children the skills and messages for functioning within two cultures and a lens through which to synthesize this dichotomy. Families who are straddling two cultures, either through immigration or ethnic minority status, are engaging in two simultaneous and integrated processes. Every child engages in the first process, as every child is a product of at least one culture. The process of gaining competence in a second

culture, however, is known as acculturation. The research on acculturation began in the early 20th century when new waves of immigrants were arriving in the United States and there were significant changes in the immigration laws and policies. As immigration has ebbed and flowed since then, as second and third generations have been born and raised in the United States and as an increasing number of immigrants are phenotypically distinguishable, there has been increased interest in understanding the process of acculturation and the risks and opportunities associated with it. Whereas the study of acculturation processes began in fields like sociology and anthropology, theory and research focused in individual level adjustment, preparation for discrimination, and identity development has been informed by the fields of psychology and area studies (e.g., African diaspora studies, Latino/a studies).

### ***Acculturation***

The concept of *acculturation* was first introduced by Park (1928) to describe the experiences of individuals who were part of the mass migrations of the early 20th century but, because of distinct phenotypic characteristics, could not assimilate. That is, because of skin tone, hair texture, or other characteristics, individuals would continue to be marked as “different” despite learning the language, values, and behaviors of the host culture. Definitions of acculturation have been fairly consistent since its early introduction. In the 1930s, it was defined as “those phenomena which result when groups of individuals having different cultures come into continuous first-hand contact with subsequent changes in the original pattern of either or both cultures” (Redfield, Linton, & Herskovits, 1936, p. 149). Other definitions pertain to individual adjustments and changes that occur when one is immersed in a new culture (Berry, 1990; Cabassa, 2003). Most practically, this refers to learning and taking on the language, behaviors, and values of the new culture while maintaining some behaviors, language, and values of the culture of origin (Berry, 1990). Early conceptualizations represented acculturation as a single continuum, with assumption that greater immersion in and identity with the host culture was concomitant with a loss of one’s original cultural identity. However, empirical data has demonstrated that acculturation and the associated identity development is bidimensional and that orientation to the host or new culture is orthogonal to an orientation to the original culture (Berry, 2003). Bidimensional conceptualizations permitted an examination of bicultural identity development and integrative identities that fuse aspects of both cultures into a single coherent

identity (Berry, 2007; Knight, Jacobson, Gonzales, Roosa, & Saenz, 2008).

Still, even bidimensional conceptualizations miss essential experiences of those adapting to a new culture (de Haan, 2011). Such conceptualization presumes common patterns or processes across individuals as they traverse an assumed common pathway to adjustment to life in the United States (Farver et al., 2007). De Haan, however, describes a concept of *cultural translation* and argues that the process of exposure to a new culture entails transformational changes and synergies that change how both cultural systems are endorsed and expressed within individuals and families. Acculturation reflects a confrontation and translation of cultural spheres that results in changes in both, rather than a more static characterization of greater or lesser endorsement and internalization of existing cultural belief systems. “Translation cannot happen without changing the original meaning” of both cultures (de Haan, 2011, p. 380). Acculturation results in identities that are not just mono- or bicultural, but hybrid in influence and nature.

### ***Acculturation and Enculturation***

Acculturation and enculturation have become a focus of study in psychology and human development because the concepts have been associated with a wide range of developmental outcomes. In studies of bidimensional orientations, both strong American and ethnic identities are associated with better psychological adjustment. Those with bicultural orientations (high on both cultural orientations) reported the best developmental and mental health outcomes (Berry, 2003). Similarly, high ethnic cultural orientation was related to fewer mental health problems and greater family support (Dinh, Castro, Tein, & Kim, 2009). In contrast, youth with high American cultural orientations and low ethnic orientations were lower in religiosity, which was in turn associated with higher mental health problems (Dinh et al., 2009). Likewise, acculturation to the United States was associated with higher levels of conduct problems in part because teens’ acculturation was associated with higher levels of family conflict (Gonzales, Deardorff, Formoso, Barr, & Barrera, 2006).

Studies that conceptualize acculturation level by generational status also demonstrate that acculturating to the United States culture is not wholly healthy (Farver, Bakhtawar, & Narang, 2002). For example, first-generation Asian Indian immigrants have lower levels of depression and anxiety and higher levels of well-being than second generation Asian Indian youth. Relatedly, the second

generation youth report higher levels of conflict and lower self-esteem (Lay & Safdar, 2003). In addition, first generation Latin American youth hold higher aspirations for achievement, perceive fewer barriers to reaching their goals, and achieve at higher levels than their second- and later-generation counterparts (Hill, Ramirez, & Dumka, 2003; Hill & Torres, 2010). Some have attributed the decline in mental health across generation levels to acculturative stress and the difficulties in garnering resources and adjusting to a new culture (Barker, Cook, & Borrego, 2010; Cabassa, 2003). So prevalent are the declines between first and later generation immigrants in achievement, mental health, and behavioral outcomes that the phenomenon has been named the “Immigrant Paradox,” and research has begun to understand how and why acculturating to the United States puts youth at risk (García Coll & Marks, 2011).

Acculturation and enculturation do not happen in isolation or as individual processes, but in family systems; indeed, the level of enculturation and acculturation of family members, especially parents, impacts children’s adjustment (S. Y. Kim, Chen, Li, Huang, & Moon, 2009; Szapocznik & Kurtines, 1993). Because the rate and goals of acculturation vary across family members, discrepancies between parents’ and young peoples’ acculturation levels and family conflict as they relate to adjustment have been ripe areas for study. Between parents and children, it is well established that children acculturate faster and are more accepting of the host culture than are their parents (Phinney, Ong, & Madden, 2000). Whereas immigrant parents may embrace the educational opportunities available to their children in their new culture, they are dismayed by many of the other values and behaviors of American youth (Hill & Torres, 2010). Highly discrepant acculturative orientations between parents and youth are associated with higher depressive symptoms and anxiety levels, along with lower self-esteem, achievement, and achievement motivation among youth (Costigan & Koryzma, 2011; S. Y. Kim et al., 2009; S. Y. Kim, Chen, Wang, Shen, & Orozco-Lapray, 2013).

Some suggest that teens who wish to adopt more American values feel rejected by their parents and stilted in the quest for identity development (Farver, et al., 2002). For their part, parents fear that they are losing their children to a culture that they do not fully understand or embrace and which they may find antagonistic with their own cultural views (Chao & Otsuki-Clutter, 2011; Farver et al., 2002; Hill & Torres, 2010). In a more complex form, parents may find that they endorse some aspects of American

culture (e.g., opportunity structures), but not others (e.g., press for autonomy/independence); they may not fully understand how to provide support for some aspects of the new culture, but not others. This is made more difficult because taking advantage of the opportunity structures in many ways requires a strong sense of autonomy. In support of these premises, family conflict and parenting practices have been found to mediate the relation between acculturation discrepancies and youth outcomes. When parents and youth were similar in their acculturation levels, there are lower levels of family conflict and teens have higher achievement levels, as well as better mental and behavioral health (Farver et al., 2002).

Parents’ acculturation levels and styles, independent of children’s, are also important in determining a family’s cultural outcomes. Comparing families representing four types of acculturation styles, families who were marginalized or separated in their acculturation style had more frequent conflict than families whose parents were integrated or assimilated (Farver et al., 2007). It is possible that integrated and assimilated acculturation styles reflect a resolution on the part of the parents that produces consistency, confidence, and efficacy in their parenting practices (Costigan & Koryzma, 2011). Mothers who maintained a stronger orientation to their culture of origin had daughters who had higher achievement levels (Dumka, Gonzales, Bonds, & Millsap, 2009). In the same study, fathers’ orientation to American culture was associated with higher conduct problems for sons. These authors concluded that school success was a way to honor their parents and propagate a strong cultural value, whereas an American orientation resulted in greater conflict.

### ***Acculturation, Family Processes, and Youth Adjustment***

Much of the research on family dynamics, acculturation, and children’s development has focused on family conflict, perhaps representing the conflicting cultural values and differing rates of acculturation between parents and youth. Other research has focused more centrally on the types of parenting practices that promote healthy adaptation and internalization of host cultures and cultures of origin (S. Y. Kim et al., 2009; S. Y. Kim et al., 2013). Unsupportive parenting has been shown to mediate the association between discrepancies between teens’ and parents’ acculturation levels and teens’ depressive symptoms (S. Y. Kim et al., 2009). Further, the conflict associated with discrepant acculturation levels undermines the warmth and quality of the parent-child relationship and increases alienation between parents and children (S. Y. Kim et al.,

2013). Such warmth was associated with lower levels of parental monitoring of youth (S. Y. Kim et al, 2009). Discrepancies between parents and teens are especially problematic when parents are lower on the host cultural identity as this often results in a power imbalance between parents and teens, especially for families from cultures that are more hierarchical and endorse greater respect for authority. This also impacts parents' ability to become meaningfully involved in their children's education and engage other services for their youth (Leidy, Guerra, & Toro, 2010). These issues are exacerbated among families from lower SES backgrounds (Portes & Rumbaut, 1996) and among families with adolescents, rather than children (Fuligni, 1998).

Because culture, most broadly conceived, is understood to reflect the nature of the context in which one lives, a fuller understanding of acculturation and parenting must include the ways parenting and children's development are impacted by the host cultural values and expectations, the culture of origin, and the more immediate context in which the family lives (e.g., neighborhood, economic, ethnic diversity). It is well established that effective parenting varies across SES (Hoff, Laursen, & Tardif, 2002; Pinderhughes, Dodge, Bates, Pettit, & Zelli, 2000), neighborhood context (Hill & Herman-Stahl, 2002; Leventhal & Brooks-Gunn, 2000), and even by perceptions of threat and opportunity (Gurland & Grolnick, 2005; Johnson, Jaeger, Randolph, Cauce, & Ward, 2003). Indeed, parents tend to be stricter, more controlling, and less interested in autonomy when they reside in neighborhoods that are less safe or lower in economic standing, and when they perceive that the chances of their child reaching their potential is at risk. Further, these parenting practices in these contexts are associated with better developmental outcomes. Interestingly, each of these demographic or contextual factors is experienced at higher levels by ethnic minorities and immigrant families and youth (Hill, 2011; Hill & Torres, 2010). Thus, immigrant and ethnic minority parents must adapt their parenting to effectively achieve their goals for acculturation, enculturation, and safe navigation of the contexts in which they live. In order to understand acculturation and enculturation as they impact parenting and children's development, it is essential to disentangle the influences of immigrant status, ethnic minority status, and economic status from culturally based influences (Chao & Otsuki-Clutter, 2011; Hill, 2006).

Somewhat surprisingly, immigrant parents often are parenting in ways that are dissimilar to both their cultures of origin and their host cultures. For example, Mexican

immigrant and Mexican American parents were found to be *more* authoritarian than their counterparts in Mexico (Varela et al., 2004). Perhaps because of their unfamiliarity with the American cultural context, Mexican immigrant parents increased their monitoring and control, were more consciously involved with their children, and permitted fewer unsupervised activities than did parents in Mexico (Reese, 2002). This greater level of behavioral control is a discontinuation from the parenting practices of their culture of origin, and is a response to characteristics of their community context and the tensions between the two sets of cultural values and beliefs. The heightened behavioral control and divergent parenting practices are more pronounced when families feel disempowered in their new cultural context.

Whereas these stricter parenting practices are often found to be associated with positive developmental outcomes for immigrant and ethnic minority youth (Chao, 1995; Hill, Bush, & Roosa, 2003; Ispa et al., 2004), they are not shown to be effective for youth in the dominant western culture (e.g., United States) (Steinberg, Dornbusch, & Brown, 1991; Steinberg, Lamborn, Dornbusch, & Darling, 1992). Four types of explanations have been posited for these differences in impact based on contextual and cultural variations. First, as already outlined, different contexts require different levels of vigilance and control to assure the safety and healthy development of youth. High risk contexts require greater control and monitoring and the potential costs of making a mistake are high (Hill, 2009). Second, these parenting practices mean different things within their cultural context. For example, parent-child relationship quality may be conveyed through warmth and acceptance by some cultures (e.g., U.S. mainstream culture), whereas it conveyed by "being there" and being of instrument support by other cultures (Chao & Otsuki-Clutter, 2011). Similarly, excessive psychological control is associated with greater manifestations of mental health problems among individualistic, independent cultures, but this is not the case among collectivist or interdependent cultures (Chao & Otsuki-Clutter, 2011). In fact, "no-nonsense" parenting and psychological control have been found to be positively related to perceptions of warmth and parent-child relationship quality among ethnic minorities but not European Americans (Hill, Bush, et al., 2003; Mason et al., 2004). Third, for those who are wholly assimilated into a Western, individualistic cultural context (i.e., middle-class European Americans), high levels of control and monitoring is inconsistent and not normative. Such parenting practices are viewed as out of line with

the types of outcomes the culture seeks to promote and therefore those who engage in such parenting are met with disapproval, resulting in less adaptive outcomes for youth (Ispa et al., 2004). Fourth and relatedly, such parenting is consistent with values that are often associated with collectivist or interdependent cultures, including social cohesion and group harmony. More directive parenting is effective in developing these characteristics.

Even as parents utilize strategies to support their children, these strategies are evolving and parents are gaining experience in using them effectively. These methods increasingly reflect parents' resolution of cultural conflicts between their cultures of origin and the host culture. Among Chinese immigrant parents in Canada, orientations to Chinese and Canadian culture were associated with better psychological adjustment for parents (Costigan & Koryzma, 2011). However, whereas orientation to Chinese culture was directly associated with psychological adjustment, the relation between Canadian orientation and adjustment was mediated by parental self-efficacy. Further, such self-efficacy was related to the use of reasoning, warmth, and monitoring. Parents' self-efficacy and use of more individualistic parenting strategies may be due to increased knowledge about their parenting roles in a Canadian cultural context. Similarly, among Japanese parents living in the United States, there was a positive association between developing an orientation toward American culture and parents' efficacy and perceptions of competence (Bornstein, Chapter 3, this *Handbook*, this volume; Cote & Bornstein, 2003) and attributions for parental successes (Bornstein & Cote, 2003).

Parenting practices, and even efficacy and confidence in utilizing these, are merely the representation of underlying belief systems and parental cognitions. Because cultural values and the processes of acculturation and enculturation are squarely in the domain of cognitions and are abstract, and because we know that cultural worldviews about parenting are implicit (Goodnow, 2002; Hill, 2006, 2009), identifying the processes and trajectories of acculturation requires an examination of implicit belief systems within each culture and the synergies that emerge when parents navigate and resolve them. That is, the field needs a richer understanding of the acculturation of parenting ideologies and cognitions (Bornstein & Cote, 2003; Cote & Bornstein, 2003). Changes in the underlying reasoning and foundation of practices may indeed change their effectiveness (Hill, 2006). Further, efforts to increase our understanding of parenting cognitions increases the likelihood that the meaning of parenting will be understood within the cultural

frame in which they are embedded. Japanese American and European American mothers of infants varied in their knowledge levels of child development and as the Japanese mothers became more acculturated, their knowledge of child development increased (Bornstein & Cote, 2003; Cote & Bornstein, 2003). However, rather than concluding that the acculturated mothers were better parents, Cote and Bornstein were careful to link the variations in knowledge to their cultural frames. They concluded that because mothers in an individualist cultural context are primarily responsible for the health and well-being of their children, are expected to notice milestones and issues in their children's development, and expected to identify and arrange for child care support and specialists as needed, European American mothers are *required* to know more about individual child development than are mothers in collectivist culture, where childrearing is more of a group endeavor. Consistent with this, European American parents were more likely to attribute parenting successes to their own ability (Bornstein & Cote, 2003), making parental self-efficacy and self-confidence increasingly salient for European American parents. However, in following these mothers and their infants for 15 months, while it appeared that Japanese American mothers' acculturation level at Time 1 was positively related to attributions of parental successes to one's ability and knowledge about parenting and child development, these results were driven by changes in socioeconomic status. In contrast, these mothers' orientation to Japanese culture was associated with greater satisfaction with parenting. The authors concluded that the fact that parenting beliefs are resistant to change suggests that acculturation is not inevitable when families immigrate but it is an active process and decision. Some of the external markers of acculturation may be adapted, such as celebrating the holidays of the host country, but deeper values and practices are maintained (Farver et al., 2007). When cross-cultural tensions and conflicts cannot be resolved, immigrant parents may exercise parenting practices that they do not feel are ideal or wholly in line with their ideology, but seem to be effective within their new cultural context.

In addition to adopting ideologies and practices of the host culture and maintaining a form of the practices of one's culture of origin, new, qualitatively different beliefs and practices can emerge in the context of acculturation (de Haan, 2011). These beliefs and practices are often in response to challenges to known ways of parenting (Farver et al., 2007), but allow parents to function across cultural contexts. The increased monitoring that is often exhibited

by immigrant parents may be a means of maintaining closeness, providing guidance, and providing a “bridging” function across the two cultures (de Haan, 2011) rather than being due to the challenges of residing in an unsafe neighborhood. This bridging function is not characteristic of either cultural orientation. Exhibiting a stronger endorsement of the beliefs and cultural practices than one might exhibit in their natal country is another adaptation. In one study, Asian Indian immigrants were found to be “more Indian” in the United States than in India (Dasgupta, 1998), likely a protective mechanism to assure that the culture is not lost.

Whereas most immigrants arrive with hopes and dreams of a better future for themselves and their children and have a desire to embrace the advantages and opportunities of a new culture and land (e.g., U.S. culture for immigrants and ethnic minorities), there are significant advantages in maintaining a strong orientation to one’s culture of origin, especially when one cannot fully assimilate because of phenotypic characteristics. Strong ethnic identity has been associated with higher achievement levels (Hughes et al., 2006; Spencer, Cross, Harpalani, & Goss, 2003; Spencer & Harpalani, 2008) and shown to weaken or buffer the negative impact of experiencing discrimination (Brody et al., 2006). Among second-generation immigrants, an orientation to one’s culture of origin was related to greater life satisfaction, whereas an orientation to U.S. culture was not related to well-being (Abad & Sheldon, 2008). The decrease in adjustment between first- and second-generation immigrants has been attributed to weakened ties to the culture of origin, as well as a lack of psychosocial character strengths and practical access to social support networks within the ethnic community (Schwartz & Montgomery, 2002). This may be due, in part, to the increase of social cohesion that is associated with stronger ethnic orientations (Fuller & García Coll, 2010). Endorsement of ethnic cultural values may be a resilience factor for immigrants because it sustains cultural norms of behavior that may be more in line with parents’ expectations (due to their often lower acculturation levels) (Gonzales et al., 2006).

### Summary

Because immigrant and ethnic minority families are raising children within cultural contexts that differ from their ethnic culture, they are the primary sources of ethnic enculturation. Indeed, their parenting beliefs and practices are associated with children’s and adolescents’ ethnic identity

and level of ethnic enculturation. For example, parental autonomy support is positively related to ethnic immersion (Abad & Sheldon, 2008). However, parents’ efforts in increasing ethnic pride is more effective when parents are highly involved, when the families reside in neighborhoods characterized as low risk, and when they exercise low levels of harsh parenting (Chao & Otsuki-Clutter, 2011). Even as immigrant parents are attempting to raise their children to reach the goals and dreams they have for them, acculturation affects the dreams and outcomes themselves. As parents prepare their children to succeed academically, emotionally, and economically, many come to realize that they must compromise and diminish their own desires for some characteristics, such as respecting authority figures, and accept characteristics that are indicative of American cultural norms, including individualism, self-expression, and assertiveness (Dumka et al., 2009), in hopes of attaining their real goal of a better life for their children. Parental influence and goals, as well as outcomes in children, are further complicated when each parent comes from different cultural or ethnic backgrounds. In the next section, we focus on multiracial children whose diverse context includes parents from different ethnic backgrounds.

### PARENTING MULTIRACIAL-ETHNIC CHILDREN

The number of interracial marriages has dramatically increased over the past five decades (Bracey, Bámaca, & Umaña-Taylor, 2004). The Supreme Court’s repeal of laws barring interracial marriages in *Loving v. Virginia* was a catalyst for changing the racial demographics of America (Brunsma, 2005; Fusco, Rauktis, McCrae, Cunningham, & Bradley-King, 2010). This legal victory, coupled with progressive social acceptance, led to a “biracial baby boom” (Root, 1992). The number of biracial children rose from 1 in 100 children during the 1970s to 1 in 19 in 1999 (Herman, 2004). When the 2000 census was revised to allow respondents to check off more than one racial category, 2% of the population described themselves as multiracial (Bracey et al., 2004; Brunsma, 2005; Gullickson & Morning, 2011). By 2050, it is expected that 20% of Americans will identify as multiracial (Lee & Bean, 2004). However, some estimates suggest that 20% is a conservative number and that anywhere from 30% to 70% of African Americans are multiracial and almost all Latino/as, Filipino/as, American Indians, and Native Hawaiians have mixed ancestry (Root, 1992). Growing—and perhaps already dominating—in numbers

and visibility, mixed-race individuals are slowly changing the racial “face” of this country (Root, 1992).

Although the term *multiracial* is used in many different ways, we define it as characterizing an individual who identifies “with two or more racial heritages that are based on socially constructed criteria” (Lou, Lalonde, & Wilson, 2011, p. 80). In a society that has historically acknowledged only monoracial classifications, multiracial children and adolescents develop and understand their own identities often in conflict with prevailing notions of ethnic and racial identity. In the following sections, we examine the history of racial assignment in America and how it impacts multi- and monoracial children’s racial identity and identification.

Throughout the history of the United States, racial assignment of mixed-race people has primarily taken place in two ways. First and more widely known, the practice of hypodescent assignment—colloquially referred to as the “one-drop rule”—assigns biracial individuals to the lower-status racial group of their two parents (Gullickson & Morning, 2011; Nakashima, 1992). From the slavery era to the time of Jim Crow laws in the Southern states, the one-drop rule was used to determine who was African American and who not (Gullickson & Morning, 2011) was. It was also used during World War II when individuals who were as little as one-sixteenth Japanese were put into U.S. internment camps (Nakashima, 1992). While it is still hotly debated, there is some evidence that the one-drop rule still affects modern society (Gullickson & Morning, 2011). The United States resident Barack Obama is often cited as evidence. While he is biracial (i.e., African American father and European American mother), he is frequently referred to as the first African American president (Gullickson & Morning, 2011). The second, lesser-known practice of hyperdescent assignment is historically rooted in classifying individuals of European and American Indian ancestry as only White. Underlying this practice was the belief that the American Indian heritage could be fully assimilated into the wider European American group (Gullickson & Morning, 2011).

These two policies reveal American tendencies to perpetuate racial oppression by viewing complex relationships in an overly simplistic Black–White dichotomy (Root, 1992). In fact, most of the research on multiracial individuals looks only at those with mixed minority and European American ancestries, not considering two or more mixed minority ancestries. This partly reflects the reality that monoracial assignment of biracial children who are part White has a much to do with the assignment

of power and social capital as it does about the blending of cultural backgrounds into a coherent multiethnic identity. As a consequence of the rigid Black–White lines, mixed-race individuals can experience rejection by both minority and White groups (Root, 1992). Minorities who have been oppressed in turn apply rigid rules to determine who can claim legitimate membership within their racial community (Root, 1992). More research needs to be done on multiracial individuals with two minority ancestries and the effect it has on their group membership (Lou et al., 2011). In sum, the past policies of hypodescent and hyperdescent classifications still have ripple effects on the racial assignment of multiracial individuals today.

### Racial Identity

Most of the extant research on racial identity focuses on samples of multiracial adults (Brunsma, 2005). Only in the past decade has there emerged a field of study involving multiracial adolescents (Brunsma, 2005). However, there are few studies on younger multiracial children (Brunsma, 2005). The paucity of studies focusing on the earlier years is largely because the issue of having multiple identities often becomes salient only in adolescence. Based on the existing literature, we first focus on models of multiracial identity and then examine the development of racial identity in multiracial children and adolescents.

Models on multiracial identity have evolved over the past five decades. From the 1960s to the 1980s, they moved from developing a positive non-White racial identity to combining all the individual’s ethnic memberships into one. Finally, in the 1990s, models began to recognize that multiracial individuals can have fluid identities that change salience based on context (Brunsma, 2005; Doyle & Kao, 2007; Root, 1992). The introduction of fluid identities has changed the research discourse, and evidence has emerged indicating that racial identity is influenced by four major factors. First, social class is a crucial variable in racial identity. Multiracial individuals of a higher social class are less likely to identify with their lower-status minority identity (Brunsma, 2005). Second, the racial composition of social networks matters in identity development (Brunsma, 2005). Multiracial individuals living within a largely minority context are more likely to identify with their minority status. In contrast, multiracial individuals with “Whiter” social networks have more flexibility to identify as multiracial or White (Brunsma, 2005). Third, family structure also affects this process. Although there is some debate on this, there is evidence to suggest that

young multiracial women more often identify with their mother's racial identity than with their father's (Brunsma, 2005). Finally, phenotype and appearance matter. Identity is shaped by how family and friends perceive a multiracial individual's skin tone (Brusma, 2005).

In developing fluid identities across childhood and adolescence and understanding the role of context, a three-stage model has been proposed (Jacobs, 1992). In Stage I, biracial children experiment with different racial identities because they do not yet understand the constancy of skin color (i.e., her or his color will not change) and its associated categories (Jacobs, 1992). Stage II occurs when the biracial child internalizes the constancy of skin color—that is, the fact that this color will not change. Last, Stage III describes the increase in the child's understanding that her or his racial group memberships are determined by parentage and not skin color (Jacobs, 1992). As multiracial children progress through these stages, they gradually grow to understand the advantages, disadvantages, status, and opportunities of each racial group (Herman, 2004).

Similar to other adolescents their age, multiracial adolescents become increasingly aware of their self-identities and their desire for peer acceptance (Herman, 2004). Social interactions are major contributors to identity development (Herman, 2004). Unlike their monoracial peers, multiracial adolescents' racial identity development is more complex. When a multiracial adolescent identifies with a particular ethnic group, his or her affiliation is based on the four aforementioned factors: class, social networks, family structure, and skin tone. As racial identity develops, it has a profound impact on self-identity. Race then becomes a key filter to view and understand oneself and one's experiences (Herman, 2004).

## Summary

Multiracial individuals can sometimes choose to be part of only one racial group or multiple groups, depending on the group's acceptance and context (Brittian, Umaña-Taylor, & Derlan, 2012; Herman, 2004). This choice is often determined by self-acknowledgment of the multiracial youth regarding their biology and membership prospects within and among socially constructed racial groupings (Herman, 2004). For instance, many Native American tribes require mixed-race individuals to demonstrate blood quantum in order to be officially admitted and receive special privileges and access to tribal lands (Doyle & Kao, 2007). Further, the identity of mixed-race individuals with African American ancestry is less fluid once it has been

vetted and agreed upon; those individuals are more likely to be subjected to hypodescent assignment and are more often identified only as Black. In fact, both mixed-race Native Americans and mixed-race African Americans have less choice over their racial identifications than members of other racial/ethnic groups (Herman, 2004). For example, parents of mixed Asian and European American children have more options in determining how they racially identify their children (Xie & Goyette, 1997). While Asian-European American parents may have more options, their choice is still dependent on contextual factors like the Asian parent's gender, degree of assimilation, and awareness of her or his ethnic heritage (Qian, 2004; Xie & Goyette, 1997). Although a child's racial identity is largely affiliated with the parents' race, society's imposed categorization of racial membership can affect how a multiracial individual classifies herself or himself. This was especially apparent during the completion of the 2000 Census, the first census to allow Americans to identify with more than one race. Research has yet to be done that identifies and examines the motivations that undergird individual's use of single and multiracial categorizations. This is especially important because the vast majority of Americans are of mixed ancestry in generations past. As multiracial identities become more common and accepted and the political and power differentials across racial categories shift, changes in the fluidity and salience of multiple identities will be important to track and understand. The process of identity, development and adjustment can be even more complicated when children raised outside of their country of origin, commonly referred to as "third culture kids." An overview of relevant studies that have explored these subgroups of children and families is presented in the following section.

## THIRD CULTURE KIDS

The number of children raised outside their country of birth is steadily increasing in our globalized world. In 2012, there were an estimated 6.32 million Americans (not including those affiliated with the U.S. government) living abroad (Association of Americans Resident Overseas, 2012). Similarly, there were approximately 5.5 million British citizens living overseas, almost 1 in 10 of the U.K. population at that time (Institute for Public Policy Research, 2006). Many of these people are parents raising children in foreign settings. The experiences of these children—often referred to as "Third Culture Kids

(TCK)”—growing up abroad will be the focus of this section. Although the prevalence of this is increasing and there is increasing awareness of their unique challenges, there empirical research on their development and trajectories is sparse (Goodnow & Lawrence, Chapter 19, this *Handbook*, this volume). Based on this limited but important body of research, we examine the TCK experience in three ways. First, we begin by defining what it means to be a TCK. Second, we examine the impact of being raised abroad on TCKs’ cultural identities. Last, we analyze the psychological impact of repatriation to the parent’s home country on TCKs.

Useem first coined the term “Third Culture Kids” (TCK) to describe the shared experiences of American children living abroad (Useem & Downie, 1976). This term was defined by Pollock and Van Reken’s (2001) book, *Third Culture Kids*. Their widely cited and accepted definition of a TCK describes a person who has spent a significant part of her or his developmental years outside the parents’ culture. The TCK frequently builds relationships in all of the cultures while not having full ownership of any. Although elements from each culture are assimilated into the TCK’s life experience, the sense of belonging is found in relationships with others of similar background (Pollock & Van Reken, 2001, p. 19).

Instead of taking full ownership of one culture, TCKs incorporate parts of three surrounding cultures: (1) their parents’ culture of origin, (2) the host culture of the nation in which they now live, and (3) the culture shared by an ever-changing community of expatriates who have access to international schools (Peterson & Plamondon, 2009). TCKs most often come from one of four contexts based on their parents’ occupations (Bonebright, 2010; Davis et al., 2010; Hervey, 2009): (1) children of the military, (2) children of diplomats, (3) children of business expatriates, and (4) children of missionaries. The experiences of growing up as “military brats” and, to a lesser extent, missionary kids are relatively well studied. However, there is a paucity of research on the experiences of their more privileged peers whose parents are in diplomacy and business. These children often go to the best international schools, live in exclusive and expensive expatriate areas, and are relatively affluent compared to their other TCK peers. Research examining all four TCK subgroups together is extremely sparse (Peterson & Plamondon, 2009).

In addition to the four groups, another way to slice the TCK experience that is rarely discussed in the research and popular literature is by nationality. Most of the books and journal articles discuss the TCK experience from

a predominantly American-centric perspective. In other words, we know a lot more about American TCKs than we do about their non-American counterparts who frequently attend the same international schools and matriculate to the same U.S. colleges. These non-American TCKs often look and sound like Americans although they are raised abroad. We know very little about their experiences: Do they display a greater cultural distance in their relationships with their parents, who may have limited experiences with American society and culture? Raised and educated with an American worldview in their international schools, do these students face challenges in assimilating back into their parents’ home country? How does their diverse upbringing affect their national and/or cultural affiliations? These are questions for future research studies.

As the range of these subgroups suggest, the TCK population encompasses a very diverse group of children. Still, while these children have diverse backgrounds, their common experience of being raised in a foreign setting brings them together. Many TCKs take on this label because it gives them a sense of belonging to a peer group and a way to find meaning in their multicultural identities.

### Cultural Identity

Researchers have found that the greatest challenge for TCKs is forming their cultural identities, due to their mobile childhoods (Fail, Thompson, & Walker, 2004; Pollock & Van Reken, 2001; Walters & Auton-Cuff, 2009). Cultural identity is formed when an individual takes on worldview beliefs and engages in actions that unite people within a cultural community (Jensen, 2003; Shweder et al., 1998). Among other ideals, a worldview provides guidance and answers to the essential questions of existence, purpose, and meaning in relation to others in society (Jensen, 2003). The process of achieving a stable cultural identity requires an adolescent to make choices about membership in a cultural community. These decisions become complex for TCKs who have lived in multiple cultures throughout their childhoods. They often feel culturally rootless and do not feel wholly connected to any one culture (Walters & Auton-Cuff, 2009). When asked, many TCKs state either that they belong to many cultures or that they belong to no culture at all (Fail et al., 2004). Like others who struggle with their identity, they are often drawn to others with similar backgrounds. Their cultural identity eventually becomes rooted in a community of fellow TCKs who share their cultural ambiguity. While researchers often

observe this TCK huddle (i.e., Pollock & Van Reken 2001; Walters & Auton-Cuff, 2009), we still know little empirically about its prevalence among TCKs and its impact on their well-being in adolescence and beyond. This leaves many questions open for the future. Do all TCKs struggle with cultural identity formation? What are some risk and resilience factors that buffer their transition to adolescence and adulthood? Do they all follow a common path of identity development? What roles do parents and peers play in their cultural identity formation and their transition back to their home culture?

### Repatriation

One of the major triggers of cultural identity crisis is when a child or an adolescent permanently returns to his or her passport country after spending time abroad. Repatriation is inevitable for an American TCK. The child leaves when the parent's work assignment is completed or after turning 18. For non-American TCKs, the repatriation may take place after they finish college in the United States or the United Kingdom. However, their repatriation is less inevitable because, if they are able to get a visa to stay, many choose not to return to their passport country. The repatriation of TCKs, however, is significant because it distinguishes the TCK experience from that of refugee or immigrant children as major international moves occur without the intent to immigrate. Next, we examine the psychological impact of repatriation and the effects of varying reentry ages on TCKs.

According to Sussman (2000), repatriation is often more stressful than the initial move abroad. It is suggested that this may be attributable to the different cognitive processes involved in a permanent move as opposed to a temporary cultural adaption of a new country (Sussman, 2000). However, we know very little about the effect of repatriation on TCKs. The few studies that are available examine the process of repatriation on adults sent abroad by their employers. Upon return to the home country, a repatriated adult may find his or her worldview changed by the experience abroad. This new worldview no longer matches the prevailing cultural norms of the home country and it may lead to high levels of psychological distress (Sussman, 2000). In contrast, some TCKs may never feel the effect of this worldview gap because they left their home countries before becoming old enough to recognize these cultural norms. Their distress comes not from the mismatch of the old and new but from having a new permanent worldview imposed on them as they hit adulthood.

For them, it is a new worldview, but without a comparable perspective or framework to anchor their experiences.

TCKs who return to their native country before adolescence tend to have fewer problems with reacclimation (Huff, 2001). Those who return during adolescence—predominantly for higher education—are surprised when they experience “reverse culture shock” (Bonebright, 2010; Fail et al., 2004; Hervey, 2009; Huff, 2001). Many feel “different” from their peers, which can lead to social marginalization. While abroad, a TCK has friends with similar international outlooks, lives a comparatively privileged lifestyle, and may look distinct from locals. Unlike traditional immigrants, their different look, style of dressing, and mannerisms confer privilege and draw interest rather than marginalization. In his or her own country, a TCK's new friends may have never been abroad. The loss of a supportive TCK community and special foreign status can be difficult. It is challenging because adolescence is a period when peer acceptance becomes especially salient and TCKs are no exception.

TCKs who repatriate for college may feel they have to put their foreign experiences aside in order to fit in with their peers (Walters & Auton-Cuff, 2009). This often leads to feelings of grief, loss, and loneliness in a place that should be “home” (Bonebright, 2010). Such feelings can and usually do ease over time with the help of supportive parents and fellow TCKs (Huff, 2001). However, there are few studies on what this personal support should look like in practice. There are also no empirical studies evaluating the effectiveness of pre- and post-repatriation seminars run by organizations seeking to ease the transition. Eventually, if and when TCKs are able to balance the international and passport country's worldviews successfully, their multicultural backgrounds can become assets in their friendships and careers.

### Summary

To summarize, the number of TCKs will inevitably increase as our world becomes more connected. As the research literature on TCKs is an emerging field, it is an area that is open for many more studies to be done. Many of the existing theories and descriptions on the TCK community come from nonscientific and anecdotally based books, articles, and websites that do not meet the empirical and theoretical rigor of a peer-reviewed journal. New directions in this field include conducting comprehensive studies on the four TCK populations, comparing the experiences of American and non-American TCKs, investigating the

factors that affect TCK's cultural identity development, and understanding parents' roles in supporting the TCK experience. Similar to the parenting issues and challenges associated with identity development among bi- and multiracial and Third Culture Kids are the experiences of youth who are raised by parents who do not share their racial or ethnic background. Transracial adoption and parenting have become increasingly important to understand, as the number of children growing up in this family context continues to increase in the United States (Jacobson, Nielsen, & Hardeman, 2012).

## TRANSRACIAL ADOPTION AND PARENTING

Rises in humanitarian efforts to care for international war orphans as well in the infertility rates of U.S. couples, along with a decrease in the availability of European American babies for adoption, has led to a dramatic increase in transracial adoptions of international and domestic children by American parents (Jacobson et al., 2012). Using data from the National Survey of Adoptive Parents, Jacobson et al. (2012) finds that 39% of adoptees have a parent from a different racial or ethnic group. While this number is quite large, it is important to note that 85% of transracial adoptions are of American parents adopting international—predominantly from Asia, Africa, Eastern Europe, Latin America, and Africa—and not domestic children (Zhang & Lee, 2011). While prospective parents adopt from abroad, the number of domestic adoptees waiting for families has increased from 20,000 in 1990 to 130,000 in 2007 (Zhang & Lee, 2011). Minority children—particularly African Americans—are largely overrepresented in this group of infants and children deemed hard-to-place (Farr & Patterson, 2009).

Transracial adoption occurs when a parent—typically of European American descent—forms his or her family with a child who is from a different racial or ethnic group (Vonk & Angaran, 2001). Transracial adoptees include children born domestically within the United States and children born abroad. Although transracial adoption in theory encompasses any family who raises a child from a different background, it is largely used in practice to describe minority children raised by European American parents. To understand why this is a phenomenon largely focused on European American parents, it is important to situate it within its historical context within the United States. Then, we analyze the effect of transracial adoption on adoptees in a range of outcomes: racial identity

development, psychosocial adjustment, and self-esteem. We conclude by examining the existing policies and programs in place to develop cultural competencies in transracial families.

### Brief Overview of Historical Patterns of Transracial Adoption

Transracial adoption has historically been a controversial issue in the United States. Patterns of transracial adoptions began to emerge after a series of wars—World War II, the Korean War, and the Vietnam War—which left behind many international orphans needing families (Jacobson et al., 2012). Beginning in the 1960s, however, two factors led to higher rates of domestic transracial adoption. First, the number of European American infants available for adoption decreased due to the acceptance of abortion, birth control, and single parenthood (Perry, 2011). Second, the civil rights movement led to greater tolerance for race mixing within marriages and families (Perry, 2011). Together, these two factors led to a rise in the number of European American parents adopting African American children: a total of 12,000 placements were made between 1960 and 1976 (Brodzinsky & Pinderhughes, 2002; Jacobson et al., 2012; Perry, 2011).

As the trend grew, this pairing of European American parents with ethnic minority children became a contentious issue. African American and Native American communities were concerned that these transracially adopted children would grow up with negative racial attitudes and identities, leading them to greater risk for psychological problems (Brodzinsky & Pinderhughes, 2002). Their voices culminated in 1972 when the National Association of Black Social Workers (NABSW) denounced the transracial adoption of African American children as a form of “cultural genocide” (Perry, 2011). They argued that European American parents were unable to equip African American children with a positive Black identity to cope with racism in our society (Jacobson et al., 2012; Perry, 2011). As a result, many child welfare organizations—including the Child Welfare League of America—sought to minimize the number of transracial adoptions, and the numbers fell from about 2,500 in 1971 to 830 in 1975 (Fenster, 2002; Perry, 2011).

In the 1980s, the NABSW's position was challenged by research revealing that African American transracial adoptees did not suffer from permanent psychological harm (Feigelman & Silverman, 1984; Perry, 2011). Additionally, the increasing number of minority children in the

welfare system and the relative lack of available minority foster or adoptive parents led agencies to allow more transracial matching (Farr & Patterson, 2009). Soon after, the Multiethnic Placement Act of 1994 became law. It prohibited federally funded agencies from delaying foster and adoption placements on the basis of race (Farr & Patterson, 2009; Perry, 2011). While transracial adoptions remain controversial, they are now more widely accepted by the public (Farr & Patterson, 2009).

### **Developmental Outcomes and Adjustment of Transracial Adoptees**

The most significant issue surrounding transracial adoption centers on how differing ethnic contexts affect adoptees' developmental outcomes. To evaluate short- and long-term effects of adoptions by parents of a different ethnicity, studies commonly look at the adoptees' racial identity development, psychosocial adjustment, and self-esteem. These three outcomes are extensively researched due to concerns over nonminority parents' ability to raise minority children and prepare them for experiences in a racialized society.

#### ***Racial Identity***

There is a strong consensus that African American parents play a significant role in nurturing their children's positive ethnic identities (Butler-Sweet, 2011). A positive ethnic identity is important because it helps to protect African American children from racism (Butler-Sweet, 2011). It is argued that European American parents cannot provide this type of socialization because they have not experienced what it is like to be a member of a minority group. To address these fears, research since the 1980s has focused on the racial identity and mental health outcomes of these adoptees.

The results from numerous studies on transracial adoptees have produced mixed results. There is some evidence that suggests lower racial identity outcomes for transracial adoptees. Butler-Sweet's (2011) review on racial identity finds evidence that compared to in-race adoptees, transracial adoptees have lower scores on racial identity measures (Padilla, Vargas, & Chavez, 2010). Similarly, a case review on Korean transracial adoptees shows that most of them preferred to identify as "American" as opposed to an ethnic-specific description (W. Kim, 1995). Investigating even further, Bergquist, Campbell, and Unrau (2003) follow adoptive families over 7 years, finding that Korean children of European Americans identify more as European American over time. It exemplifies the

transracial adoption paradox: Although they are visible racial minorities, they are perceived by their families and even by themselves as members of their parents' European American culture (Shiao & Tuan, 2008). However, among people unfamiliar with their familial and adoptive backgrounds, they are perceived and treated as racial minorities. Their lack of a minority racial identity may make them unprepared to face and resist racist encounters.

On the other side, four major longitudinal studies find no significant differences in racial identity development after following transracial and same-racial adoptees for at least 12 years (Bagley, 1993; Brooks & Barth, 1999; Feigelman, 2000; Vroegh, 1997). The samples are diverse, comprised of children, adolescents, and adults from a variety of backgrounds: Afro-Caribbean, African American, Asian American, European American, Latin American, and mixed-race (Bagley, 1993; Brooks & Barth, 1999; Feigelman, 2000; Vroegh, 1997). All four studies agree that when compared with same-racial adoptees (children that are adopted by parent of their race), transracial adoptees have similar outcomes on racial identity and cultural identity measures (Bagley, 1993; Feigelman, 2000). Furthermore, they predominantly continue to identify as minorities from childhood to early adulthood (Vroegh, 1997). Brooks and Barth (1999) assess adoptees on their feelings (i.e., discomfort, pride, and embarrassment) concerning their ethnoracial appearance or birth group. They report no significant differences in the responses of transracially and same-racially adopted adults. Adoptees in their sample are mostly classified as having "secure" (65%) or "strong" (35%) racial identities (Brooks & Barth, 1999).

Given evidence suggesting both problematic and neutral impacts together, we find that the body of research on racial identity development in transracial adoptees is inconclusive. To determine how to support the healthy identity development of transracially adopted youth, two contextual factors have been identified. First, there is evidence suggesting that European American parents who decide to live in more diverse communities tend to have transracial children who experience less discomfort about the incongruence of their appearance and that of their immediate family members (Feigelman, 2000). More research should be conducted on the impact of a family's residential context choice on adoptees' racial identity outcomes. Second, researchers have observed that a majority of African American adoptees are biracial (Vroegh, 1997). These adoptees tend to have lighter complexions (Vroegh, 1997). As a result, they may find it harder to find acceptance in both Black and White communities (Russell,

Wilson, & Hall, 1992; Vroegh, 1997). Additional work needs to parse out these ethnic distinctions for connections to biracial identity formation.

### ***Psychosocial Adjustment***

In addition to considering parent-child relationships in transracial adoptions, psychosocial adjustment of transracial adoptees later in life is of significant interest. If European American parents are unable to instill a strong minority identity, do these children fare worse than their same-racially adopted peers or nonadopted siblings? Numerous studies converge on the consensus that transracial adoption is not detrimental to the psychosocial and developmental needs of adoptees from the time of adoption to adulthood (Bagley, 1993; Weinberg, Waldman, van Dulmen, & Scarr, 2004). Transracial and same-racial adoptees have similar reported levels of adjustment outcomes (Brooks & Barth, 1999; Feigelman, 2000).

Several researchers report that differences in developmental outcomes (i.e., behavioral problems and learning difficulties) only emerge when adoptees are compared to their nonadopted siblings (Sharma, McGue, & Benson, 1998; Weinberg et al., 2004; Whitten & Weaver, 2010). Some categories of adoptees are at greater risk. Male adoptees exhibit more maladjustment than female adoptees (Brooks & Barth, 1999), and domestic adoptees more than international adoptees (W. Kim, 1995; Whitten & Weaver, 2010). Although these differences in adjustment exist, they are small and should not be overinterpreted (Weinberg et al., 2004; Whitten & Weaver, 2010). Vroegh (1997) points to individual factors as an explanation for adolescent psychosocial adjustment outcomes. One such factor is the age at which a child is placed in a family; those placed in families at younger ages generally show better long-term adjustment outcomes (Weinberg et al., 2004). These findings suggest that while transracial adoptees do not seem to differ from same-racial adoptees on psychosocial adjustment outcomes, there are small within-group differences that must be considered. Many of the studies on adoptees' psychosocial adjustment are based on parents' reports. There is a possibility that parents can overestimate or underestimate their adoptees' behavioral problems to researchers (Weinberg et al., 2004). Future research should attempt to collect reports and assessments directly from adoptees.

### ***Self-Esteem***

Transracial adoptees may feel negatively about their birth parents' relinquishment and about physical dissimilarities

with their adoptive parents (Juffer & van IJzendoorn, 2007). While these negative feelings might lead to a range of mental health issues, self-esteem is often the most salient indicator. Two decades of evidence reveals that transracial and same-racial adoptees do not differ significantly in self-esteem (Alexander & Curtis, 1996; Bagley, 1993; Juffer & van IJzendoorn, 2007; Vroegh, 1997). While adoptees overall do exhibit higher self-esteem than their institutionalized peers, a meta-analysis by Juffer and van IJzendoorn (2007) casts doubt on several other presumed causes of low self-esteem. Contrary to popular belief, a child adopted before his or her first birthday is just as likely to have low self-esteem as one adopted later (Juffer & van IJzendoorn, 2007). Similar levels of self-esteem are recorded between adolescent and nonadolescent adoptees, and between international and domestic adoptees (Juffer & van IJzendoorn, 2007). In sum, there is some empirical support that suggests that adoptees—regardless of age of placement, country of birth, and race—are able to develop normative levels of self-esteem (Juffer & van IJzendoorn, 2007). Future work can focus on identifying protective factors, such as racial-ethnic socialization, in the adoptive family context that encourage resilient self-esteem outcomes in adoptees (Juffer & van IJzendoorn, 2007).

### **Transracial Parental Socialization and Cultural Competencies**

Complementing the debate on racial identity development, there is now an emerging field of research that focuses on developing adoptive parents' cultural competencies to help them raise minority children. There are federal laws governing adoption that apply differently based on the child's origin (Evan B. Donaldson Adoption Institute, 2008). The three adoption categories are foreign-born children, Native American children, and foster care children (Evan B. Donaldson Adoption Institute, 2008).

Due to international and federal laws, parents interested in adopting internationally are required to receive appropriate training and counseling related to the adopted child's ethnic and national background (Evan B. Donaldson Adoption Institute, 2008). Similarly, Native American children receive special protection from the Indian Child Welfare Act of 1979 that ensures that their cultural background is preserved. This law was instituted as a response to the removal of Indian children from reservations to institutions or non-Indian homes (Evan B. Donaldson Adoption Institute, 2008). It actively seeks to keep Native American

children with families of the same ethnic heritage (Evan B. Donaldson Adoption Institute, 2008). All other U.S. children in the foster care system are subject to the Multiethnic Placement Act of 1994, which prohibits delaying or denying an adoptive placement on the basis of race (Evan B. Donaldson Adoption Institute, 2008). Parents who adopt these children are not required to be familiar with the child's racial, cultural, or ethnic needs.

As a result of this legislative disparity, children in the U.S. foster system are the least protected among the three groups. This means that among all adopted children African American and Latino/a American children are the only ones for whom laws have not been enacted to ensure that adoptive parents are prepared to support these children's ethnic, cultural and racial identity development. By some estimates, half of private and public adoption agencies have tried to resolve this inconsistent regard for these children's race or ethnicity by providing cultural competence training for parents (Evan B. Donaldson Adoption Institute, 2008; Vonk & Angaran, 2003). This suggests that in the best of circumstances, only half of all parents who adopt transracially are prepared for the challenges related to race and culture (Vonc & Angaran, 2003). Even more discouragingly, many of these trainings are offered to all prospective adoptive parents and are not exclusively tailored to the needs of transracial adoption (Vonc & Angaran, 2003).

Cultural competency training usually occurs preadoption and covers three key areas of transracial adoption—(1) racial awareness: developing the parent's sensitivity to racism and discrimination and examining personal stereotypes and prejudices; (2) multicultural planning: highlighting the importance of facilitating opportunities for their transracially adopted children to engage with their birth culture and community; and (3) survival skills: equipping parents to prepare their adoptive children for racism and discrimination (Bergquist et al., 2003; Vonk & Angaran, 2001; Vonk & Angaran, 2003). Taken together, these three core competencies are crucial in successfully nurturing minority children.

While the curriculum has generally been lauded, a valid criticism of the cultural competency training and support is that it stops upon adoption. According to Vonk and Angaran (2003), few public adoption agencies and less than a third of private agencies offer postplacement training. This is highly illogical since issues relating to the child's racial identity and socialization only concretely emerge after adoption and become most salient in late childhood and adolescence (Evan B. Donaldson Adoption

Institute, 2008). Parents play a pivotal role in how well their children thrive and more research needs to be done on how to better support transracial adoptions over time. There are also few studies evaluating the content and impact of the cultural competence training (Vonc & Angaran, 2003). Program evaluations would be helpful in identifying effective programs and comparing the quality of instruction between private and public adoption agencies (Vonc & Angaran, 2003).

## Summary

Our review of the literature on transracial adoption suggests that even though transracial adoptions may have positive outcomes, the unique challenges that these parents and children face are complicated (Brodzinsky & Pinderhughes, 2002). Despite these difficulties, many transracial adoptees seem to do just as well as their same-racial peers on measures of racial identity, psychosocial adjustment, and self-esteem. They seem to do especially well when their parents are sensitive and proactive about their racial and cultural needs. More research needs to be done on how best to develop, support, and sustain cultural competencies in transracial families, along with policy interventions to ensure that adoptive parents are adequately prepared to support their children. Of course, families are only one context that influences the healthy development of ethnic, racial and more general identity development. Other contexts, such as schools and peers, play equally important roles.

## SOCIAL POSITION, SOCIAL STRATIFICATION, SCHOOL CONTEXT, AND ACADEMIC OUTCOMES

Given that children spend more of their waking hours at school than anywhere else, the school environment is considered of primary importance to child development (Eccles & Roeser, 2003). Racial and ethnic categories and associated meanings attributed by systems at multiple levels influence how children define and understand themselves as they mature into adulthood. Particularly influential is how one's own racial and ethnic backgrounds fit into social contexts, such as the school setting. These issues have implications for policy as many U.S. schools in the post-*Brown v. Board of Education* context are moving back toward segregation despite heterogeneity in neighborhood contexts (Tarasawa, 2012).

### Social Interaction Patterns in School Settings

Whereas youth develop their identities based on interactions with others, it is important to understand who the “others” are with whom they are interacting. The fact that some youth develop in multicultural contexts might lead us to assume that they interact with diverse groups of individuals. On the other hand, the fact that so many have posed questions—for example, Why are all the Black kids sitting together in the cafeteria? (Tatum, 2003)—indicates this may not necessarily be the case. Researchers studying youth development in school settings have focused on peer nominations to determine with whom students form friendships, and with whom they may experience conflict. Results of these studies suggest that in heterogeneous schools, there are simply more opportunities for either type of contact with members of other racial-ethnic groups (Goldsmith, 2004b). Some evidence has demonstrated that African American students are more likely to nominate their same group peers for both positive and negative interactions, indicating that even in diverse schools; they may be especially likely to form homogeneous peer groups (Bellmore, Nishina, Witkow, Graham, & Juvonen, 2007).

In addition to peer interactions, researchers have recognized that other factors are associated with differential outcomes for children. For example, recognizing that poverty level of a school is highly conflated with minority composition (Logan, Minca, & Adar, 2012). Potential positive outcomes for school diversity are thought to be more equal access to academic resources, which would foster academic success of students in academically marginalized racial-ethnic groups, and development of more harmonious societal interactions between members of different groups. Negative outcomes assumed by opponents of integration are diminished academic opportunities for European American students, increased conflict or violence. There also has been interest in possible mediators of academic outcomes for youth, including attachment to the school and academic aspirations.

With decades of school integration in place, researchers are able to examine the result of heterogeneous school settings. Typically, these studies have included European American, Latino/a American, African American, and, to a lesser extent, Asian and Native American children, thus reflecting the conceptualization and representation of racial-ethnic groups in the United States. Research in this area has focused on academic achievement, as well as elements thought to mediate the relations between

diversity and academic success, such as conflict between groups (discrimination, aggression, and peer victimization) and individual protective mechanisms including attachment to schools, bonding, self-worth, and racial-ethnic identity.

### Predictors of Academic Success

Predictions related to academic success have primarily been based on assumptions that integration would be positive for children in marginalized racial-ethnic groups, including African American, Latino/a American, and Native American students, and negative for more academically advantaged students. Contrary to expectations, some research has found that more diversity at the school level is associated with greater achievement. For example, reading and math scores were higher in diverse elementary schools in Florida (Borman et al., 2004). In opposition to this finding, Benner and Crosnoe (2011) found that the diversity of elementary schools is not associated with academic success for African American, Latino, or Asian American students, but only for European American students, particularly when there was also a high level of European American students in the school (Crosnoe & Benner, Chapter 7, this *Handbook*, this volume).

Studies at the high school level also are mixed. A larger amount of minority membership in a school is associated with decreased GPA and graduation rates (Ryabov, 2011). In contrast, another study demonstrated that across African American, Latino, Asian, and European American high school students, school heterogeneity was positively associated with GPA and high school graduation (Goza & Ryabov, 2009). This association appears to be mediated by the diversity of the peer network. Noteworthy is that this conclusion offers support for the earlier point discussed—that simply because there is diversity within the school does not necessarily mean that youth are interacting across racial-ethnic groups and that these interactions are the driving factor. Further, peer social capital, including the GPA and SES of the peer group, explains a substantial amount of the academic disparities faced by African American and Latino/a American students (Ryabov, 2011). Important to note is that these associations vary across racial and ethnic groups, with peer group heterogeneity being negative for Asian American students, and differ depending on whether the outcome is GPA or graduation. Moreover, school attachment and experiences in school contexts also are important factors that are associated with academic performance.

### ***School Milieu, School Bonding, and Academic Aspirations***

School attachment is thought to be an important link between the racial and ethnic diversity of a school and academic success by increasing school engagement. Evidence partially supports the theory. For example, students in schools with more members of their racial-ethnic group have been found to feel more attached to schools, in terms of feeling connected to people and the institution itself, and happy to be there (Johnson, Crosnoe, & Elder, 2001). However, this did not translate into attending classes, paying attention, or completing assigned work.

Another theory relating the racial and ethnic composition of schools to academic aspirations and school success proposes that students of minority backgrounds will benefit from exposure to other students with increased expectations related to academic attainment (Benner & Crosnoe, 2011). In contrast, there is evidence that when African American and Latino/a American students are in schools where they are the majority or where the student body is highly diverse, they have higher academic aspirations than in more homogenous schools. European American students also had higher aspirations in schools with more diversity. Of concern, however, is the extent to which being in highly diverse school setting heightens cross-racial-ethnic group conflict among students.

### ***Peer Conflict and Victimization in School Settings***

Expectations related to integration of schools predicted high levels of conflict between groups. Research has examined patterns of conflict between disparate racial and ethnic groups, in the form of victimization or discrimination. This is an outcome of importance in its own right and has also been identified as a predictor of academic success. Both positive interactions and conflict between interracial groups are more likely to occur in schools marked by more diversity (Goldsmith, 2004b). As with academic achievement, it is important to consider the racial and ethnic background of the individual youth within the larger school context, and again, the results of these studies have been mixed. For example, a qualitative study found that experiences of discrimination are common among African American students in the rural South, except in predominantly African American neighborhoods (Berkel et al., 2009). Alternatively, studies conducted in urban locales produced the inconsistent findings, reporting that African American students in predominantly African American schools were more likely to be victimized

(Hanish & Guerra, 2000) and victimized even more in less diverse schools (Juvonen, Nishina, & Graham, 2006). For Latino/a Americans, research has found minimal victimization across contexts (Hanish & Guerra, 2000), lower victimization and higher levels of school safety in more diverse contexts (Juvonen et al., 2006), yet, higher levels of discrimination in more diverse schools (Benner & Graham, 2011). The inconsistencies in findings are likely due to differences in metropolitan status (i.e., urban vs. rural) and measurement, which will be summarized at the end of the section, yet are critically important in understanding youth outcomes as discrimination negatively influences perceptions of the school climate, and in turn, attendance and grades (Benner & Graham, 2011). Other mediators also have been considered to further explain differential effects of school contexts on academic outcomes of youth of color.

### ***Internal Mediators of Conflict and Adjustment***

Perceptions about oneself, including racial or ethnic identity, are thought to mediate the relation between intergroup conflict and youth adjustment. Racial-ethnic identity has been identified as being important for self-esteem amongst members of racial-ethnic minority groups, but not for members of the majority European American population (Phinney, Cantu, & Kurtz, 1997). An important consideration is whether the effect of being a minority in the United States is washed out when a student is in the majority within the school setting. To investigate this question, Umaña-Taylor (2004) theorized that ethnic identity would be less important for Latino students when they were in the majority. In contrast, ethnic identity is protective for students irrespective of the demographic breakdown.

Racial and ethnic composition of both the school and the classroom level may be influential on internal indicators of child adjustment. Diversity at both the school and classroom levels was associated with more self-worth and less loneliness among African American and Latino/a American students (Juvonen et al., 2006). Minority status, however, might be protective when experiencing peer victimization. Graham, Bellmore, Nishina, and Juvonen (2009) found that self-blame was a mediator for the link between peer victimization and maladjustment (i.e., depression and self-worth) across Latino/a and African American students. They then examined the school composition by comparing these effects across contexts where students are in the numerical majority versus minority in the classroom. Consistent with hypotheses, they found that the victimization only leads to self-blame when the student

is a member of the numerical majority. Students in the minority were able to attribute victimization to the global prejudices of the victimizer, whereas power differentials favoring members of the classroom majority group made students who were victimized, despite being a member of the majority, assign the cause of the victimization to themselves. Often not considered in studies examining the contribution of individual level factors association with school related experiences is the role that immigration status plays in forecasting academic outcomes.

### **The Immigrant Paradox**

As noted earlier in the section on acculturation and parenting, accounting for the recent occurrences of family immigration to the United States is important for understanding adjustment among ethnic minority youth. The protective role of connection and identity with one's natal country emerges consistently. Contrary to earlier theories, adolescents born in the United States are at greater risk of adjustment problems than those born in their counties of familial origin, a phenomenon that has become known as the "immigrant paradox" (Escobar, Nervi, & Gara, 2000). Crosnoe and Lopez-Gonzalez (2005) hypothesized that the relation between generational status and academic achievement may be moderated by the context to which adolescents are acculturating. Specifically, acculturation in more advantaged schools would result in improved outcomes over time, whereas acculturation into disadvantaged schools would be associated with more extreme evidence of the immigrant paradox. Consistent with prior research, they found a decline in achievement between the first and second generations of students. Contrary to expectations, the effect of school ethnic composition (measured as proportion of immigrants) has no effect on first-generation students. For second-generation students, being in schools with higher levels of immigrants was even more detrimental for academic achievement. It is worth noting that there is a paucity of studies examining ways in which teachers can affect the school experiences and subsequent academic outcomes of students. In the following section, a summary of studies examining the influential role of teachers is provided.

### **Teachers as Influencers of School Contextual Effects**

Compared to the effects of the racial-ethnic composition of students, the role of teachers in the link between school

composition and child adjustment is a relatively unexplored component of children's developmental relational systems. It has been suggested that teachers in diverse schools may be more effective because they have more training, experience or interest in working to facilitate positive intercultural interactions (Juvonen et al., 2006). Prior research has found that Latino/a American students in schools with more teachers with racial-ethnic minority backgrounds experience less discrimination (Benner & Graham, 2011). Having a teacher of minority background, as well as a high proportion of minority teachers in a school, reduce the amount of conflict (Goldsmith, 2004b). Further, minority teachers have positive effects on students' academic orientation. Latino/a American and African American students are more optimistic and positive about their education and future careers as the proportion of minority teachers increases (Goldsmith, 2004a). The functional substitution hypothesis suggests that the presence of any given resource can compensate for resources that are missing (Crosnoe, Johnson, & Elder, 2004). Often African American and Latino/a American students have less social capital to support themselves in the school context. Consequently, these relations may be more influential across ethnic (European American, African American, and Latino/a American) and gender categories. Students with higher levels of bonding to teachers are more successful, but this effect is especially strong for Latina students (Crosnoe et al., 2004). Further, students in schools with higher levels of their same ethnicity peers have higher levels of bonding with their teachers. Again, this relation was stronger for Latina students. Crosnoe and Benner (Chapter 7, this *Handbook*, this volume) theorized this finding may be due to the fact that Latina students have more to gain from bonding, given that their parents may be less familiar with the United States school context, and they may be more adept than boys due to culturally based gender roles that promote their interpersonal skills. Great consideration has been devoted to addressing the academic disparities among racial-ethnic minority students. Highlighted in many of these studies are the processes through students' developmental systems and dynamic interactions with in school settings promote or inhibit academic outcomes.

### **Summary**

In sum, researchers' findings regarding the role that school contexts play in children's development are marked dramatically by their complexity. To move this area of research forward, future research should examine interactions

between individual-level process variables, such as racial identity, with the composition of their school (Eccles & Roeser, 2011), including how cross-racial-ethnic friendships influence youth developmental systems. Several additional limitations were identified and will be discussed later in this chapter.

### RACIAL-ETHNIC HETEROGENEITY IN FRIENDSHIPS

As previously mentioned, youth spend most of their time in schools. When in school, youth are not only focused on academics but also the development of relationships, which impact emotional, academic, and behavioral well-being. This is particularly true for adolescents who are individuating and separating themselves from their parents and becoming more reliant on and integrated with their peers. Social relationships and connections are important aspects of the human experience (Barber & Olsen, 1997; Rubin, Bukowski, & Bowker, Chapter 5, this *Handbook*, this volume). As life course theory suggests, these relationships develop over time and may function differently at various life transitions. The social institutions and settings that individuals, particularly youth, are engaged in have become increasingly diverse, which offers opportunities for interracial friendships (Elder, Johnson, & Crosnoe, 2003). According to social contact theory (Allport, 1954), the increased likelihood that children and youth will encounter ethnically diverse peers on a daily basis should mean that cross-ethnic or cross-race friendship rates will also be on the rise. Consistent with this, cross-ethnic friendships are more common now than in the past (Fletcher, Rollins, & Nickerson, 2004; Graham & Cohen, 1997; Kupersmidt, Griesler, DeRosier, Patterson, & Davis, 1995). In fact, some studies show that the majority of middle school or high school students report at least one cross-ethnic or interracial friendship (McGill, Way, & Hughes, 2012; Hamm, Brown, & Heck, 2005; Kao & Joyner, 2006; Quillian & Campbell, 2003; Way & Chen, 2000). Yet, these friendship types are not the norm (Aboud, Mendelson, & Purdy, 2003; Hamm, 2000). Based on a nationally representative sample of adolescents, youth were 1.8 times more likely to nominate a same-race friend than a cross-race friend (Moody, 2001). Even though opportunities to befriend cross-ethnic peers have increased, students' preferences for homogenous friendships persist (Hamm et al., 2005). Further, European American and Asian American youth are more likely to have same-race friendships (Aboud et al.,

2003; DuBois & Hirsch, 1990; McGill et al., 2012; Quillian & Campbell, 2003; Way & Chen, 2000) than their peers. Given the increasing diversity of schools and opportunities to develop cross-ethnic friendships, same-race friendships remain the norm. Why may this be the case? Accepting the assumption inherent in the similarity hypothesis and social contact theory (Allport, 1954) helps to explain this paradox.

Similarity is a central aspect in the friendship literature and it may be a particularly important selection variable for choosing friends. Ethnic homophily among friends may be the result of selective and primary attention to physical characteristics (e.g., race, age, and gender), truncating opportunities to explore and development friendships based on other common interests (Epstein, 1986; Kandel, 1978; Moody, 2001). Adolescents are not immune from this process, and they may focus on similarity in physical or demographic characteristics as a default (Hamm, 2000; Kandel, 1978; Tolson & Urberg, 1993). Similarity matters most for the deepest and most intimate relationships—close or best friend selection (Hamm, 2000; McGill et al., 2012). However, despite ethnically and racially diverse youth developing in more heterogeneous contexts with opportunity to development friends based on common interests, personalities, and activities that cut across race and ethnicity, children are still more likely to select friends that are ethnically similar to them.

Prolonged interaction or contact with an individual increases the likelihood of the formation of a friendship (Davies, Tropp, Pettigrew, & Wright, 2011; Joyner & Kao, 2000; Quillian & Campbell, 2003). Given the increasing diversity of the United States and the many proximal contexts (e.g., school, neighborhood, and work) that children and youth are involved in, it is plausible to assume that the prevalence of cross-ethnic and interracial friendships will increase and that race and ethnicity will decrease in salience in friendship formation (Lease & Blake, 2005). However, the mere presence of a diverse context does not equate to the development of cross-ethnic or interracial friendships (Allport, 1954; A. M. Pettigrew, 1979; T. F. Pettigrew, 1998) due to the unequal status of racial and/or ethnic groups in the United States (Moody, 2001), prejudicial racial attitudes (Binder et al., 2009; Carr, Dweck & Pauker, 2012; Davies et al., 2011; Margie, Killen, Sinno, & McGlothlin, 2005; Wright, Aron, McLaughlin-Volpe, & Ropp, 1997), and experiences of discrimination (Fordham & Ogbu, 1986; Tropp, Hawi, Van Laar, & Levin, 2012). Given this, how do cross-race or cross-ethnic friendships develop and how do these friendship groups impact socioemotional development during adolescence

and other developmental periods? In the remainder of this section, we review the empirical literature on ethnic heterogeneity in the friendship of children and youth, with particular attention to correlates of cross-ethnic friendships and interracial friendships associations with youth development. We then highlight important and emerging areas of research that will inform our understanding of diverse friendships.

### **Cross-Ethnic Friendships Among Diverse Children**

As already noted, adolescents demonstrate strong preferences for friendships with same-race peers (Kao & Joyner, 2006). A similar pattern is found during childhood, such that African American and European American 8- and 9-year-old girls preferred same-race friends (O'Connor, Brooks-Gunn, & Graber, 2000). Eighty-four percent of European American adolescents and 71% of African American students nominated same-race friends. However, the rates seem much lower for Asian American (42%) and Latina/o American students (34%) (Mouw & Entwisle, 2006) and for Vietnamese students in diverse schools (Chan & Birman, 2009). These cross group patterns suggests that ethnic homophily is more pronounced among African Americans and European Americans. Extant research has not identified the extent to which historical political tensions between African Americans and European Americans drive these differences or variations in diversity of school context for African Americans and European Americans, compared to Latina/o Americans and Asian Americans. However, interesting work has been done to examine patterns of cross-ethnic friendships.

Although ethnic similarity is a powerful predictor of friendship formation, (Hamm et al., 2005), interracial friendships exist. African American and Latino/a American students nominate one another as friends more readily than they do European American friends (Hamm et al., 2005). However, other research shows that ethnic minority youth nominate European American peers more often than European American youth nominate minority peers (Hallinan & Teixeira, 1987; Quillian & Campbell, 2003). When Asian American students nominate other-race friends, European American friends (including European American Latino/a Americans) are the preferred choice (European American students are also relatively likely to nominate Asian American youth as friends) (Quillian & Campbell, 2003). Generally speaking, European American youth are more likely to nominate Latino/a Americans than African Americans as friends, but Latino/a Americans are

more likely to nominate African Americans than European Americans (Moody, 2001). Relative to other racial groups, African American youth tend to be segregated from other racial/ethnic groups in terms of friendships, suggesting that there continues to be a significant divide between African American youth and their non-African American peers (see also Hamm et al., 2005; Kao & Joyner, 2004; Quillian & Campbell, 2003). For example, controlling for the percentage of students of other races or the measure of opportunity, Latino/a Americans and Native Americans were more likely than European Americans to have cross-race friendships, while African Americans and Asian Americans were less likely than European Americans to nominate any cross-race friends (Joyner & Kao, 2000). Therefore, the question becomes, what determines whether an individual will develop a cross-race friendship?

### **Demographic, Contextual, and Sociocultural Correlates of Cross-Ethnic Friendships**

Demographic characteristics such as gender, race/ethnicity, and socioeconomic status play a major role in friendship formation, with friendships in early adolescence being primarily same-race and same-gender (Graham & Cohen, 1997; Graham, Cohen, Zbukowski, & Secrist, 1998; Kuper-smidt et al., 1995). There is a dearth of literature that examines socioeconomic heterogeneity in friendships. Most of this work was conducted in the early 1990s (Aboud & Mendelson, 1996; Billy, Rodgers, & Udry, 1984; Tolson & Urberg, 1993), focuses on adults (Pearson et al., 2006), or has examined socioeconomic status as a correlate to friendship selection (Fong & Isajiw, 2000; Pearson et al., 2006). From the limited available evidence, research suggests that adults are more likely to select friends who have similar socioeconomic characteristics (Billy et al., 1984). Among adults, SES has been shown to impact friendship structure, particularly network size, proximity, and type (Ajrouch, Blandon, & Antonucci, 2005). SES is also associated with a higher likelihood of cross-race/ethnic friendships. In a large sample of Canadian adults aged 18 to 65, Fong and Isajiw (2000) found that SES characteristics (e.g., annual income and education level) strongly predict coethnic friendships. Eighth-through 11th-grade adolescents from suburban schools are less similar on parent education level, an indicator of socioeconomic status, than on other attributes (Tolson & Urberg, 1993). Looking at smoking behaviors among friends, there is more similarity among friends with similar

(as measured by parent's occupation; Eiser, Morgan, Gammage, & Brooks, 1991; Ennett & Bauman, 1996). Parent education level of adolescents is associated with choosing more similar friends for African American youth such that greater similarity is seen in friendships when parents had higher education levels (Hamm, 2000). With pre-school children, Ramsey (1991) found that children are uncertain as to whether people from different social classes could be friends. From qualitative interviews with middle class and 5- to 14-year-old poor children, Weinger (2000) examined how social class impacted friendship choice. She found that 53% of respondents selected a friend within their own socioeconomic class due to what was "normal" (e.g., similarity) and due to a need for sincere and close friendships. It should be noted that these friendships were imagined based on vignettes and depictions of middle class and poor peers using pictures of homes. Nevertheless, given the economic heterogeneity of the United States, it is important for researchers to not only consider how race and ethnicity are associated with friendship formation, but also explore how social class may affect the development of friendships.

Research investigations of factors associated with cross-ethnic friendship formation are quite limited. The scarcity of studies has been attributed to the difficulty children and youth have in discerning an individual's socioeconomic status (Ramsey, 1991). This is due to the way school-aged children (first and fourth graders) utilize visible phenotypic characteristics like skin color to determine friendship choice (McGlothlin & Killen, 2005) and the limited research that systematically examines children and youth's understanding of social class (Weinger, 2000). Nevertheless, given socioeconomic disparities in physical and mental health, researchers should focus on how friendships within and across different social classes may increase social capital and confer positive benefits on health for diverse children and youth.

A few studies have shown that cross-ethnic friends may vary by gender. Specifically, during adolescence, interracial friendships are more often seen with boys than girls (Hamm et al., 2005; Lease & Blake, 2005; Way & Chen, 2000; Way & Greene, 2006). For example, Asian American male students are more likely than their female peers to nominate a cross-ethnic friend (Hamm et al., 2005). However, among elementary-aged (third and fourth grade) children, girls have a higher percentage of cross-race friendships than boys. Further, among all girls (first–sixth grade), social network ethnic diversity is greater than it is among boys (Lee, Howes, & Chamberlain, 2007).

The frequency of cross-ethnic friendships has been shown to relate to the age of youth; however, the research is mixed and the majority of these investigations have been conducted with adolescents rather than children. Various researchers suggest that the frequency of cross-ethnic friendships may increase with age (Hamm et al., 2005), decrease with age (Aboud et al., 2003), or be more common among younger children (Lease & Blake, 2005). Among African American high school students, Hamm et al. (2005) showed that older youth (e.g., 11th and 12th graders) are more likely to have a cross-ethnic friend than their younger counterparts (e.g., 9th and 10th graders). However, Aboud et al. (2003) found that older youth (fifth and sixth grade) have fewer cross-race (40%) than same-race friends (60%), but younger children (first to third graders) have equivalent numbers of both. With rural elementary school children, a trend was found such that younger students are more likely to have a cross-race friend than their older peers (Lease & Blake, 2005). Still, other studies suggest that children tend to play more with same-race peers (Leman & Lam, 2008), prefer same-race friends (DuBois & Hirsch, 1990), or have more same-race friends (Graham & Cohen, 2006). This discrepancy in findings for cross-ethnic peer relationships may result from different operationalizations of friendships. For example, Lease and Blake (2005) examined self-reported cross-race friendships while Leman and Lam (2008) looked at playmates, which may be different from "friends." Further, it is important to note that although school-aged children may prefer same-race friends, it does not preclude these children from establishing cross-race friendships (DuBois & Hirsch, 1990). The settings and environment youth are a part of may influence the degree to which cross-ethnic friendships are formed. For example, several scholars have observed that interracial friendships are more likely to form in heterogeneous environments (Crosnoe, Cavanaugh, & Elder, 2003; Hamm et al., 2005; Kao & Joyner, 2006; Moody, 2001; Quillian & Campbell, 2003). However, with elementary school students, classroom diversity is unrelated to cross-ethnic friendship nominations (Lease & Blake, 2005). Among adolescents, racial heterogeneity of the school increases with friendship segregation or intraracial friendships (Moody, 2001). However, at the most extreme level of school diversity, same-race friendships decrease. These findings suggest that the relation between school racial and/or ethnic diversity is not linear, but curvilinear. This implies that there is a tipping point at which the friendship segregation in schools becomes friendship integration or the formation of interracial friendships. Understanding these tipping points

is important if cross-ethnic friendships and understanding is to be promoted in our school contexts.

In addition to demographic characteristics, researchers have shown other factors such as ethnic identity, racial-ethnic socialization, and perceptions of discrimination to be related to cross-race friendship formation. An individual's internalization of a group identity and the messages she/he may receive about race may be related to the likelihood of cross-friendships. Although limited, most of the work examining this issue has focused primarily on adolescents and in singular research groups. During adolescence, the desire for same-race peers is heightened (Hamm et al., 2005). Hamm (2000), with a diverse sample of high school students, found no association for ethnic identity and cross-ethnic friendship formation. However, Hamm et al. (2005) showed that adolescents with strong in-group preferences are less likely to report any cross-ethnic friends (Hamm et al., 2005). Edmonds and Killen (2009) found that 9th and 12th graders' perceptions of their parents' racial attitudes and messages are related to cross-race friendship formation and parents' reactions to cross-race friendships. Youth who perceive their parents to have negative racial attitudes report that parents are more likely to react negatively to cross-race friendships. Not only does one's ethnic identity and perceptions of parents' racial/ethnic attitudes appear to be associated with interracial friendships, but experiences with race-based discrimination can affect cross-ethnic relationships as well. Based on qualitative interviews with Chinese-, Latino/a-, and Asian American high school students, students' with and without cross-ethnic friendships held different perceptions of discrimination (Rosenbloom & Way, 2004). African American and Latino/a American youth reported feeling resentment over their perceptions of teachers' preferential treatment of Asian American students. Asian American students reportedly felt fearful of their African American and Latino/a American peers who harassed them during school hours. Such feelings caused racial tension, which impeded cross-ethnic friendship formation, especially between Asian American and non-Asian American students.

The focus on economic heterogeneity and friendships is replete. Research in this domain may be limited because of the difficulty children and youth have in discerning an individual's socioeconomic status (Ramsey, 1991). This is due to the way school-aged children (first and fourth graders) utilize visible phenotypic characteristics like skin color to determine friendship choice (McGlothlin & Killen, 2005) and the limited research that systematically

examines children and youth's understanding of social class (Weinger, 2000). Nevertheless, given socioeconomic disparities in physical and mental health, researchers should focus on how friendships within and across different social classes may increase social capital and confer positive benefits for the development of diverse children and youth.

### Cross-Ethnic Friendships and Youth Adjustment

Given that cross-ethnic friendships have been linked with beneficial outcomes in both achievement (Hallinan & Williams, 1990; LaFromboise, Coleman, & Gerton, 1993) and social domains (Hunter & Elias, 1999; Lease & Blake, 2005) and that research in social psychology has shown cross-ethnic friendships can significantly reduce prejudice (Aboud et al., 2003; T. F. Pettigrew & Tropp, 2000), the paucity of research relating cross-ethnic friendships to subjective well-being, psychosocial adjustment, and academic achievement is surprising. Due to exposure, contact, and the development of relationships, cross-ethnic friendships allow individuals to enhance their multicultural competence and expand their social networks. Among adolescents and adults, cross-ethnic friendships reduce friendship conflict, increase friendship support, reduce anxiety about intergroup contact, and improve intergroup relationships. For African American and Latino/a American middle school students, having a cross-ethnic friendship is associated with lower friend conflict (McGill et al., 2012). Among Latino/a American and European American students, cross-race friendships reduce anxiety, as measured by cortisol level (Page-Gould, Mendoza-Denton, & Tropp, 2008). This relation is most pronounced among individuals with high race-based sensitivity (Mendoza-Denton, Downey, Purdie, Davis, & Pietrzak, 2002). Further, research provides evidence that cross-ethnic friendships are related to school success and adaptation in adulthood as well as more positive intergroup relationships (Davies et al., 2011; Hamm et al., 2005). Having cross-ethnic friendships may enhance one's social capital through extended networks and access to varied resources.

During students' middle and late childhood, researchers have found academic benefits, increased prosocial skills and more peer support in cross-race friendships. Rural elementary school children with a cross-race friend are perceived as smarter than their peers who did not have a cross-race friend (Lease & Blake, 2005). Cross-ethnic friendships are associated with more peer support and less relational victimization (Kawabata & Crick, 2011).

For African American children, cross-ethnic friendships that persist in out-of-the-school context are associated with higher self-esteem (Fletcher et al., 2004). Teachers also see the benefit of these types of friendships, such that youth with more cross-race friendships exhibit more prosocial behaviors (Kawabata & Crick, 2008), including greater racial sensitivity (Hunter & Elias, 1999). Cross-race friendships seem to enhance positive development across the lifespan; however, more research is needed to replicate these findings and explain the mechanisms by which these benefits are conferred. Friendship dynamics is an area that is studied at the individual or dyad level with a focus on individual level characteristics as the impetus for their development. Cross-ethnic and cross-racial friendships, however, are driven by contextual factors, including historical and political antagonisms, as well as perceived and real discrimination, the diversity of the peer sociocontextual and cultural environment, and the extent to which these contexts encourage cross-race and cross-ethnic interactions. For example, with ever increasing technological advances complicating the dynamics of potential cross-ethnic friendships, it is becoming important to examine how “virtual” friendships may be similar and or different from “live” peer relationships. An important domain to examine with regards to ethnic heterogeneity in friendships is social media (Calvert, Chapter 10, this *Handbook*, this volume). Seder and Oishi (2009) examined the degree to which individuals have interracial Facebook friends and how this friendship pattern is associated with well-being. They found that for European American college students, intraracial friendships are associated with more positive well-being; however, this relation did not hold for non-European American (i.e., African American, Asian American, Latino/a, Middle Eastern, or multiracial) college students.

### Summary

Taken together, studies reviewed in this section of cross-race/ethnicity and cross-social class friendships have been linked to numerous positive developmental outcomes for both minority and majority children (Witherspoon, Schotland, Way, & Hughes, 2009). These friendships are thought to the social capital of enhance racial/ethnic minority youth through extended networks and access to varied resources. This is particularly important for those raised in low resource families and communities. Diverse friendships have been associated with increased school success, prosocial behaviors (Kawabata & Crick, 2008),

and greater racial sensitivity (Hunter & Elias, 1999) among majority children and children of varying socioeconomic status. It is worth noting that studies of cross-intragroup friendships do not reflect the experiences of children who are classified as sexual minorities.

## EMERGING ISSUES IN STUDIES OF CHILDREN IN DIVERSE CONTEXTS

As we prepared this chapter, two new areas of research in emerged in our synthesis of extant studies of children in diverse context. A few studies, for example, examined ways in which sexual orientation influences children’s development; and other studies placed geographic spatial patterns as a core element that needs to be considered in studies of children in diverse contexts. A summary of available studies is provided in the following section.

### Sexual Minorities

The implication of sexual identity for children’s development in diverse context has not been well studied. While there has been much concern about the victimization of lesbian, gay, bisexual, transgendered, and queer youth, there is a paucity of studies examining ways in which marginalization as being in the sexual minority influences their development. LGBTQ youth form another population gaining attention due to recent experiences of victimization that have become prevalent in the media. While low prevalence rates make it difficult to examine the effects of heterogeneity in terms of sexual orientation or gender identity, researchers have begun to consider their minority status in schools as a risk factor for victimization and adjustment (Toomey, McGuire, & Russell, 2012). Toomey and colleagues found that 16% of participating students report peer victimization due to gender nonconformity in California schools; there was substantial variability at the school level in perceptions of safety for gender nonconforming students. LGBTQ students in rural areas can feel particularly isolated. Sexual minority status in rural Kentucky was associated with reduced levels of school belongingness, lower achievement, and greater alcohol use (Rostosky, Owens, Zimmerman, & Riggle, 2003). Both sexual minority status and harassment due to that status predicted feelings low self-worth and depression (Martin-Storey & Crosnoe, 2012). In the Netherlands, intergroup contact with sexual minorities led to acceptance of gender nonconformity and, in turn, reductions

in prejudice (Collier, Bos, & Sandfort, 2012). Variability among schools contributes significantly to students' attitudes towards gender nonconformity. Having Gay-Straight Alliances and LGBTQ inclusive curricula is associated with better perceptions of safety for male gender nonconforming peers (Toomey et al., 2012). While the concept of sexual minorities in the field of child development is in its infancy, increase prevalence of sexual minorities in the media suggests the need for greater consideration in studies of child development in diverse contexts. Understanding how these varied contextual experiences interact with children's developmental systems to promote or inhibit developmental outcomes of children is an emerging issue that warrants future consideration. Another emerging issue in studies examining the role of context on child development is the changing geographic spatial residence patterns of children of color in every region in the United States.

### **Spatial Residence Patterns of Children**

According to demographers, the distribution of racial ethnic minority children and their families is spatially broad. The highest proportion of families of color resides in urban areas, with noticeably increased population growth in southern, southwestern, and western regions of the United States. The population of children of color and their families is concentrated in six states: California, Texas, Florida, New York, Illinois, and Georgia. Further, many states are witnessing a major decline in percentage of European Americans, which fell below 60% in Hawaii, New Mexico, California, Maryland, Georgia, Nevada, and the District of Columbia (Johnson & Lichter, 2010).

Examination of demographic distribution patterns of children in rural communities reveal that the majority of children are non-Latino/a American European Americans, primarily residing in the Appalachia regions of the United States, which stretch from southern New York to northwest Mississippi. African Americans and Latino/a Americans, on the other hand, are more likely to reside in rural communities in the South, Southwest, and Midwest regions of the United States (Lichter & Campbell, 2005). Residence concentration comparisons of African American and Latino/a Americans residing in rural regions reveal that the majority of African American children are more located in the Black Belt, which runs from North and South Carolina through Georgia, Tennessee, Alabama, Mississippi, Arkansas, and Louisiana. Rural Latino/a American children are more heavily concentrated in Texas,

where in some counties they exceed 50% of the population (Albrecht, Albrecht, & Murguia, 2005). In addition, many of the rural Latino/a American children in rural communities reside in families of recent immigrants (Jensen, 2008). Two groups of children that are often included in studies of children in rural communities are American Indian and Asian American children. American Indian children are more likely to reside on reservations in the Southwest and Northern Plains, whereas rural Asian American children, representing approximately 14,000, primarily reside in the rural Midwest and West.

Increased concentration of racial and ethnic diversity in certain states and townships does not necessarily mean that communities at the town or neighborhood level are integrated and diverse. In fact, the majority of communities remain segregated with few opportunities for daily interactions between youth and families with different racial, ethnic, and cultural backgrounds (Economic Research Service, 2005; Lichter et al., 2010).

The United States is witnessing geographic divides that are not only decreasing opportunities for racial and ethnic mixing, but also will increase economic gaps between high resource and low resource communities and neighborhoods. Spatial inequalities and changing geographic distribution of families increase the likelihood that rural children of color will continue to be disproportionately poorer than nonrural European American children (Friedman & Lichter, 1998). Thus, children growing up in the United States (and thus the population) are increasingly diverse in their individual characteristics and grow up in increasingly diverse contexts; the field of human development can no longer relegate issues of diversity and context to people of color. The changing demographics and neighborhood settlements of families in the United States are impacting the course of all children's growth and development.

### **REFLECTIONS, CONCLUSIONS, AND SUGGESTIONS FOR FUTURE RESEARCH**

The explosion of diversity occurring in every state in the union will cause a major population shift in our country by the year 2025 (Fry & Passel, 2009). One out of every three Americans is a person of color (U.S. Census Bureau, 2010). At the intersection of population growth of minorities in the United States is the booming population of youth in the vanguard of America's diversity. Yet, research studies of child development from 2000 to 2012 continue to presume that generic conceptions of race/ethnicity and

poverty are useful constructs to capture the collective experiences of non-European American children residing in the America.

Our review examined the intricate and complex ways in which children's context varies as a function of race, ethnicity, immigration status, geographic residence, and socioeconomic status. The ecological theory and other frameworks selected to guide our review offer support for the importance of recognizing that *all* youth are nested in interlocking developmental systems that are influenced by broader social contexts, culture, history, and time (Bronfenbrenner & Morris, 2006). Thus, in order to understand human development it is essential to consider the processes through which systemic changes in a child's social environmental settings are influenced by broader and proximal social interaction.

Based on this theoretical perspective, several noticeable patterns emerged in our review. As expected, studies of children in diverse contexts are marked most dramatically by the continued use of the terms race-ethnicity to understand various domains of adjustment and development. Further, ethnicity and culture are often used when studies focus on acculturation and ethnic socialization among Latino/as or transracial adoptions. Yet, all children are exposed to cultural socialization (Gonzales et al., 2002), as a normative process through which children become functional members of their society (Farver et al., 2007). Parents of color, however, are confronted with the challenge of adapting their parenting to effectively achieve their goals for acculturation, enculturation, and safe navigation of the contexts in which they live. Variability in cultural/ethnic/racial socialization, however, may be influenced by the extent to which parents internalize ideologies and practices of their own culture and the dominant culture. Still, none of the studies considered ways in which cultural context influences non-Latino/a American children's development, such as African American, American Indians/Pacific Islanders, Asia American, or European American children. When children are studied only in one racial/cultural context, broader aspects of development and family dynamics are assumed to be "natural" or "universal." It is only when human development and family processes are studied in diverse contexts that true culturally embedded aspects emerge (Cole, 1996).

A major context that is needed to more fully understand child development is the proximal relational processes that emerge through parental socialization. Socialization is the process through which individuals learn and internalize the ways of being, interacting, and knowing that they are

represented in their own culture (Gauvin & Parke, 2010). A plethora of studies have examined the role of parenting in child development, with specific attention given to differential effects of parental discipline on children. There are consistent findings that stricter parenting practices are often found to be associated with more positive developmental outcomes for immigrant and ethnic minority youth (Chao, 1995; Hill, Bush, et al., 2003; Ispa et al., 2004) when compared to European American children. Both contextual and cultural effects have been offered as plausible explanations for these differential effects. Many minority children grow up in high risk situations that influence parenting practice, requiring greater control and monitoring because the potential costs of their child making a mistake are high (Berkel et al., 2009; Hill, 2009; Murry et al., 2009). In addition, cultural contexts not only influence the meaning of parenting but also serve as a foundation for belief systems and parent's desired goals and expectations for their child. These processes may change over time through the synergies that emerge as a by-product of parental efficacy and confidence. Parenting practices are dynamic processes that are formed through representations of their belief systems and worldview, and manifested through cognitions that are exhibited as parenting practices. The extent to which this evolvment is associated with plasticity in children is an area that has been understudied. Future studies in this area offer advancement in several domains and will hopefully explain how parents' definition of parenting is linked with balancing the adoption of ideologies and practices of the dominant culture while maintaining those of one's culture (de Haan, 2011), and which in turn will explain variability in the association between parenting and child development.

Several studies have been conducted to understand how and why acculturation among younger generations of immigrants is associated with increased vulnerability on multiple domains of development and adjustment—achievement, mental health, and behavioral outcomes (García Coll & Marks, 2011). Increased enculturation and acculturation among later generations has been labeled the "Immigration Paradox." Because culture, most broadly conceived, is understood to reflect the nature of the context in which one lives, a fuller understanding of acculturation and parenting must include the ways how parenting and children's development are impacted by the host cultural values and expectations, the culture of origin, and the more immediate context in which the family lives (e.g., neighborhood, economic, ethnic diversity). Given this need, future studies are encouraged to disentangle the

influences of immigrant status, ethnic minority status, and economic status from culturally based influences (Chao & Otsuki-Clutter, 2011; Hill, 2006).

The extent to which these developmental systemic changes are similar or dissimilar among parents raising children of color, including those raising multiracial children (Brunsma, 2005) and parents of transracial adoptees group (Brodzinsky & Pinderhughes, 2002; Vonk & Angaran, 2001) need further consideration. Unique to transracial adoptive parents is the fact that their contexts are more likely to include dynamic interactions with legal and international institutions within and across cultural influences. Little is known about how these experiences affect parenting and transracial adoptive children's identity, psychosocial adjustment, and behavioral outcomes. Further, conceptual frameworks beyond mainstream developmental theories and traditional conceptual models of parenting are needed to guide future studies. Finally, the processes through which *all* parents raising children in diverse contexts negotiate and navigate parenting are not well understood (Fuller & García Coll, 2010; Lopez et al., 2010).

The centrality of other social contextual relations also was observed, namely school and peer relations. Diversity explosion in the United States increases the likelihood that children will be educated in a multicultural context with opportunities to interact with diverse groups of students and teachers. Findings from our review for this chapter indicate the fact that "all the Black kids [are] sitting together in the cafeteria" (Tatum, 2003) continues to reflect not only friendship patterns of African Americans, but also those of most students in the United States. In-group friendship should not be a surprising phenomenon because similarity facilitates and promotes relational processes. Intimate relationships including friend selection are based on homophily among those with whom we have contact (Moody, 2001). An abundance of studies have linked cross-race-ethnic friendships to several positive developmental outcomes, including increased race-based sensitivity (Mendoza-Denton et al., 2002), positive subjective well-being, psychosocial adjustment (Lease & Blake, 2005), reduced prejudice (Aboud et al., 2003; T. F. Pettigrew & Tropp, 2000), and lower peer conflict (McGill et al., 2012). Cross-ethnic friendships also have been associated with long-term positive development and adaptation in adulthood (Davies et al., 2011; Hamm et al., 2005). Replicative studies are needed to confirm these findings. In addition, the mechanisms by which cross-peer friendships are made beneficial remain unknown.

Resolving this issue is particularly important given that findings supporting the benefit of integration for child development are mixed, especially in predicting the academic success for African American, Latino/a American, and Asian American students. Diversity of student population was only associated with increased academic success for European American students, not youth of color (Benner & Crosnoe, 2011). This lack of positive academic outcomes for youth of color was mediated by diversity of peer network. This suggests that attending a mix-race/ethnic school, in and of itself, does not forecast academic success; the dynamic relational interactions are the driving force in this developmental system. Mixed race-ethnic schools provide a social-environmental setting for members of race-ethnic groups to feel connected to students and their school. However, this interactional process does not translate into increased academic performance (M. K. Johnson et al., 2001), but this context does foster increased self-worth and less loneliness among African American and Latino/a American students (Juvonen et al., 2006). Diverse schools and classrooms, on the other hand, do matter when youth of color are in the majority or when the study body is highly diverse, and result in higher academic aspirations. Studies examining other developmental outcomes of diverse school context found reports that Latino/a American students experience more discrimination as school diversity increased, which negatively influenced their perceptions of the school climate and, in turn, their attendance and grades (Benner & Graham, 2011). Further, perpetration of aggressive behavior across students categorized, including European American, African American, and Latino/a American students, increases as school diversity increases (Rowe, Almeida, & Jacobson, 1999). The sporadically consistent and incomplete nature of these studies highlights the need to further understand the contributions of the interlocking dynamic relational systems in school contexts on child development.

It is noteworthy that a few studies have shown that racial and ethnic composition of both the school and the classroom level not only affect academic related processes, but also aggression and peer victimization, as well as internal indicators of child adjustment. In particular, having a teacher of minority background, as well as a high proportion of minority teachers in a school, reduces racial discrimination experiences, race-ethnic peer conflict, and fosters increased optimism, academic orientation, and future career opportunity perspective among Latino/a American and African American students (Goldsmith,

2004b). It was suggested that the positive influential role of teachers in diverse schools may be attributed to training, experience, or interest in working to facilitate positive intercultural interactions (Juvonen et al., 2006). A final note regarding school context and child development is the lack of consideration given to dynamic relational interaction process variables and school context. The work of Umaña-Taylor et al. (2013) provides a model for future consideration. This model examines the moderating impact of heterogeneity of school context on the relation between parental socialization and ethnic identity development in Mexican American youth to offer support for the contributions of school context as a platform for adolescents to process ethnic socialization messages from their parents. Further, Eccles and Roeser (2011) provide a study of the interactions between individual-level process variables, such as racial identity and the composition of a school that is also informative.

A common finding across these studies is that while all students in a mixed race/ethnic school benefit when teachers reflect the diversity of the school milieu, Latino/a (male and female) students and African American males benefit more. These findings offer strong support for the premise that school contexts for children's development are marked most dramatically by their complexity. To advance this area of study, there is need for clearer understanding of how school composition influences development. An urgent matter observed in our review is the need to address measurement flaws regarding how school composition is calculated in terms of assessing the overall diversity of schools, obtaining proportions of different racial-ethnic groups and/or student/teacher ratio of schools, assessing presence versus absence of same group peers, or determining a proportion of majority at a given school. For example, school composition measurement varies greatly across studies, including studies that assess the overall diversity at a school (the likelihood that two students pulled at random would represent the same racial-ethnic group), the balance of different racial-ethnic groups, the proportion of same-group students/teachers at a school, the presence versus absence of same group peers, and the proportion of majority students at a given school. Each of these ways of measuring school composition appears to be conceptually different, yet equally important. In this regard, the effect of homogeneity of a school on developmental outcomes for an African American student would likely be very different depending on if the school population was homogeneously African American or homogeneously European American.

Several limitations were observed in the breadth of our review. First, none of the studies examined the mechanisms through which social stratification influences child development or in which socioeconomic status was conceptualized as a core contextual factor of child development. The majority of studies focused on economic segregation, specifically the consequences of poverty for development of children of color. Across multiple domains of child development, studies continue to collapse distinct racial-ethnic groups who would not realistically affiliate with one another (e.g., Latino/a Americans and Asian Americans) (Bellmore et al., 2007; Umaña-Taylor & Fine, 2001), given their unique customs and histories that are often marked by significant conflict (e.g., Taiwanese and Chinese) (Bellmore et al., 2007). Further, studies of children of color continue to target those residing in urban, low-income settings, without regard for ethnic-racial population concentration. Residential housing, income, and population segregation are often confounded with demographic factors such as immigration status and neighborhood resources, both closely associated with children's developmental outcomes.

Efforts to eliminate this limitation may be aided by the advancement of methodological approaches in research design, in particular identifying ways to standardize methodological approaches and strategies by more fully understanding how measures of race/ethnicity and socioeconomic status uniquely or collectively contribute to child development.

Another limitation observed is that none of the studies specified how socioeconomic status or even poverty influence children's immediate environment. For example, how does poverty cascade through a child's family to affect her/his development, such as the mechanisms through which parental unemployment or underemployment influence the developmental trajectories of children growing up in low-resource families and communities? We did note, however, that studies of socioeconomic status were often narrowly focused on examining the consequences of poverty for a plethora of negative outcomes for children, such as linking low parental education with deviant peer affiliation or determining whether children of higher socioeconomic status (exclusively European American) are willing to explore friendship formation with those of low-income backgrounds. In fact, comparative studies of development among middle-class children of color are nonexistent, and only a few studies of low-income European American youth exist. Given this, little is known about youth developmental outcomes in predominantly

same-race/ethnicity or mixed-race/ethnic environmental settings of varying social economic status. The lack of attention to these issues has led to the inability to specify models to account for the contribution of socioeconomic status, both intragroup and intergroup, in developmental competences of children, both nonminority and minority.

We end our chapter by acknowledging that much work is needed in the field to adequately understand how contextual effects of social class, culture, ethnicity, and race affect a child's development. The continued use of the terms *race* and *ethnicity* as category variables to capture the experiences of children of color dilutes and obscures important moderating effects of ancestral heritage, immigration history, religion, and traditions of normative and maladaptive development (Lin & Kelsey, 2000; Mio et al., 1999). Given this, the challenges set forth many decades ago by García Coll et al. (1996) to guide the study of children of color and those of low-income background remain. Most notable is a lack of progress in identifying the unique normative processes of development among children of color. Thus, the field continues to grapple with identifying critical aspects of these children's social environmental contexts that have profound influence on their growth and development. An observed pattern in our review is that instead of identifying factors and processes that explain the contribution of social stratification for children's growth and development, most studies use race-ethnicity and poverty as proxies of developmental contexts of child of color. The use of these constructs perpetuates the marginalization of these children and is based on the perceived notion that their development is primarily a function of their social positions and socioeconomic status. To advance the research agenda on studies of children in diverse contexts, more consideration needs to be given to documenting the processes through which discrimination and marginalization cascade through children's developmental systems and affect not only their social interactions, but also development over the life course. The negative consequences of institutionalized racism for people of color have been well documented, however, manifestations of broader contextual effects of discrimination (i.e., work force, legal, housing, education, health care systems) for child outcomes have not been adequately included in studies of children of color. As racial-ethnicity, transracial-ethnic, transracial adoptee, Third Culture Kids, low-income, inner-city, rural, and sexual minority youth growing up in the United States, social positions and social stratification are core components of children of color development. Given their salience, greater understanding

of factors and processes that promote optimal development among children in diverse social contexts is needed. For example, realms of competencies may include adaptive coping with marginalization as a consequence of phenotypic characteristics, transracial adoption, multiracial histories, language, culture, place of residence, and family income. In closing, the diversity explosion in the United States increases the likelihood that all children's development will occur in a multicultural environment. For this reason, we charge the field to give greater consideration to identifying the mechanisms through which social positions, social stratification, and places of residence for *all* children, and not only for children of color, forecast both normative and nonnormative child development.

## OVERVIEW

Children live in a world dense with actions, objects, people, and events. Through time these phenomena provide the structure for development and the ingredients that help determine its course. Children actively engage the people and things resident in the places they inhabit. They are not mere passive recipients of whatever a setting contains. Indeed, children help determine what they encounter. But what children do and what it means for long-term development depend on what those places contain. This chapter is about children's intimate surroundings, their content and structure, with a particular focus on housing and the physical environment. Some attention will be given to social aspects of environments, but mostly to highlight the connection between physical circumstances and social interactions.

In this chapter attention will be given to various aspects of the houses children live in and the natural and built environments surrounding them, with a view to explicating how each is implicated in children's behavior and development. The chapter begins with a consideration of several conceptual frameworks that bear upon *how* children might experience the structures, objects and sensory stimuli in places where they spend time and *what* those experiences might mean for their health, competence and adaptive functioning. Thereafter, is a review of what is known about various aspects of housing conditions and the nearby physical environment, with attention to how each may affect children's behavior and well-being. The third section moves beyond a consideration of particular aspects of the environment to a consideration of overall environmental chaos (i.e., how the structure of events and conditions in space and time affect

health and behavioral tendencies). The chapter concludes with an effort to put issues pertaining to the physical environment in historic context, with a view to the future.

Housing and the nearby environment contain so many elements, it would be impossible to fully review all or to adequately integrate what is known about the interplay of child and environment. Accordingly, I have chosen to focus on those aspects of children's housing and physical environment that research indicates have a measureable impact on children. In the process there has been an effort to consider multiple aspects of well being (health, competence, and adaptive functioning) and to consider how exposure to certain environmental conditions may have implications for multiple aspects of overall well-being at various periods of development, consistent with ecological-developmental theory and general systems theory.

## CONCEPTUAL FRAMEWORKS

The section begins with a consideration of several conceptual frameworks that bear on *how* children might experience the structures, objects, and sensory stimuli in places where they spend time and *what* those experiences might mean for their health, competence, and adaptive functioning.

### Historical Ideas About the Affordances of Settings

It has long been recognized that human environments are complex and include a diversity of resources arranged in a multitude of ways (Chen, 1993). Anthropologists, biologists, sociologists, or psychologists (scientists from other disciplines as well) have carved up the environment into components considered salient for human behavior and functioning. Each scholar has conceptualized the interplay between people and their environments in ways deemed critical toward a given end (Weems, 1999). As useful as many of these efforts have been, almost all the scientists who have studied the interface of humans and their environments would admit that scholars typically consider only part of what is a very complex and dynamic interplay of people, places, and things. Efforts to separate organism from environment are understandable—even useful to a degree—but misleading. We are part of the larger network of things and people with whom we interact: We are environments. We are hosts to myriad bacteria, viruses, parasites, and the like. It is not the purpose of this chapter to dwell on the complexities of human-environment interplay or to provide a more inclusive model of this interplay.

Rather, the point is to make clear at the outset that anything said about children and their physical environments should be evaluated in terms of the inseparability of human action from the circumstances in which it occurs and the deep connection between experience and development through time. For this reason, the notion of environmental affordances, introduced by James Gibson (Gibson, 1982), would seem to have utility.

The affordances of the environment are its *functionally significant* properties, considered in relation to a particular individual (Heft, 1993). An environmental affordance is something perceivable and psychologically meaningful to the individual; that is, it is something that is relevant given that humans engage in actions directed at psychologically meaningful goals. But this conception is probably a bit too narrow to cover all types of human needs and goals (Wachs, 1999). Affordances are not exactly properties of the environment per se (Chemero, 2003). Rather, affordances pertain to relations between features of the environment and the capacities and proclivities of humans that encounter them. The exact same physical feature or arrangement of features may provide a different set of opportunities or challenges to different children, depending on age, gender, health status, culture, personal history, or the other features present. Accordingly, knowing the contents present in a given setting does not fully determine what the setting affords a particular child by way of promoting or hindering a given developmental goal.

How a particular affordance of the environment is engaged depends on what an individual brings to it, including the individual's prior learning and history of social experience. Kyatta (2002) connected the idea of affordances to ideas about different types of actions people take: free or spontaneous actions, promoted actions, and constrained actions. The latter two types of actions are often informed by culture (see Goodnow & Lawrence, Chapter 19, this *Handbook*, this volume) or social networks, which may help establish the value or appropriateness of the actions. When circumstances change, such as when a family moves or a community provides new types of infrastructure, the affordances of particular environmental features may change as well.

### Engagement and the Construction of Life Niches

Neufeld et al. (2006) proposed that engagement is the force that mediates the person-environment unit; that is, engagement is the hub of what affordances mean as regards human development. The level, type, and constancy of

engagement determine what results from the interplay of person and environment. Engagement has three components (negotiation, participation, and evaluation), which together determine the outcome in any person-environment encounter. Negotiation refers to an ongoing process during a person-environment interaction in which both the individual and features of the environment make adjustments to accommodate each other (i.e., establish a degree of person-environment fit). Negotiation is most prominent with respect to social aspects of the setting. Participation is the degree of positive interactions between a person and features of the environment in the psychological, physical, and emotional domains. Participation involves the degree to which a person's capacities and predilections are activated during encounters with the resources and structures presented in the environment. Evaluation consists of the individual's appraisal and emotional responses to interactions with the environment. To the degree that participation is strong and evaluation is positive, the degree to which environmental affordances support positive development is high.

Children are constantly in the process of constructing their own idiosyncratic life niches. Life niches result from attempts to satisfy simultaneous constraints attributable to one's own abilities, desires and temperament, and situational presses and affordances (Tesser, 2002). The life niches perspective highlights the importance of interactions between self and settings as regards the path of development. According to self-determination theory, humans need environments that promote competence, relatedness, and a sense of autonomy (Ryan & Deci, 2000). Such environments maximize the expression of intrinsic motivational tendencies; and in so doing promote task persistence, subjective well-being, and better assimilation of the individual to critical social networks. In effect, settings that are relatively rich in resources and that are relatively easy to negotiate (i.e., that have meaningful structure but do not pose too many constraints) are likely to provide the most supportive life niches for children.

### Dynamic and General Systems Theory

Wachs (1999) contended that a given niche is not equally available for exploitation for all those who inhabit it; nor does everyone in a niche have an equal level desire or wherewithal to exploit the affordances the niche provides. For example, the organization of materials within a niche may privilege some inhabitants more than others, as may social expectations and constraints. Not only

do present circumstances matter as regards how much a given niche affords a person by way of opportunities for enhancement and development; but the individual's history of prior experience in that niche can do so as well (the chronosystem as described by Bronfenbrenner, 2005). Most ecological-developmental theories depict human beings as self-stabilizing. Niches can act to promote such tendencies or to disrupt them. In the first case, they will help consolidate behavior tendencies and maintain expectations as regards oneself and one's goal pursuits. The second situation will move the individual toward withdrawal or behavioral adaptation (perhaps even toward a change in stable central attractors to use the nomenclature of dynamic systems theory). Part of the response to any given niche at any given point in time will depend on how many niches an individual tends to engage in and through time and the consistency of affordances in those niches. A person's response also depends on the breadth of skills the individual brings to the niche. The greater the number of positive valences a niche contains, the greater the likelihood of good person-environment fit and the greater the likelihood of optimal development. The reverse is true for niches that contain a high level of negative valences—especially if the individual is restricted to only that or similar niches.

### Coping and Adaptation

When a situation is perceived as threatening or just highly challenging, a number of psychobiological processes may be invoked. An individual's efforts to adapt to the demands of the situation often proceed through a series of stages. Theorists differ on precisely how to categorize various forms of stress and coping processes. However, there is general agreement that when individuals are unable to engage sufficiently powerful internal and external supports to overcome the challenges present, there are likely to be negative psychological and biological consequences (Repetti, Robles, & Reynolds, 2011). Settings vary not only in the extent to which they present threats and challenges but also in the extent to which they contain features that increase the likelihood of adaptive and effective responses from an individual.

Central to successfully coping with threats and challenges is the expectancy that one is able to cope with them (Prilleltensky, Nelson, & Peirson, 2001); that is, one can exercise some manner of personal control to effect a desired outcome. Those expectancies derive both from the physical and social features present in the situation

and from the person's sense of control regarding them. A positive expectancy, "coping," arises when a person concludes that he or she can handle the situation with positive results. By contrast, when the individual concludes that there is no relation between anything he or she can do and the outcome, an acquired expectancy of "helplessness" emerges. This sense of helplessness can generalize to other situations and settings to the detriment of the individual. When an individual concludes that most or all responses lead to a negative outcome, the acquired expectancy is "hopelessness." Hopelessness and coping share one key attribute; specifically, the sense that one can exercise some measure of control. The difference is that hopelessness derives from the sense that no matter what one chooses to do, the result will still be negative.

### Life History and Lifestyle Analysis

Children grow up in wildly different settings. Settings can change markedly through childhood. What the settings afford by way of challenges and opportunities creates substantially different prospects for the development of particular competencies, motivational tendencies, behavior patterns, and health. Children are active agents and meaning makers. As a consequence of increasing competence and experience, children do increasingly more to select and reconstruct the environments they encounter as they age. There is negotiation and co-evolution. For example, Min and Lee (2006) found that children living in large high-rise high-density planned neighborhoods placed high value on nearby park areas because those places supported behavior the children wanted to engage in. That said, some environments are so resource poor, disorganized, and threatening that they discourage agency and undermine coping. In any case, the person-environment interplay produces a life niche that has consequences for developing both a sense of agency and coping skills.

The places one inhabits penetrate to every level of psychobiological functioning. Medical researchers (see Zuckerman & Keder, Chapter 15, this *Handbook*, this volume) have joined with historians (see Stearns, Chapter 20, this *Handbook*, this volume) and anthropologists in an effort to better understand how experiences in varied environments over the life course have consequences for such health issues as immune function and inflammation, as both represent types of adaptations to physical and social affordances within a context. As human environments have changed and as human patterns of mobility and lifestyles have shifted (each resulting in changes in

exposures to various pathogens), local and global rates of various diseases have likewise shifted (McDade, 2003). In some cases an attribute of the physical environment (e.g., cleanliness), can have positive consequences for some health conditions (lower rates of certain communicable illnesses) but negative consequences for others (higher rates of certain atopic illnesses) (Platts-Mills, 2005). Similarly, an object (e.g., a TV) that generally has a positive valence for some aspects of adaptive functioning (i.e., it could lead to learning or skill development) could also have a negative valence as regards other aspects of adaptive functioning (i.e., it could lead to lower levels of physical activity, which increase the potential for inflammation and obesity) (Corbo et al., 2008). In sum, theory and research pertaining to lifestyles and life history are beginning to illuminate how spending time in certain kinds of places has implications for adaptive functioning in multiple domains of development.

### Summary

In his seminal article on complex adaptive systems, Holland (1992) argued that humans operate by no single governing equation. Humans are constantly evolving in ways that help them adapt to their environments. Because humans are complex adaptive systems engaged in ongoing interplay with complex environments, it is difficult to construct a theory that adequately explains why people behave the way they do or precisely predicts an individual's developmental course. Even so, humans are governed systems and operate in accordance with rules; and they use internal models to anticipate the future, basing their actions on an assessment of the affordances present in any circumstance and their anticipation of expected outcomes. To do well, children need well-structured, manageable, and sustained exchanges with people and objects in their immediate surroundings. Otherwise they experience stress and fatigue, which leads to withdrawal or negative patterns of behavior. Children also need the skills to cope with whatever challenges their surroundings present and that allow them to construct supportive life niches (Prilleltensky et al., 2001; Repetti et al., 2011). There is ongoing renegotiation with the physical and social elements present in environment aimed at a good (a.k.a., adaptive) fit (Neufeld et al., 2006). There is no one theory, or simple blending of theories, that fully captures this ongoing process of person-environment interaction and how it determines a child's course of development. Each of the conceptual frameworks discussed in this section would seem to usefully inform

research that captures part of the evolving process. The engagement model of person-environment interaction (Neufeld et al., 2006) would seem especially useful as it is specifically directed to understanding how individuals evaluate and negotiate the path toward person-environment fit. Integrating of ideas from self-determination theory (Ryan & Deci, 2000) might help expand the boundaries of current research on person-environment fit in ways that are especially helpful in a rapidly changing world. Self-determination theory (SDT) derives from notions concerning people's inherent growth tendencies and innate psychological needs. In effect, optimal fit between person and environment can only occur when the affordances of the environment allow for the realization of these tendencies and needs. In the sections that follow, research pertaining to how various aspects of housing and the physical environment are implicated in children's behavior and development will be considered from the vantage point of these theoretical frameworks, together with more general theories of learning and motivation.

## HOUSING QUALITY

In this section attention is given to various aspects of the houses children live in and to the natural and built environments surrounding them, with a view to explicating how each is implicated in children's behavior and development. The review begins with a broad consideration of housing quality, including such things as construction materials and interior facilities. Specific attention is given to spatial arrangements, including crowding and esthetics. As well there is attention given to potentially noxious indoor conditions such as dampness and noise. Special consideration is given to toxic exposures more generally as well as to surrounding conditions. The final portion of the section focuses on the various objects and materials contained within the home that potentially support children's development and adaptive family functioning.

### The Accoutrements of Place

For decades, scientists, policy makers, artists, and humanitarians have addressed issues related to housing quality and its effects on human behavior and well-being. There are classic depictions in novels, movies, and religious documents. Access to adequate housing remains a centerpiece of geopolitics, being enshrined in the United Nations' Millennium Goals. According to the most recent report, there

has been a decline in the percentage of urban dwellers that continue to live in substandard houses, where there is poor construction, inadequate access to water, poor sanitation facilities, and overcrowding (United Nations, 2012).

Relatively elaborate assessment procedures have been available for characterizing housing quality for nearly half a century. These evaluation schemes typically include a consideration of the type of construction materials used and the diversity and quality of facilities contained within the residence (N. E. Johnson & Nelson, 1984). In some cases, the evaluation instruments focus exclusively on the residence itself. In other cases, there is a consideration of what is available in the nearby environment as well (Moughalu, 1991). The latter represents a more accurate instantiation of "home life" for children and adults as proposed by ecological developmental systems theorists and anthropologists (Altman, 1977; Leventhal & Newman, 2010). The more expansive view incorporates as a central notion the idea that places are most usefully understood in terms of the activities and perspectives they afford (Weisner et al., 2001).

Moughalu (1991) argued that an assessment of housing quality should include a detailed consideration of three aspects of the physical environment connected with a person's place of residence: (1) the structural materials used to compose the roof, walls, and floors; (2) interior facilities for water, cooking, bathing, and sanitation; and (3) facilities and amenities in the surrounding neighborhood. Many concerned with overall health and social justice have made similar arguments (Kutty, 1996; Yongsu & Ntetu, 2008), especially researchers concerned with health conditions that increase child mortality, such as diarrhea (Mock, Sellers, Abdoh, & Franklin, 1993; Woldemicael, 2004). In a study done in Cameroon, Yongsu and Ntetu (2008) found that a composite index of housing quality was associated with the level of childhood diarrhea (19.9% prevalence rate in high-standard homes versus 49.2% prevalence in low-standard homes). Even in the United States, where there is less concern about issues connected to slum dwelling and lack of access to community facilities such as potable water and sewage treatment, the most recent American Housing Survey included a broad spectrum of indicators pertaining to household facilities, provisions for safety, and general neighborhood conditions (U.S. Census Bureau, 2008).

### Construction Materials

Research done in less developed countries has often focused on relations between child health and the types

of materials that compose roofs, walls, and floors. In Tanzania 89% of rural homes and 29% of urban homes had dirt floors in 2004. Correspondingly, 63% of rural homes had roofs made of grass or leaves, whereas 87% of urban homes had roofs made of iron—neither of which provides appropriate protection from the weather (Delamonica & Minujin, 2009). Using data from 85 UN-sponsored Demographic and Health Surveys, Montgomery and Hewett (2005) estimated that roughly half to about 95% of urban households in Latin America, North Africa, Sub-Saharan Africa, Southeast Asia, West Africa, and South and Central Asia had finished floors. In a multivariate model that included a diverse array of demographic variables, Guatemalan children living in houses with dirt floors were at increased likelihood of being short and underweight (Pebbley & Goldman, 1995). One of the main problems with poorly constructed homes is that there is increased likelihood of exposure to rodents, mosquitoes, and other carriers of disease (Bonner et al., 2007).

### Disrepair

Even when the construction materials used to build a home are adequate, houses in disrepair are more likely to also have roach and rodent infestations that can lead to health problems (Bradman et al., 2005; Nriagu, Martin, Smith, & Socier, 2012). Asthma rates also appear to be higher in homes with high levels of deterioration (Nriagu et al., 2012; Suglia, Duarte, Sandel, & Wright, 2010). Parents living in dilapidated homes were also more likely to show signs of depression (Evans, Wells, Chan, & Saltzman, 2000; Wells & Harris, 2007). However, it is critical when looking at the impact of disrepair to recall reverse causation. Adults with mental illness or limited cognitive skills may more often move into poor quality housing or allow it to deteriorate. Given that the United States has one of the highest GDPs in the world, some may be led to believe that few homes are in serious disrepair. However, the Annual Housing Survey of 2007 estimated that 37% of dwellings have at least one consequential problem pertaining to external conditions (U.S. Census Bureau, 2008).

### Provisions for Water and Sanitation

The World Health Organization (WHO), in cooperation with the UN Children's Fund Joint Monitoring Programme for Water Supply and Sanitation (2008) estimated that only 58% of people in sub-Saharan Africa had access to improved drinking water sources (i.e., either piped into

the home or from other nearby sources such as public taps, tube wells, boreholes, protected dug wells, protected springs, or rainwater collections). About 70% of households in Lima, Peru, had water in the home (Meng & Hall, 2006). Children without access to clean water and proper sanitation are at much higher risk of diarrheal diseases and for waterborne diseases such as cholera and enteric fevers. There are also more likely to have heavy worm and parasite burdens and an array of skin and eye diseases (Bartlett, 2005). Not surprisingly, mortality among such children is also much higher. WHO and the UN Children's Fund estimated that water-related deaths account for 4% of all deaths and nearly 6% of all disease for young children.

Even when communities (or countries) make provisions for improving access to drinking water, the source of water and the manner in which water is transported can present problems for children's health. Ground-water arsenic contamination is not common in developed nations, but there are areas (especially in less developed countries) where the potential for contamination is relatively high. High levels of exposure prenatally can result in poor fetal growth, infant mortality, and respiratory illnesses (Rahman et al., 2010). Exposure in early childhood can result in both malignant and nonmalignant lung disease and liver cancer (Vahter, 2008). Ground water can also be contaminated with manganese, which has been shown to increase externalizing problems in school-age children (K. Kahn et al., 2011). A longitudinal study conducted in Bangladesh found the children who drank from wells contaminated with arsenic and manganese for at least 5 years had lower scores on most subscales of the Wechsler Intelligence Scale for Children–IV when they were between 8 and 11 years old (Wasserman et al., 2011).

When water does not come into the house, the storage of water becomes a major issue as regards contamination. Young children may dip their hands into water or drop water scoops on the floor, which then becomes a major source of disease. In Ethiopia, the prevalence of diarrhea among small boys was higher when they dipped water from storage containers (Teklemariam, Getaneh, & Bekele, 2000). In a poor neighborhood of Abidjan, Côte d'Ivoire, *E. Coli* was found in about 1% of source water samples but in 41% of stored water samples (Dunne et al., 2001). Peruvian children living in households where water was stored in containers without faucets had about twice the rate of diarrhea per year as children living in households that had containers with faucets (Yeager, Lanata, Lazo, Verastequi, & Black, 1991).

When water is not piped directly into the house, the distance to potable water becomes a major issue as regards contamination. The distance family members have to travel to get water determines the feasibility of obtaining a sufficient amount of clean water on a daily basis. There is a direct correlation between ease of access and the amount of water used in households (Nandy & Gordon, 2009). The implications for health are considerable. In an urban settlement in Papua New Guinea, the presence of a standpipe within the compound was associated with a 56% reduction in diarrhea morbidity for children under 5 (Bukonya & Nwokolo, 1991). When children are young, the distance to water points, the predictability of water supply, and time spent waiting to obtain clean water can be an especially serious concern given the overall burden most parents have for managing daily affairs (Bartlett, 2005). Hands, food, utensils, floors, cooking surfaces, and children are all less likely to be kept clean when water must be carried any distance. An analysis of data from 74 countries showed that persons under the age of 5 were most likely to live in houses that had no access to clean water (Nandy & Gordon, 2009). As children get older, some of the burden of getting water can be shifted to them, sometimes at a cost of injury, poor musculoskeletal growth, and missing school (Geere, Hunter, & Jagals, 2010).

At present, almost half of the world's households lack a sanitary means for disposing of human waste. The World Health Organization in 2008 estimated that 18% of the world population practices indiscriminate or open defecation, and another 12% uses an unimproved sanitation facility that does not ensure hygienic separation of human excreta from human contact. Not having proper facilities to deal with waste contributes to childhood illness and mortality (Podewils, Mintz, Nataro, & Parashar, 2004). The largest number of cases involve diarrhea, which is caused by a *mélange* of bacterial, viral, and parasitic pathogens connected to poor hygiene and sanitation (Podewils et al., 2004). The higher incidence of intestinal parasites in urban children has been repeatedly associated with shared toilets or a lack of connection to city sewer systems, partly because it increases the likelihood that there will be pools of water containing sewage nearby (Mahfouz, El-Morshedy, Farghaly, & Khalil, 1997).

Problems with contamination from human excreta can result from poor community sanitation facilities as well as poor facilities for managing sanitation within the home. Where sanitation is generally poor within a community, many people resort to defecating in the open or into some

form of bag or container. Excreta can accumulate rapidly in areas frequented by urban children. In these communities drainage facilities can become clogged during rains, causing wastes to be spread in the surrounding area. This leads to an accumulation of pathogens in places where children may play or simply walk on their way to school or other community facilities. In some urban neighborhoods it is nearly impossible for children not to come into contact with the byproducts of these wastes. Although a higher proportion of rural homes function without adequate sanitation facilities, the overall characteristics of rural environments (including less density of households) may decrease rural children's rates of exposure relative to children living in dense urban slums; but the research on these issues is limited.

Children's vulnerability to pathogens from contaminated water and poor sanitation relates to both their exposure level and their level of immunity. Unsanitary conditions can lead to poor growth and other morbidities through disruptions in the immune system. Infants who are breastfed have some protection from early exposure to pathogens. Unfortunately, in the absence of clean water and hygienic conditions, formula-fed infants are highly vulnerable. A study done in India revealed that 53% of milk samples used to feed infants contained significant levels of bacteria. The odds of contamination were 25 times as high when feeding utensils were not properly cleaned (Ray, Nath, & Reddy, 2000).

Not having adequate toilet facilities at home is particularly problematic for young children. Taking young children any distance to defecate is impractical given their limited capacity to withhold bowel movements. Maintenance of shared toilets is a problem, and young children fear using pit latrines. They often use yards, increasing their exposure to pathogens. Some of the diseases can lead to malnutrition because they can decrease food intake as well as interfere with digestion and absorption (Stephenson, 1999). Some have argued that there are broader impacts on cognitive development and social competence stemming from low energy and lack of adequate stimulation (Fernald & Grantham-McGregor, 1998; Gardner, Grantham-McGregor, Himes, & Chang, 1999). In its most recent report pertaining to the Millennium Goals, the United Nations (2012) decried the slow progress on addressing undernutrition in children. They pressed for continued efforts to improve water and sanitation infrastructure in developing countries and to reducing poverty more generally.

### Food Storage/Refrigeration

Another common source of contamination is food. If there are not containers available to allow fresh vegetables and meats to be separated from one another as well as from other household objects, the potential for cross-contamination is high. As well, many pathogens multiply far more quickly at room temperature than when refrigerated or frozen. Thus, having facilities for properly storing and refrigerating food is critical to reducing disease exposure. Demographic and Health Surveys done in developing countries show that fewer than 25% of urban households in Sub-Saharan Africa have a refrigerator (Montgomery & Hewett, 2005). Only about one-third of households in Southeast Asia and one-half of the households in Latin America have refrigerators. Because young children can hold only limited quantities of food in their stomachs at any given time, they often need several small meals a day to obtain the necessary calories and nutrients. However, food-borne illnesses are common for household members of all ages when homes lack adequate facilities for when homes have inadequate facilities for food preparation and storage, it often means food is left out for later consumption, thus increasing the likelihood of contamination (Bartlett, 2005). Although cooking foods often kills bacteria in the short term, studies have shown that microbes quickly multiply when cooked foods are not properly stored. A study done in Bihar, India, where the climate is warm and humid, showed high levels of fungal microbes in cooked food samples collected from homes (Tabassum, Kumar, Sharfuddin, Mohanka, & Komal, 2011). Studies pertaining to food contamination have led to well-developed guidelines pertaining to storage and refrigeration of raw and cooked foods of most varieties as well as to proper sanitation practices related to such storage (U.S. Department of Health & Human Services, 2012). However, many households in developing countries lack such facilities; and the extent to which storage and refrigeration facilities are properly utilized in households having them remains unknown.

### Dampness and Mold

According to the U.S. Environmental Protection Agency (2012, p. 39), "When moisture problems occur and mold growth results, building occupants may begin to report odors and a variety of health problems, such as headaches, breathing difficulties, skin irritation, allergic reactions, and aggravation of asthma symptoms; all of these symptoms

could potentially be associated with mold exposure." Molds can produce toxic substances called mycotoxins that can be especially problematic for those predisposed to allergy and asthma (Norback, Bjornsson, Janson, Palmgren, & Boman, 1999). However, household occupants who are exposed to high levels of molds can develop hypersensitivity pneumonitis even though they may have no predisposing condition; and studies link mold concentrations and the incidence of respiratory problems in household inhabitants of all ages (Stark, Burge, Ryan, Milton, & Gold, 2003; Stevens, 2004). There is evidence that high concentrations of molds may increase respiratory tract infections during infancy (Stark et al, 2003). Children living in homes with high levels of mold are at increased risk of wheezing, persistent cough, and common colds (Koskinen, Husman, Meklin, & Nevalainen, 1999). There is also evidence that living in a house high in mold concentration increases risk for asthma and inflammation in adult residents (Pirhonen, Nevalainen, Husman, & Pekkanen, 1996). Climatic conditions can affect the likelihood of having high mold concentrations. Consequently, there is particular concern for addressing issues pertaining to mold levels in regions of the world that are warm and humid (Li & Hsu, 1997).

Because mold growth accelerates as household humidity increases, controlling moisture levels to the extent possible and disinfecting areas prone to mold can help reduce the likelihood of health problems related to mold, a situation that may be especially important for those with weak immune systems (C. Cook, Cole, Dulaney, & Leese, 1999; Institute of Medicine, 2004; Stevens, 2004). In some respects the scientific literature on household humidity (or dampness) tracks the literature on molds present in residential and commercial places (Verhoeff, van Strien, van Wijnen, & Bruenkreff, 1995). However, the relation between relative household humidity, the presence of molds and other pathogens like dust mites, and respiratory illnesses is anything but simple (Strachan & Sanders, 1989). Accordingly, the Institute of Medicine (IOM; 2004) focused on issues connected with "excessive dampness" in homes and other indoor environments. As they argued, "Indoor environments are complex" (p. 184). It is hard to disentangle exposures to various organisms or encounters with various social and physical stimuli or to eliminate various types of selection biases in analyses pertaining to a given pattern of exposures. The data from many household surveys are quite inexact, making attributions related to specific types of pathogens quite problematic. More focused clinical studies now include biological markers of inflammation, but most

of these markers have yet to be applied in studies of dampness or mold in indoor spaces. Despite such limitations, the IOM report concluded that there was sufficient evidence to support a relation between living in a damp indoor environment (and exposure to mold) and upper respiratory tract infections. They drew the same conclusion with respect to cough and wheeze. There was less convincing evidence as regards shortness of breath, sinusitis, and mucous irritation syndrome. There was also inadequate evidence to support a linkage between indoor dampness and airflow obstruction in persons not otherwise predisposed to asthma or chronic obstructive pulmonary disease. For those with predispositions to asthma, a damp indoor environment increased the symptoms present; however, there was not sufficient evidence that dampness or exposure to mold was responsible for the development of asthma. A similar conclusion was drawn regarding hypersensitivity pneumonitis. A subsequent meta-analysis produced stronger evidence the indoor dampness and mold are associated with a wide range of respiratory and allergic conditions, including the development of asthma and eczema, albeit the authors acknowledged that the studies produced insufficient proof of causal relations (Mendell, Mirer, Cheung, Tong, & Douwes, 2011). At present there are too few methodologically sound studies pertaining to fatigue, mood disorders, or cognitive functioning to draw strong conclusions. Neither is there enough to draw sound conclusions pertaining to rheumatologic or immune diseases.

### Electricity

A major reason that families in developing countries lack adequate refrigeration is that they have limited access to electricity. Most indices of overall housing quality include access to electricity as a component (Chen, 1993; Meng & Hall, 2006; Moughalu, 1991). Many of the household amenities that support health and education require electricity, an obvious new one being access to the Internet and use of computers (Hollingsworth, Mansaray, & Allen, 2011). Estimates suggest that 1.3 billion people lack predictable access (International Energy Agency, 2012), with rural areas in developing countries being the most seriously affected (United Nations Development Programme & the World Health Organization, 2009). One of the major problems not having electricity imposes on health is that families must use some sort of solid biofuel to cook or to provide heat. Such devices often produce smoke that is not properly ventilated. The resultant high level of indoor pollutants contributes to premature death, especially for

children. It contributes to other illnesses and injuries as well, including pneumonia, chronic pulmonary disease, and lung cancer (Bates et al., 2013; Dherani et al., 2008; International Energy Agency, 2012; WHO, 2005). The lack of electricity to support reading, computer use (see Calvert, Chapter 10, his *Handbook*, this volume), television, and the like contribute to poor cognitive performance and school achievement (Fish, Li, Butler, et al., 2008). An analysis of access to electricity in developing countries shows a clear relation to levels of literacy (Kanagawa & Nakata, 2008).

### Ventilation and Cooking Facilities

The annual housing survey done in the United States in 2011 revealed numerous households with incomplete kitchen facilities, heating units without flues, fire places without flues, and no heat source other than a cooking stove (U.S. Department of Housing and Urban Development, 2013). The World Health Organization (2005) estimated that 2.3 billion people in developing countries use biomass fuels or coal for cooking, particularly those living in rural areas with limited access to electricity. Having an open stove with no chimney in the household increases indoor pollutants that can pose health risks. Having open fires in the house or a poorly vented stove increases susceptibility to respiratory illness and burns (Desai, Mehta, & Smith, 2004). In poor nations, acute respiratory illness associated with exposure to indoor air pollution is a leading cause of death among children (Gauderman et al., 2004). Long-term exposure also drives up blood pressure in mothers (McCracken, Smith, Mittleman, Diaz, & Schwartz, 2007).

Having natural or machine-based means of ventilating homes appears to have a positive impact on health for children and adults. The overall pattern of evidence suggests that inadequate ventilation increases the likelihood of asthma, respiratory infections and inflammation. Poor ventilation also increases the number of sick days adults take from their jobs (Sundell et al., 2011). The introduction of outdoor air into the home generally has a facilitative effect on the health of residents, but it is not without potential risks, as some outdoor environments have high concentrations of pollutants. The introduction of outdoor air to help with indoor pollutant can be especially challenging in developing countries where winters are extreme, as cold indoor temperatures can also lead to increased health problems and restrictions on behavior.

One of the great challenges to estimating the contribution of ventilation and cooking facilities to child health and adaptive functioning is that few studies have

simultaneously documented the actual level of exposure to multiple particulates. Most often, household dust samples are gathered to determine exposure levels; but even when dust samples are carefully gathered, accepted methods of assessing certain types of particulates are not available (Breysse, Galke, Lanphear, & Farr, 2002).

### **Color, Lighting, Temperature, and Overall Esthetics**

There is general agreement that everyday esthetics in the human-made and natural environment affects mood and patterns of behavior (Irvin, 2009). Even so, there is surprisingly little research on how esthetic conditions present in home environments affect the behavior of adults or children. There has been greater attention to school environments, but the research on school-like environments provides little in the way of definitive information on how particular features in indoor space affect children's behavior (Evans, 2006). In the broad sense, there is research and theory to support the notion that the sensory affordances of the house should encourage exploration, play, and social interactions, but specific research on particular sensory affordances of households or the impact of arrangements of objects in homes is largely lacking.

#### ***Lighting***

There is growing attention to how lighting within indoor environments affects mood and productivity. The majority of studies have taken place in schools and work environments, with a major focus on how much daylight is present in the key spaces in the environment (i.e., spaces where good visibility is critical for managing essential tasks). One study indicated that children in windowless classrooms showed disturbances in diurnal cortisol rhythms and ability to concentrate (Kuller & Lindsten, 1992). Some have suggested a possible connection between the amount of daylight available in classrooms and academic performance; however, two reviews found limited support for the hypothesis that the lighting conditions present in most schools has marked effect on mood, health, or classroom performance (Boyce, 2005; Higgins, Hall, Wall, Woolner, & McCaughey, 2005).

Studies of indoor lighting show some impact on emotions, memory, perceptual orientation, and problem solving (Knez & Kers, 2000). However, a difficulty with the body of research available is that almost none has been conducted in homes, where variations in the illumination available could often fall outside the ranges reported for commercial

buildings and classrooms. It is likely that most homes have access to sufficient natural light most of the time. However, homes near the North and South Poles would have significant issues pertaining to daylight during their winter seasons. Moreover, there are individual and cultural variations as regards the tendency to open curtains so as to allow outdoor light to penetrate and the use of indoor illumination. The research on seasonal affective disorder in children is limited, but there appears to be an increase in symptoms during winter months, especially among post-pubescent females (Glod & Baisden, 1999). Importantly, the symptoms are most notable among people during early to mid-adulthood, the time period during which adults have the heaviest responsibilities for childcare.

#### ***Color***

There is a fairly substantial literature on how color affects motivation and productivity, most of which has been conducted in commercial or school environments (Stone & English, 1998). Color is part of a haptic environment. There is general belief (with some evidentiary support) that young children respond more positively to warm, bright colors and that their color preferences change somewhat as they mature, moving from bright, medium-cool colors to ones with darker hues. Adolescents respond less favorably than younger children to large displays involving primary colors in favor of more nuanced displays involving blended and more subdued colors (Englebrecht, 2003). Different colors produce different physiological responses; but research suggests that physiological response pertains not just to the color but also to color saturation and brightness (Daggett, Cobble, & Gertel, 2008). These responses are associated with particular mood states and motivational tendencies (Knez, 2001). There is evidence for gender differences with respect to color and brightness, with females having a stronger preference for spaces with a high brightness level (Hidayetoglu, Yildirim, & Akalin, 2011). Although research in the field of color psychology has produced reasonable consistency as regards how color, color saturation, and brightness affect motivation, three things are important to bear in mind when interpreting the findings. First, the majority of studies have not been done with young children. Second, the vast majority of studies have been done in commercial and school settings. Third, almost all the studies involve perceptions of esthetics in unfamiliar surroundings. To what extent the findings hold as regards highly familiar home surroundings is unclear.

### ***Indoor Temperature***

Climatic conditions influence “people” comfort and performance. Children manifest performance decrements when engaged in demanding academic tasks requirements when exposed to high levels of heat at school (Schoer & Shaffran, 1973). More recent studies have focused on the advantages of having air conditioning; however, studies have shown that use of air conditioners may increase the level of pollutants indoors, thus contributing to ill health (Ahman, Lundin, Musabasic, & Soderman, 2000). The evidence pertaining to air-conditioning is inconclusive, as most of the studies have serious methodological shortcomings (Higgins et al., 2005). But there is reasonably good evidence that low inside temperatures can have negative consequences for respiratory health, particularly for young children.

### **Plants: Indoors and in the Nearby Environment**

The practice of having living plants indoors goes back more than 2,000 years, with arguments made for both their esthetic and restorative value. Given that people spend considerably more time indoors now than during any time in human history, the issue of whether having plants indoors promotes well-being for children and adults has taken on increased value. To date, the number of studies on having plants indoors is small, and most have taken place with adults in workplace, hospital, or school-like settings. There is an argument that being around plants indoors gives a sense of relief from daily tasks that has the effect of restoring the capacity for attention (S. Kaplan, 1995). However, studies with adults provide limited support for such a notion (Shibata & Suzuki, 2002). Based on their review of the literature, Bringslimark, Hartig, and Patil (2009, p. 431) expressed “strong reservations about the claims that indoor plants cause beneficial psychological changes.” Particularly unclear are the conditions that might be necessary for exposure to plants indoors to result in positive benefits for children and the mechanisms that might account for such benefits.

Recent interest in the potentially restorative value of having plants indoors derives from the long-held belief about the generally restorative properties of being engaged with nature. There are arguments from evolutionary psychologists that human beings, as a species, have spent hundreds of thousands of years living in natural surroundings and have developed various physiological responses as well as symbolic attachments to various aspects of nature

(Hinds & Sparks, 2011). P. H. Kahn (1999) proposed the biophilia hypothesis; specifically, there is a fundamental human need to affiliate with life and lifelike processes. There is an emerging body of evidence that people have a preference for environments that contain natural features such as lakes and oceans (Ogunseitan, 2005; White et al., 2010). Furthermore, there is a small amount of evidence that positive reactions to natural surroundings may be fairly widespread (Korpela, Hartig, Kaiser, & Fuhrer, 2001), albeit, natural aspects of the environment can also evoke negative responses in some (Staats, Gatersleben, & Hartig, 1997). Recent studies of place attachment and neighborhood satisfaction appear to corroborate the idea that people feel a stronger and more positive connection to their surrounding community when it affords them encounters with vegetation and other natural elements, including opportunities for gardening (Hur, Nasar, & Chun, 2010; Scannell & Gifford, 2010).

There are indications that humans may be genetically predisposed to respond positively to environments that contain “natural” elements such as trees, water, flowers and the like (Hartig, Mang, & Evans, 1991; Hinds & Sparks, 2011; Wells, 2000). For example, research by Abraham, Sommerhalder, and Abel (2010) and Groenewegen, van den Berg, de Vries, and Verheij (2006) indicates that having exposure to the natural environment helps with the restoration of cognitive performance for those stressed by overexertion and it evokes positive emotions. Likewise, R. Kaplan (2001) found that being able to see trees from one’s home, whether in the suburbs or inner city, was associated with a heightened sense of ease and relaxation. Because there is a nascent belief that being close to nature has restorative benefits and can help promote key social and competence goals, there is a general worry that growing up in the inner city could limit productive activity and compromise development for children. However, a study of 64 urban public housing outdoor spaces revealed considerable variability in access to green spaces with more than half having considerable vegetation (Sullivan, Kuo, & DePooter, 2004; Taylor, Wiley, Kuo, & Sullivan, 1998). Of the 262 children observed, most (73%) were involved in meaningful play and most (87%) were being supervised to some degree. That said, involvement of adults was less in the more barren spaces, and the play of children was less creative. Moreover, surveys done with housing project residents indicate that good maintenance of trees and grass in nearby space increased the perception of safety and reduced the level of crime (Kuo & Sullivan, 2001). Natural

landscaping encourages greater use of outdoor areas and attracts a more diverse group to the space (Kuo, Bacaicoa, & Sullivan, 1998). For children residing in poor urban environments, having natural green spaces nearby has a restorative effect. Children who moved to homes with much higher levels of greenness had the highest levels of cognitive functioning after the move (Wells, 2000).

Despite studies showing positive responses to living in or near trees, grass, lakes, streams and other aspects of nature, at present empirical studies provide only limited support for the idea that humans are genetically predisposed to benefit from either indoor or outdoor exposure to nature and only limited support for the benefits of such exposures. The situation is especially unclear as regards the short and long-term benefits of childhood exposures. Part of the problem lays in the relatively small number of high-quality studies done on large samples. Another part derives from the difficulty of separating aspects of the physical surroundings that tend to co-occur; specifically, being nearby to nature generally means living in less dense neighborhoods and in houses that are not as crowded. Living near to lakes and trees also tends to be associated with other social and physical affordances in the geographic area that may promote well-being; and there is a built-in selection bias as regards area of residence—humans are not randomly assigned to geographic areas. Granting the limitations of current studies, the available evidence tilts in the direction that having access to nature in areas nearby to one's home likely increases the opportunities for relaxation and certain types of physical activities that are deemed enjoyable and that may promote certain types of competence, including a kind of self-directedness. That said, there is evidence that some of these “natural benefits” may be producible in areas with limited access to nature if communities take care to assure the availability of even small parks and recreational facilities (Castonguay & Jutras, 2010).

### Indoor and Outdoor Contaminants

Just as there are potential benefits from having access to nature indoors and in the nearby surroundings, so there are potential hazards from exposure to indoor and nearby contaminants. Air pollution is implicated in a diverse array of illnesses in both children and adults, with young children being especially susceptible. Exposure of women to air pollution during pregnancy has been associated with increased rates of child mortality, intrauterine growth retardation, prematurity, low birth weight, and birth defects

(Aguilera et al., 2013; Ebisu & Bell, 2012; Dadvand et al., 2013). Molecular studies have identified DNA adducts (i.e., biological markers of exposure) connected to disruptions in the endocrine system in processes connected to fetal growth (WHO, 2005). Such findings are consistent with those from the GenR study in the Netherlands showing that exposure to airborne particulate matter (PM) during pregnancy leads to less adequate placental growth and function (van den Hooven et al., 2012).

During the early years after birth, air pollution is particularly harmful to the developing respiratory system (WHO, 2005). A birth-cohort study done in Spain showed that prenatal and postnatal exposures to NO<sub>2</sub> and benzene were related to rates of lower respiratory tract illnesses and ear infections during the first 18 months of life (Aguilera et al., 2013). An 8-year study conducted in California showed that exposures to pollutants such as nitrogen dioxide, acid vapor, particulate matter, and elemental carbon was associated with decreased lung function in children from Age 10 to 18 (Gauderman et al., 2004). Even relatively low doses of exposure can damage postnatal lung development. There can be disruptions to normal biologically programmed patterns of growth and branching in the lungs that lead to permanent structural and functional damage. Exposure to nitric oxide and ozone during the early years of life can initiate a cascade of inflammatory and functional responses that injure the airways. Such exposure can interact with dust mite antigen in ways that multiply damage to lung tissue, leading to asthma, rhinitis, and related pulmonary problems. These allergic responses result from polarization of the immune system such that there is a release of Immunoglobulin E rather than Immunoglobulin G or Immunoglobulin M as is normal for the immune system. Exposure to diesel fumes or ragweed pollens (and the like) from the nearby environment can further exacerbate the allergic inflammation leading to sensitization to allergens that otherwise would not cause problems in a child. Critically, these processes can play a role in the way the entire immune system functions to sustain health in children, such as increasing susceptibility to other infectious agents such as rhinoviruses. There are indications that children living in communities with high levels of sulfur dioxide and nitrogen dioxide show a higher prevalence of upper respiratory tract infections as well as broader indicators of acute respiratory infections (e.g., school absence; WHO, 2005). In studies that have made comparisons between areas of high traffic congestion versus low traffic congestion within a community, there tends to be fairly consistent evidence that high exposure is associated with asthma,

hay fever, and atopic eczema (Clark et al., 2010; WHO, 2005). In the review commissioned by WHO (2005), experts concluded that living in areas with high levels of ozone had a negative impact on growth of small airway function, especially during infancy and early childhood. They found less evidence that exposure to nitrogen dioxide and sulfur dioxide had an independent effect on lung development for children, citing complexities attached to atmospheric composition and uncertainties regarding mechanisms of effect. Granting these uncertainties, the World Health Organization's overall appraisal was that "living in areas of high air pollution is associated with lower lung function... (and)... chronically elevated air pollution is associated with lower rates of lung function growth" (2005, p. 124). One study even implicated living in areas with high levels of air pollutants (i.e., nitrogen dioxide) with high traffic congestion may be associated with elevated risk of childhood leukemia (Amigou et al., 2011). Finally, although some attention has been given to estimating how much potentially damaging air pollutants (e.g., atmospheric lead) may contribute to other developmental problems (e.g., lowered cognitive functioning or increased maladaptive behavior), it has been hard to establish a causal connection to such problems thus far (WHO, 2005). Part of the difficulty stems from inability to determine the actual source of contamination because children who most likely to intake harmful pollutants via the lungs are also most likely to intake the same pollutants via ingestion. For similar reasons, it is difficult to isolate the impacts of prenatal and postnatal exposures (Aguilera et al., 2013).

One of the concerns about home ventilation is that air pollutants from outdoors can be dispersed or concentrated indoors depending on the type of ventilation system employed, the fraction of air recirculated, the type of filtration technology used, and the level of humidity present (Sundell et al., 2011). Carbon dioxide is prevalent in the atmosphere in some locales; thus, there is concern that improper ventilation could lead to concentration levels that have adverse consequences for household members.

Historically, much attention has been paid to sources of pollution that emanate from outdoors, some of which penetrate indoors to negatively affect health and development. However, newer studies are showing that pollutants from indoors (e.g., those emitted via dryer vents) may be contributing to outdoor pollution as well (Steinemann, Gallagher, Davis, & MacGregor, 2011). More attention has been paid to the impact of pollutants that remain indoors, including phthalates. Phthalates are mostly used as plasticizers or softeners in polyvinyl chloride (i.e., vinyl). Boas

et al. (2010) found that phthalate concentrations were negatively associated with thyroid function and growth in Danish children. Prenatal exposure to phthalates was also associated with reduced anogenital index (AGI) and reduced height in boys (Swan et al., 2005) and subsequent reduced masculine play behavior (Swan et al., 2010). Studies conducted in Korea show a positive association between phthalate metabolites in children's urine and symptoms of ADHD as well as a negative association with measured intelligence (Cho et al., 2010; Kim et al., 2009). It is not easy to confidently identify the source of phthalates in individual children, as they may come from air, soil, or engagement with various plastic objects, including the mouthing of teething rings and toys.

Exposure to formaldehyde also has been subject to considerable study. Formaldehyde is found in many products associated with housing: particle board, insulation, carpet, and certain types of furniture. A meta-analysis revealed that asthma was more common in children with higher levels of exposure to formaldehyde, a result not surprising because formaldehyde is a known irritant affecting multiple lung tissues and has been associated with a decline in pulmonary function (McGwin, Lienert, & Kennedy, 2010). A study done in France showed that infants exposed to higher levels of formaldehyde, measured by 7-day air samples in their bedrooms, were more likely to manifest lower respiratory tract infections (Roda et al., 2011). Another study, this one conducted in the United Arab Emirates, measured exposure to formaldehyde along with exposure to four other types of indoor pollutants: sulfur dioxide, nitrogen dioxide, hydrogen sulfide, and carbon monoxide (Yeatts et al., 2012). These indoor pollutants were also measured passively for a 7-day period in 628 households. The levels of hydrogen sulfide and sulfur dioxide were associated with wheezing and asthma. Adults in households with higher concentrations of formaldehyde reported greater difficulties concentrating, more dizziness, and more headaches as well. A recent study, done on macaques, showed that inhalation of formaldehyde had impacts even at the molecular level (Rager et al., 2013).

Part of the concern about housing quality in general and living in homes with serious structural defects in particular is that homes in disrepair are far more likely to be infested with dust mites, rats, cockroaches, and other pests that have potential to harm residents (Rao & Phipatanakul, 2011; Rauh, Chew, & Garfinkel, 2002). Infants exposed to indoor wood smoke and cockroaches were also more likely to develop asthma (Salam, Li, Langholz, & Gilliland, 2004). According to a survey done in 2005, about 10% of homes

in the United States have levels of cockroach allergen sufficient to cause such problems (Cohn, Arbes, Jaramillo, Reid, & Zeldin, 2006). Not surprisingly, adults in those households are far more likely to use pesticides to help in the management of pests (Landrigan et al., 1999). A study done in southern California showed that children exposed to pesticides during the first year of life were twice as likely to develop asthma. A systematic review and meta-analysis also showed relations between exposure to pesticides and childhood leukemia (Turner, Wigle, & Krewski, 2010). In addition, exposure to pesticides, both pre- and postnatal, is associated with various cognitive processing difficulties and ADHD (Bouchard, Bellinger, Wright, & Weisskopf, 2010; Eskenazi et al., 2013; Jurewicz & Hanke, 2008). Impacts seem to depend on both the timing and duration of exposure. For children living in agricultural areas, there is increased risk for neurodevelopmental problems (Jurewicz & Hanke, 2008; Rauh et al., 2011).

One of the most widely studied home environmental pollutants is tobacco smoke, with evidence showing that it is implicated in asthma and other respiratory diseases (Biagini et al., 2006; Cook & Strachan, 1999; Rao & Phipatanakul, 2011). The strongest evidence is that prenatal exposure has long-lasting effects (Ruckinger et al., 2010). Exposure to tobacco smoke frequently co-occurs with exposure to other indoor pollutants, with evidence that it has an independent impact on lung function (Kohli et al., 2012; Mullane & Le Souef, 2010). There is mixed evidence regarding relations between maternal smoking and children's cognitive functioning, with somewhat stronger evidence pertaining to prenatal smoking (Julvez et al., 2007; Niemela & Jarvenpaa, 1996). Far more certain is the relation between prenatal maternal smoking and child maladaptive behavior. Evidence of its effects begin in infancy with dysregulation and manifests itself throughout childhood in terms of conduct problems, internalizing and externalizing behaviors, difficulties with impulse control, criminality, and use of substances (Bruin, Gerstein, & Holloway, 2010; Cornelius & Day, 2009). There is evidence that prenatal exposure has effects on developing brain structure and interacts with genes to promote antisocial behavior (Jacobsen et al., 2007; Wakschlag et al., 2010).

The full impact of exposure to airborne particulate matter and other environmental teratogens remains to be determined. However, measurement of long-term exposures to most forms of teratogens indicates that the likelihood of exposure varies by ethnicity, social class, age, and geography (Trasande, Attina, Sathyanarayana, Spanier, & Blustein, 2013). An intensive study of exposure to airborne

particulate matter (PM) in the United States (215 selected census tracts) showed demographic variations in exposure rates for fine particulate matter. Greater levels of exposure were evidenced for children, non-Whites, and those living in poverty (Bell & Ebisu, 2012). Studies of the impact of particular teratogens are especially needed in areas where they are most highly concentrated. For example, children's exposure to polybrominated diphenyl ether flame retardants is especially high in parts of California. A recent study showed that in utero exposure levels of PBDEs were associated with children's attention, motor functioning, and IQ at Ages 5 and 7 (Eskenazi et al., 2013).

According to WHO (2010), lead poisoning accounts for almost 1% of the global burden of disease for children. Depending on housing quality, place of residence, source of water and the kinds of toys and products available in the household, children can be exposed to levels of lead that can have serious consequences for health and development. Ingestion is the most common route of exposure for most children, including ingestion of dust containing lead from handling materials that touch the floor or ground. Inhalation can also be a route of exposure, but is less common than ingestion. In developed countries, lead has been eliminated or drastically reduced in such sources as paint, gasoline, cosmetics, and pipes carrying water; but not even all households in developed countries are free from every source of potential lead poisoning. As it happens, lead comes in a multiplicity of forms and some children live in places near mining sites or incinerators that produce air- or soil-borne lead or they live in areas where water sources remain polluted with lead. In such areas, blood lead levels in children can be high enough to compromise health and adaptive functioning.

The impact of lead on humans has been widely studied with evidence indicating that it affects all organ systems. It has damaging effects on teeth and bones, the kidneys, the cardiovascular and immune systems, and the nervous system, with effects varying by level of lead burden, age, and duration of exposure (White et al., 2007). Research has shown that the brain is particularly sensitive to lead exposure and that lead is able to pass the blood brain barrier (Lidsky & Scheidner, 2003). Lead poisoning results in loss of myelin sheath in children, as well as reducing the number of neurons, decreasing neuronal growth and interfering with neurotransmission (Mycyk, Hryhorczuk, & Amitai, 2005). Relatedly, increased blood lead levels have been correlated with lower IQ, problems in reasoning, attention and short-term memory, lower scores in reading and math, and a greater likelihood of school dropout

(Canfield et al., 2003; Lanphear, Dietrich, & Auinger, 2000). There is also evidence that high levels of lead increase aggressiveness and other forms of externalizing and antisocial behavior (Dietrich, Ris, Succop, Berger, & Bornschein, 2001; Needleman, 2004) and that they are implicated in impulsivity and hyperactivity (Bellinger, 2008; Stein, Schettler, Wallinga, & Valenti, 2002).

One of the challenges in fully delineating how lead exposure is implicated in children's development is that lead exposure is more likely for children living in poverty. This problem has to some extent been addressed in studies where SES has been used as a covariate in the analysis. However, poverty has many cofactors; therefore, it is difficult to fully address the problems of confounding—and many studies have not done so.

Mercury is another well-known neurotoxicant (Trasande, Landrigan, & Schechter, 2005). It exists in three forms: as a metallic element, as an inorganic salt, and as part of organic compounds. Each form has different bioavailability and toxicity. There are natural sources that release elemental mercury into the environment (e.g., volcanoes, emissions from coal-fired electric generation facilities, waste incineration, and some other industrial production activities). Consequently, living near such sources increases the likelihood of contact with elemental mercury. Elemental mercury is readily aerosolized and can, thus, travel great distances to eventually become deposited into soil and water. These deposits become transformed into methyl mercury in microorganisms consumed by fish (Myers et al., 2003). Ingested methylmercury is readily absorbed in the intestines and transported across the blood-brain barrier and the placenta (Kerper, Ballatori, & Clarkson, 1992). When pregnant women consume such contaminated fish in large quantities, it can have severe consequences for the developing brain because brain development is so rapid during the period prior to birth. There is an accumulating body of research showing that high levels of mercury concentration in blood are associated with decreased performance on measures of language, memory, attention, and general intelligence (Grandjean et al., 1997; Trasande et al., 2005). The impact on neurodevelopment depends on the level of mercury present, with some evidence suggesting that low levels may pose less danger of long-term consequences (P. W. Davidson et al., 1998; Trasande et al., 2005). However, mercury poisoning may also pose long-lasting consequences for cardiovascular health as children with higher levels of exposure to methylmercury had greater difficulty maintaining normal heart rate variability (Grandjean, Murata, Budtz-Jorgensen, & Weihe, 2004).

Polychlorinated biphenyls (PCBs) are fat-soluble chemicals that used to be produced in high quantities for industrial use. Their production has been banned in most industrialized nations but they have persisted in soil and sediments and become part of the food chain, especially in beef, dairy products, and fish with high fat content (Stein et al., 2002). Children who live near landfills, incinerators, and hazardous waste sites are at greatest risk. The primary targets of PCBs are the endocrine and nervous systems (U.S. Environmental Protection Agency, 2009). Prenatal and early life exposure to PCBs show impacts early in life, including lower birth weight, decreased head circumference, motor immaturity, poor lability, hyporesponsiveness to visual and auditory stimulation, and deficits in recognition memory (S. W. Jacobson & Jacobson, 2000; Rogan et al., 1986). Lai, Guo, Guo, and Hsu (2001) found impacts on cognitive functioning lasting into adolescence. Granting that prenatal and early postnatal exposures to PCBs increases the likelihood of decreased neuropsychological functioning, the specific impact of particular PCB congeners (dioxins, furans, planars, mono-orthos, di-orthos, etc.) is not well characterized; and there is evidence that some of the effects on prenatal PCB exposures may be mediated through postnatal exposures (Schantz, Widholm, & Rice, 2003).

Studies point to immune system compromises such that children with high levels of exposure have greater difficulty fighting normal infections (Dallaire et al., 2006; U.S. Environmental Protection Agency, 2009); Van den Heuvel et al., 2002; Weisglas-Kuperus et al., 2000). Importantly, there is evidence that prenatal and early postnatal PCB exposure may impact thyroid hormones during infancy (Chevrier, Eskenazi, Bradman, Fenster, & Barr, 2007; Longnecker, Gladen, Patterson, & Rogan, 2000; Winneke, Walkowiak, & Lilienthal, 2002) and menstrual cycles during early adolescence as a consequence of disruptions in the endocrine system (Denham et al., 2005; Yang et al., 2005). Acute high dose exposures to PCBs have also led to skin lesions in both children and adults (Aoki, 2001).

Like exposure to lead and mercury, exposure to PCBs can also have significant consequences for neurocognitive development (U.S. Environmental Protection Agency, 2009). In early childhood, prenatal PCB exposure is associated with a variety of cognitive impairments (reduced memory and attention, decreased verbal ability, impaired information processing) and reduced psychomotor development (Grandjean et al., 2001; J. L. Jacobson & Jacobson, 1996; Stewart, Reihman, Lonky, Darvill, & Pagano, 2003; Walkowiak et al., 2001). In preteen years, prenatal PCB

exposure is associated with decreased reading comprehension, decreased full-scale and verbal IQ, and reduced memory and attention (Patandin et al., 1999; Vreugdenhil, Mulder, Emmen, & Weisglas-Kuperus, 2004). Continued postnatal exposure is also associated with impaired memory and cognitive performance, even among adults (Newman et al., 2006; Schantz et al., 2001). Pre- and postnatal PCB exposure has also shown adverse behavioral and emotional effects in decreased sustained activity, decreased high-level play, increased withdrawn and depressed behavior, increased activity level, increased aggression, and increased emotional reactivity (Lai et al., 2002; Perera et al., 2012; Vreugdenhil, Slijper, Mulder, & Weisglas-Kuperus, 2002). In children, prenatal PCB was also associated with impaired response inhibition and with decreased volume of the splenium of the corpus callosum, a brain structure related to inhibition through Age 9 (Stewart et al., 2005). As with other types of toxicant exposures, exposure to PCBs is often confounded with other physical and social factors that contribute to poor development, but some of the studies identified negative impacts on children's health and development even with careful controls for other environmental factors including levels of stimulation and socioemotional support available in the home environment (Walkowiak et al., 2001). That said, most studies of PCBs, like most studies of heavy metals, have not consistently considered how other aspects of the ecology may serve to moderate the effects of exposure. As an example, Hubbs-Tait, Nation, Krebs, and Bellinger (2005) found that higher SES was protective against lower levels of lead exposure even though it afforded insignificant protection against higher levels of exposure. Moreover, some of the inconsistency in findings may reflect the specific nature of PCBs ingested, with research only beginning to identify effects associated with different types of PCB exposures (Newman et al., 2009).

## Noise

When Evans (2003) composed a cumulative risk index for the purpose of understanding how various aspects of the home environment contribute to allostatic load, noise was one of the factors included in the index. That decision was based on accumulated research indicating that exposure to excessive levels of noise was distracting and contributed to stress and a sense of learned helplessness. Some of the noise children experience at home emanates from within (e.g., loud music or TV), but more often it penetrates into

the interior as a consequence of the home's location near major highways, railways, airports, or industrial sites. Chronic exposure to noises within and outside the home also has a pronounced effect on long-term memory and school achievement (Hygge, Evans, & Bullinger, 2002; Sorqvist, 2010; Stansfeld et al., 2005).

Exposure to noise affects sleep in both children and adults (Ohrstrom, Hadzibajramovic, Holmes, & Svensson, 2006) and contributes to elevated blood pressure and neuroendocrine stress hormones in children and adults as well (Evans, 2003; Evans, Bullinger, & Hygge, 1998; Ising & Ising, 2002; Regecova & Kellcrova, 1995). Chronic exposure to noise is associated with reduced motivation to engage in challenging tasks (Evans, Lercher, Meis, Ising, & Kofler, 2001; Maxwell & Evans, 2000). Consistent relations are also found with hyperactivity (Stansfeld et al., 2005; Stansfeld et al., 2009).

It is hard to determine how much noise contributes to well being in children and adults, given that high noise is associated with poverty; and many of the co-factors of poverty are also implicated in poor motivational tendencies, poor academic performance, more maladaptive behavior, and poor school performance. Indeed, it is not uncommon for homes with high levels of noise to also manifest high levels of disorder. A. Johnson, Martin, Brooks-Gunn, and Pettrill (2008) found that household disorder was strongly correlated with children's reading competence, with noise showing little relation once household order and the quality of the home literacy environment were included in their regression model.

Efforts have been made to reduce the impact of both interior noise and noise that penetrates from outside by using building materials and designs that counter some of their effects. Sound reverberates on hard surfaces, so proper absorptive treatments for walls, floors, and ceilings are crucial to effective communication, a sense of privacy, and relaxation. As yet there are limited studies on how such building properties affect children in areas where ambient noise tends to be higher—most involve studies of school environments.

## Crowding

The negative consequences of crowding have long been of concern (Evans, 2006). As it happens, overcrowding often coincides poor overall housing quality (e.g., poor ventilation, lack of household facilities, poor external construction); for example, Wells and Harris (2007) found high correlations between crowding and structural quality

( $r = .73$ ), hazards present in the home ( $r = .66$ ), and cleanliness ( $r = .74$ ). For that reason, it is not surprising that studies have frequently shown relations between household crowding and poor health among family members (Evans, 2006; Leventhal & Newman, 2010). Crowded conditions have been associated with respiratory illnesses, meningitis, and gastrointestinal problems in children (Baker, Taylor, Henderson & the ALSPAC Study Team, 1998; Galpin, Walker, & Dubiel, 1992; Solari & Mare, 2012; Stanwell-Smith et al., 1994). Crowding encourages the spread of infection and increases the likelihood of injury (M. Baker et al., 2000; Jaine, Baker, & Venugopal, 2011). Crowding may also increase the likelihood of injury and death as a consequence of some life style choices like cosleeping. For example, Blair et al. (1999) made the argument that when poor parents select to sleep with their newborns, it may be a factor in sudden infant death syndrome.

In essence, there is ample evidence that household crowding is implicated in a diverse array of health problems for both children and adults (Office of the Deputy Prime Minister, 2004). However, findings implicating crowding in health problems are inconsistent; and many studies lack adequate controls over confounders and measures of crowding. Importantly, the mechanisms for all observed effects on health have not been fully determined, but stress induction is likely involved in a number of cases.

An exhaustive literature review conducted by the British government concluded that there was some evidence to show how crowding affects health. For example, Evans, Lepore, Shejwal, and Palsane (1998) found that residential crowding was related to higher blood pressure among 10- to 12-year-old males (the same result was not observed for females). Evans and Saegert (2000), in a study of 8- to 10-year-olds, found that children in higher-density apartments had elevated overnight epinephrine and norepinephrine, especially when there was greater family turmoil in the household.

Household crowding also appears to have a negative impact on cognitive processing and educational attainment. The evidence for preschool age children is somewhat mixed, with some studies showing significant effects on measures of cognitive functioning and others not, with no clear pattern emerging from the many samples used and the varied measures employed (Evans, 2006). Relations with academic achievement appear somewhat more consistent (Conley, 2001; Evans, Lepore, et al., 1998; Goux & Maurin, 2005; Solari & Mare, 2012). Part of the relation between crowding and educational performance may pertain to children's perceptions of themselves as

learners, as Evans and Saegert (2000) found a negative relation between household crowding and perceived academic competency. Relatedly, Evans, Lepore, et al. (1998) observed an association between crowding and lower academic attainment likely also relates to reduced motivation for task engagement and a sense of learned helplessness. Part of the relation between household crowding and poor academic performance may devolve from poor parent-child relationships (Evans, 2006). However, it is difficult to fully delineate the mechanisms responsible since crowding is associated with numerous other factors that may give rise to low academic achievement.

In their study using data from LA FANS and the Panel Study of Income Dynamics, Solari and Mare (2012) also found positive relations between household crowding and maladaptive behavior in children. Such findings are consistent with the idea that living in confined space increases the likelihood of stress and of poor treatment by others in the household. For example, parents living in crowded conditions are less responsive to their children and engage in less effective monitoring (Bradley & Caldwell, 1984; Evans, Maxwell, & Hart, 1999; Wachs & Camli, 1991). Evans and Saegert (2000) found that punitive parenting mediated relations between household crowding and psychological stress outcomes in children Age 8 to 10. In general, such findings support the notion that crowding leads to strains in interpersonal relationships that negatively impact mental health for children (Evans, Lepore, et al., 1998). Such findings are consistent with the larger literature on crowding showing that people in general and children in particular show both more social withdrawal and more aggression in high-density environments (Evans, 2006). Studies involving families from quite diverse geographic areas done over the last quarter century demonstrate that living in crowded conditions is associated with physiological stress and adjustment problems in children from early childhood through adolescence (Blackman, Evason, & Melaugh, 1989; Evans & English, 2002; Hunt, 1990). However, the studies conducted by Blackman et al. and Hunt point to the difficulty of clearly attributing children's poor mental health to the fact they live in crowded conditions. Living in crowded conditions is associated with exposure to many other conditions associated with poor mental health as well (noise, dilapidated housing, inadequate resources, family disorganization, family conflict, general chaos), including genetically mediated factors (Evans, Wells, & Moch, 2003). Thus, it remains for future research to isolate how crowding by itself contributes to poor adaptive functioning.

### Summary

There is substantial research on relations between various household conditions (aspects of quality) and children's well-being. Even so, the picture that emerges is far from complete for many household conditions. Most studies have focused on only one or two aspects of housing and have not adequately controlled for other potentially consequential conditions in the residence or the broader family context. In many cases, the observed "significant" findings may well represent the cumulative effects of multiple conditions. Moreover, findings obtained in one study are often not replicated in other studies, and there may well be selection biases operative that account for some of the significant findings that have emerged (Leventhal & Newman, 2010). Part of the challenge facing researchers who wish to more precisely delineate how various housing conditions affect development course pertains to the difficulty of mounting long-term studies of housing that are comprehensive in design. Another part stems from a lack of more integrative theoretical frameworks that could help identify critical mechanisms responsible for particular outcomes at particular points in the life course. There is need for theories that can help specify the interplay among several mechanisms responsible for particular outcomes, consistent with ideas from living systems and bioecological theories of human development.

### MATERIALS AT HAND

Those who are involved in constructing curricula for children have long espoused the value of children's engagement with objects, both natural and man-made (Bronson, 1995; Guyton, 2011). Proponents draw from brain science and cultural anthropology alike (McManus, 2002; F. Wilson, 1998). From objects designed for play and instruction (e.g., puzzles, shape sorters, LEGOs, board games, doll houses, cards, electronic toys, construction sets), to objects used in adult activities (e.g., needles, cloth, beads, paintbrushes, power tools, hammers, bows and arrows, crucifixes), to objects found in nature (e.g., seashells, twigs, dandelions, rocks from river beds, skeletons, animal hides), from nuts that grow on trees to nuts that attach to bolts: Objects are seen as sources of pleasure, healing, and learning for children. There is a vast literature showing that manipulation of objects, using objects in the service of a goal, and involvement with others while engaged with objects

helps to develop a wide diversity of skills (Wolff, Levin, & Longobardi, 1974; Wolfgang, Stannard, & Jones, 2003).

In this section there is a brief review of ideas about children's play and how access to various types of objects evokes different forms of play and purposeful activity. This is followed by a consideration of the processes whereby engagement with objects promotes development in different domains, with attention to how the use of various objects reflects individual and contextual factors (i.e., how objects are part of what the broader context *affords* towards particular developmental goals for particular groups). The remainder of the section is devoted to a consideration of different types of classes of objects (e.g., homemade, natural, toys, tools and household materials, equipment of different sorts, media) and what is known about their relation to children's behavior.

### Play

There are particularly strong advocates of the notion that authentic play, often involving engagement with objects has benefits for both learning and mental health (Hirsh-Pasek, Golinkoff, Berk, & Singer, 2009; F. Wilson, 1998). Engagement with objects not only appears to have benefits of its own as regards learning and adaptive behavior, but it often occurs in the context of social interactions that have the potential to engender trust, joy, and scaffolded learning. Brown and Vaughan (2009) argue that such engagements result in new connections between neurons and between disparate brain centers, ultimately helping to sculpt brain organization.

Educators argue that consideration needs to be given to selecting play materials and arranging play areas so that children can derive maximum benefit as regards their engagement with objects and people (Doctoroff, 2001). Considerations include how to make toys and pieces of equipment easily accessible, having variety of materials so as to encourage engagement in various forms of learning and social interactions, having materials that encourage social interaction as well as manipulation, and arranging materials so it is easy for children to identify objects of interest. Research has shown that the affordances of particular kinds of objects are different and, therefore, encourage different types of actions and interactions for children and adults (Rubin, 1977). As an example, preschool children spent more time in outdoor play when they had bigger backyards and more outdoor play equipment (Spurrier, Magarey, Golley, Curnow, & Sawyer, 2008).

## Use of Toys and Equipment

Throughout most of human history adults have fashioned or obtained objects to help them promote the development of children and to simply provide opportunities for recreation. There are archeological accounts (Baxter, 2005; Kemp, 2003) and anthropological analyses (Bishop, 2009; Huizinga, 2008) of objects and their uses, but limited understanding regarding the extent of use or developmental value for most identified objects. Over the past century there has been an upsurge in the production and use of complex materials and apparatus for children, many of which have quite specific purposes. Gibson (1988) contended that objects afford opportunities for exploration and that such exploration leads to changes in perception, action patterns, and cognition. Critically, each type of change leads to adjustments in the other two; thus, perceptions, actions, and cognitions are constantly evolving. Leibham, Alexander, Johnson, Neitzel, and Reis-Henrie (2005) found that access to high levels of materials in the home was associated with sustained interest in particular classes of activities connected to the materials available. New opportunity structures are perceived, new types of actions emerge, and new meanings for the actions and objects are constructed. For example, a study on play with LEGOs in preschoolers showed that advanced levels of play with LEGOs during that period was associated with better performance on mathematics achievement tests in seventh grade, even controlling for IQ (Wolfgang et al., 2003). Play with LEGOs requires that a child build spatially with large numbers of LEGOs and conceive of imaginary structures that represent real objects. That experience appears to initiate cognitive changes that allow better formal operations thinking in the area of mathematics downstream.

There is theoretical (and some empirical) support for the idea that access to toys and other objects promotes both psychomotor and cognitive skills (Tomopoulos et al., 2006; Wachs, 1985). A case in point, play with blocks has long been considered useful in the development of spatial skills (Liedtke, 1995). Likewise, there is research on early language development showing that presenting objects to children contributes to their learning the names of those objects (McDonough, Song, Hirsh-Pasek, Golinkoff, & Lannon, 2011). Objects are high in what language scientists call “imageability,” making it easy for children (or anyone) to connect the name of the object to the visual image of the object. There are stages in the process of learning that

begin with identification of an object’s properties, followed by manipulation or assembly of an object to understand its functions, and then use of the object in the service of some goal or activity (Franchin et al., 2011). Thus, children need access to particular types of objects for a sufficient period of time so that all stages of learning can take place. The process can be difficult for young children, but becomes easier with age.

More research attention has been given to devices aimed at early psychomotor and language development than to devices aimed at other domains of development. A case in point is research on the use of various types of equipment connected to early motor development (e.g., playpens, infant seats, highchairs, swings, jumpers, walkers, saucers, bouncers). There have been controversies and contradictory findings as regards the benefits versus harmful effects of using particular pieces of equipment, including suggestions that some devices may prevent normal patterns of psychomotor development and even encourage counterproductive patterns of locomotor movements (Simpkiss & Raikes, 1972; Talebian et al., 2009). There is even some evidence indicating that high levels of use of baby walkers leads to increased rates of injury (Reidner, Schwartz, & Newman, 1986; Shiva, Ghotbi, & Yavari, 2010; Walker, Breau, McNeill, Rogers, & Sweet, 1996). In some respects the injuries connected to the use of baby walkers points to a broader problem pertaining to the use of objects whose primary purpose is to enhance the experience of children; notably, the use of some objects such as trampolines is connected to increased likelihood of injuries.

Abbott and Bartlett (2001) examined relations between use of several types of equipment and motor development in 8-month-old infants. The pattern of findings that emerged was revealing, granting the relatively small sample used ( $N = 43$ ). Overall time spent with pieces of equipment was negatively related to psychomotor development; however, patterns of relations varied widely across types of equipment. Relations were negative for equipment that was confining (high chair, infant seat, infant swing, jumper), neutral for equipment that allowed some mobility but did not encourage fully normative patterns of movement (playpens, walkers), and positive for equipment that encouraged high levels of movement (saucers).

Greatest attention to the iterative processes connecting engagement with objects and learning has been focused on young children; but there is no theoretical reason for believing that they are less applicable to later age periods. A longitudinal study involving measurement of learning

stimulation in the home when children were in kindergarten showed relations to executive functioning when children were 6 to 8 years old (Mezzacappa, Buckner, & Earls, 2011). Likewise, Sansour et al. (2011) found that access to learning materials and experiences were related to working memory and expressive language skills among school-age children. A longitudinal study that followed children from Age 8 to Age 13 showed that a cognitively stimulating home environment was associated with increasing academic achievement motivation (Gottfried, Fleming, & Gottfried, 1998).

There are social class differences (see Duncan, Magnusson, & Votruba-Drzal, Chapter 14, this *Handbook*, this volume) in maternal conceptions regarding how young children should use toys (Bernstein & Young, 1967). Lower-SES mothers, more so than higher-SES mothers, felt that the purpose of toys was to keep children entertained. By contrast, higher-SES mothers, compared to lower-SES mothers, felt that toys were important in preparing children for school and to let them know that the mother cared about them when she was not with them. There are also cultural (see Goodnow & Lawrence, Chapter 19, this *Handbook*, this volume) and historical (see Stearns, Chapter 20, this *Handbook*, this volume) differences in values and mores pertaining to the use of materials (Gauvin, 2001). Over the past century, as technology has increasingly pervaded all aspects of life and as the nature of employment has shifted, the emphasis on using various means to stimulate children's learning has increased (Bradley, 2009). Engagement with objects (toys and tools included) in the company of more competent others enables children to develop increasingly complex action plans as regards their own behavior. Joint activity is often the venue for these encounters, but the sequence of individually guided and socially guided actions with objects varies and helps to determine a child's pattern of intellectual, psychomotor, and social growth (Gauvin, 2001). There is considerable variation both within and across socioeconomic and cultural groups as regards how often children are exposed to particular types of objects and materials (Bradley, Corwyn, McAdoo, & Coll, 2001). In Latin America and the Caribbean, parents tend to put less emphasis on stimulation and teaching of academic skills, especially early in life, partly because they believe that children attain developmental milestones at a slower pace (Durbrow, Pena, Masten, Sesma, & Williamson, 2001; Pachter & Dworkin, 1997). Cultural models of parenting in Arab countries place less emphasis on stimulation of school achievement than do Western democracies and

Asian countries like Taiwan, South Korea, and Japan. Accordingly, a study done in Bahrain indicated that children there had generally lower numbers of stimulating toys in the house (Hadeed & Sylva, 1999). However, it is important to maintain a broad ecological perspective as regards such findings given that houses in Bahrain tend to be somewhat smaller, thus making accumulation of materials less feasible.

As the diversity of objects in a home increases, so do encounters between household members involving those objects. Notably, as the number of books in a home grows larger, so too does the number of times parents tend to read to children (Tomopolous et al., 2006). Such social interactions between parents and children involving toys and objects have been found to predict children's development (Roggman, Boyce, Cook, Christiansen, & Jones, 2006).

Although there is a substantial literature linking access to learning materials and toy play with achievement and cognitive development, such observed relations may not reflect a simple causal connection between the two (Bradley et al., 1989; Senechal & LeFevre, 2002). More specifically, what a child has access to and that child's developmental course reflect the child's characteristics and the behavior of those in the child's social network (parents, teachers, siblings, playmates, etc.) and the broader affordances of the child's context. As living systems theory would suggest, there are confounds between the physical and social affordances present in a person's life and the characteristics of the person; thus, simple causal attributions about one subset of affordances (e.g., the toys and materials present) and developmental course must be viewed with some skepticism (Farah et al., 2008; J. E. Miller & Davis, 1997). For example, having more stimulating objects in the home was associated with higher levels of achievement, social skills, or cognitive development in several studies; but in the same studies so was having a more involved parent; moreover having a more involved parent was associated with having more stimulating objects (Bradley & Caldwell, 1984; Tesh & Holditch-Davis, 1997). A similar pattern emerged between having more stimulating materials at home and having more enriching out-of-home experiences; namely, each was associated with higher achievement and each was associated with the other (Bradley & Caldwell, 1984; Sansour et al., 2011). In effect, it can be difficult to disentangle relations between engagement with objects and other affordances connected to one's life as they influence developmental course. The complexity of these relations is all the more evident when one considers that the strength of relations between access to enriching materials and

outcomes such as achievement and self efficacy varies by race and ethnicity (Bradley et al., 2000).

Finally, Sirin (2005) found that the average correlation between family SES and achievement was substantially lower than the average correlation between educational resources in the home and achievement. Thus, there is reason to believe that it is engagement with diverse types of materials that is instrumental in promoting a variety of adaptive skills and propensities. This general proposition accepted, it is also clear that children with equal access to materials at home do not necessarily enjoy the same access to other social experiences that help convert such “capital” into adaptive development, most notably interested and informed parents (Sansour et al., 2011). As Lareau and Horvat (1999) posited, there is a difference between possession and activation of family capital, the former necessary but not sufficient for the latter. In effect, what a child derives from access to a particular subset of environmental affordances depends on the broader set of environmental affordances present (physical and social) and what the child brings by way of competencies and proclivities when engaging that subset.

As children age, parents tend to provide different types of toys and materials for them to play with and learn from. Interesting in this regard is research showing that gender preferences for certain types of toys emerge by the second year of life (Jadva, Hines, & Golombok, 2010). Important too is understanding that affordances provided by various classes of toys and other objects typically used by children may affect their development in particular domains. Studies show that during early childhood boys and girls tend to select toys that clearly promote gender identity and various forms of social action connected to gender (e.g., dolls, cuddly toys, princess books, power rangers, transformers, toy airplanes, train sets). However, in the case of girls, toy selections also lead to the promotion of esthetic sensibilities; whereas toys favored by boys tend to promote psychomotor, technical, and construction skills (Francis, 2010). Research shows that the gender stereotypes in toy preferences that emerge in early childhood tend to persist (Cherney & London, 2006). Boys tend to select toys requiring active manipulation and the use of spatial abilities, whereas girls tend to select toys that involve the use of communicative and social skills (Subrahmanyam & Greenfield, 1994). These gender differences also apply to computer games (see Calvert, Chapter 10, this *Handbook*, this volume), with boys much more likely to play games that contain violence (Cherney & London, 2006). Boys’ higher level of use of video games may reflect the fact that

fewer games are produced that have content interesting to girls, a factor that may be changing as more games and websites are developed. Ethnic-based reasoning about toy preferences emerges by Age 6 or 7 as well (Lam & Leman, 2003), but there is little research on the degree to which such differences may lead to consequential variations in cognitive, psychomotor, or social skills.

### **Homemade Toys and the Use of Natural Materials**

Most research on relations between access to materials and competence in children focuses on books and purchased play materials. Less attention is paid to objects from the natural environment and various tools and materials used as part of everyday family activities. In this section attention is given to materials not expressly purchased for children’s pleasure or development, with a view to how they may help determine the well being of children.

#### ***Using Tools Connected to Home Life and Parental Work***

It obvious that children use household objects for recreational, instrumental, and symbolic purposes, but the way in which they use such objects and the developmental consequences of such uses have rarely been studied. There have long been discussions on the potential value of using objects such as mirrors to teach children about self-identity and body parts; as well discussions on the use of cups, bowls, and laundry baskets for ideas and techniques regarding nesting and stacking (Bronson, 1995). There is high likelihood that utensils designed for cooking will be used toward cooking-related knowledge for children. Pots, pans, stoves, knives, and other cooking utensils and appliances are likely to be used for other purposes as well, purposes that likely would have an impact on the development of psychomotor and cognitive skills. That said, research has yet to delineate the nature of such impacts. The use of household objects by children resurrects ideas from theoretical concepts connected with environmental affordances (Gibson, 1982); specifically, that the functional utility of an object depends on how tightly it is connected to an individual’s interests and competence. Some objects are more open-ended with respect to the kinds of uses they induce, whereas others are more closed-ended. Some toys (likewise some tools) are designed to serve a rather narrow purpose (e.g., a sewing needle)—quite often a solitary purpose. There is not much about them that encourages broad applicability, imaginative play or social engagement. By contrast, some toys and tools lend themselves to transformative actions and collaborative activities, like

construction toys, toys that combine physical and virtual components (Petersson & Brooks, 2006).

Gauvin (2001) argued that children come to understand how particular objects can be used as a consequence of observing how others use them and by engaging in joint activities. Through time such interactions help determine the meaning and significance of the object for a child and aids a child in planning how to use the object. In effect, a child's cognitive development reflects the nested structure of everyday actions involving household objects.

Wachs (1985) argued that there is no simple relation between engagement with objects and patterns of development. He invoked the notion of "specificity" as regards functional relations between engagement with particular objects and development of particular competencies or proclivities. He contended that engagement with a particular object may promote development in one domain but not others and with some children and not others. The more open-ended the object, the more likely its effects will be multiple and wide ranging, partly owing to the greater likelihood it will engage children's intrinsic motivations and promote feed-forward loops among areas of competence (Cunha & Heckman, 2007).

Finally, although most research on household objects and family tools focuses on the advantages they bring to children, not all objects necessarily bring such advantages. Narang et al. (2010) reviewed a growing literature on the costs to children of having guns in the home. Data from the Centers for Disease Control and Protection (CDC) indicated that 5,285 American children were killed by guns in 2005 (CDC, 2006). With adolescents, guns are a primary means of suicide (M. Miller & Hemenway, 2008).

### *Using Materials From Nature*

Children use objects found in nature for recreation and learning (rocks, sticks, sand, leaves, seashells, nuts, bark). As children in highly technological societies have moved to using human-made toys, Louv (2005) voiced worries that the types of experiences afforded by "natural" objects are being lost. In some respects this worry connects to ideas pertaining to the value of authentic play (Hirsh-Pasek & Golinkoff, 2003) and to the restorative qualities of nature (Wells, 2000). To date there has been little research that investigates the advantages of play with natural objects, albeit there is some regarding the link between play outdoors and adaptive functioning (Hinds & Sparks, 2011). As one might expect, there is some evidence that being in natural surroundings and engaging natural objects increase certain facets of sensory awareness (Louv, 2005).

More generally, it would seem that the affordances of most natural materials lend themselves to rather open-ended play and utilization, contrasted to many man-made objects that are designed to afford more prescribed functions.

The idea that materials found in nature may have different affordances than materials produced commercially has an analog in the idea that affordances found in nature tend to be different from the affordances in built environments. Fjortoft (2001) looked at how play in different natural environments (landscapes) induced different types of play behavior and how more play in natural landscapes improved psychomotor skills. The experimental children were taken to five chosen natural habitats for 1 to 2 hours a day as part of kindergarten. The comparison group had access to kindergarten playgrounds with recreational equipment. Observations made in the five different habitats showed that each had affordances that encouraged distinct types of play and physical activities. By the end of the year, children randomly assigned to the natural environments group showed better performance in two areas of psychomotor development directly related to the differential experience in the natural versus human-made habitats. In their study of inner-city children, Taylor et al. (1998) found that, when families lived near areas with high levels of vegetation, children engaged in more overall play and that their play was more creative.

### **Equipment, Devices, Spaces, and Physical Activity**

Because modern lifestyles have led to higher levels of sedentary behavior (Matthews et al., 2008; Nader, Bradley, Houts, McRitchie, & O'Brien, 2008; Strong et al., 2005), with concomitant increases in obesity and associated health problems (Ekelund et al., 2007; Koplan, Liverman, & Kraak, 2005), there has been an acceleration of interest in factors that may increase physical activity in children. Experimental and observational studies, mostly done in school or park environments have shown that having access to playground equipment and apparatus markedly increases the amount of moderate to vigorous physical activity children engage in (Ridgers, Fairclough, & Stratton, 2010; Rosenberg et al., 2010; Spurrier et al., 2008). For young boys, access to parks in the neighborhood also increased the amount of physical activity (Roemich, Epstein, Raja, & Lin, 2007).

In contrast to having playground equipment, having electronic equipment (see Calvert, Chapter 10, this *Handbook*, this volume) in the home, especially in a child's bedroom, decreased the level of physical activity

(Rosenberg et al., 2010). Analysis of data from the Children Living in Active Neighborhoods study showed that having more materials to support sedentary behavior in the home was related to body mass index and the amount of moderate to vigorous physical activity during adolescence, with some gender differences identified (Crawford et al., 2010). A separate study involving 294 adolescents found that having access to equipment for physical activity was connected to the amount of moderate to vigorous physical activity for boys but not girls (Patnode et al., 2010). Another study of 358 adolescents found that the density of physical activity equipment in the home was negatively associated with low-density lipoprotein, total cholesterol, insulin resistance, and percent body fat, whereas the density of media present in the home was positively associated with the same biomarkers (Dengel et al., 2010). Such findings are consistent with research showing that watching TV is associated with obesity and intervention studies showing that reducing time spent watching TV and on the computer lead to reduced BMI in children (Epstein et al., 2008; Robinson, 1999). However, Gattshall, Shoup, Marshall, Crane, and Estabrooks (2008) found that having more equipment in the home to support physical activity does not always guarantee children will engage in more active play. In that sense, access to equipment may function much like having access to nutritious foods, which does not induce appropriate food consumption by itself.

In addition to what toys and objects themselves directly afford children by way of opportunities for motivation and learning, their availability increases the likelihood of social interactions between children and other household members (Tomopolous et al., 2006). There are also studies showing that having access to playground equipment is related to increased levels of social interaction among peers; but with findings suggesting that pathways of influence between physical-environmental and social affordances may operate in both directions (Giles-Corti & Donovan, 2002; Hume, Salmon, & Ball, 2005). Having such resources available at home or the nearby environment increases the probability of social exchanges that promote psychomotor, language, cognitive, and social development and that could lead to self-productivity in learning (Cunha & Heckman, 2007). They could lead to a stronger sense of agency, self-directedness, and learning motivation (Ryan & Deci, 2000). That said, there is uncertainty as regards the pathways and moderators of these relations; and the cross-sectional design of most studies leaves ambiguous the primary direction of effect as regards how availability

of materials and spaces for physical activity may encourage active social exchanges.

One of the more intriguing findings from the study by Hume et al. (2005) was how strongly children's perceptions of the physical and social affordances of their homes influenced actual levels of activities (see Vandell, Larson, Mahoney, & Watts, Chapter 8, this *Handbook*, this volume). This finding may connect to the broader literature on socioeconomic differences in family environments. Specifically, chronic poverty and other risk factors (e.g., poor quality housing) can lead to stress and depression in household members, which then leads to higher levels of negative and lower levels of positive interactions between them (Bradley & Corwyn, 2003). This latter circumstance could easily contribute to negative perceptions of home life and lower levels of productive activity in children. Another finding emerged in a study by Spurrier et al. (2008). Specifically, they found that the level of play among young children not only reflected the amount of playground equipment available at home but the size of their backyard. So, as theory would predict, it not just what is in a space that matters, but the amount of space as well.

### **Books and the Home Literacy and Numeracy Environment**

A survey done in 43 countries showed that number of books in the home was positively correlated to reading comprehension in 15-year-olds (Chiu & McBride-Chang, 2006). Not surprisingly, measures that attempt to capture the home literacy and numeracy environments also tend to include items pertaining to activities with materials such as books, painting and drawing supplies, games and writing implements, playing cards, board games, calendars, calculators, and the like. Such activities are associated with achievement and linguistic competence (LeFevre et al., 2009; Melhuish et al., 2008). Moreover, parents' engaging in these activities with their children connects to children's interest in books and learning materials (Farver, Xu, Eppe, & Lonigan, 2006).

Griffin and Morrison (1997) found that the home literacy environment predicted language-based skills but not number-based skills in both kindergarteners and second graders, controlling for child IQ and maternal education. Likewise, A. Johnson et al. (2008) found that access to books was related to child vocabulary attainment, controlling for household chaos and maternal reading ability. A. Johnson et al. (2008) also found that the number of books available to a child was associated with the child's

vocabulary skills but that the time children spent amusing themselves with books was related to strength of vocabulary and to phonological awareness. These distinct patterns of relations suggest that somewhat different patterns of exposures undergird the development of vocabulary and reading comprehension. Further support for such a notion derives from a study by Melhuish et al. (2008). Specifically, a group of items documenting general routines and social encounters within the family did not predict academic achievement, whereas a group of items documenting activities that provided clear learning opportunities did. Further support for the idea of specificity of environmental action comes from the study by Farver et al. (2006). Specifically, emerging reading skills in children was significantly correlated with the parent's specific involvement in literacy activities with their children, not the parent's own literacy habits. Moreover, the parent's literacy habits were only moderately correlated with the degree to which they spent time engaged in literacy activities with their children ( $r = .42$ ).

LeFevre et al. (2010) presented a model for the development of mathematics competence that includes the development of linguistic skills, quantitative skills, and spatial attention. There is evidence that the first of these pathways, linguistic skills, is supported via access to reading materials and activities involving language; but the third, spatial attention, would likely be supported by having materials requiring the use of spatial skills—although the details regarding this possibility have yet to be examined. Dearing et al. (2012) found that the general level of investments for learning available in the home (including materials and enriching activities) were related to arithmetic and spatial performance for first-grade girls; however, the direct involvement of parents in helping children learn math was also a factor in math performance. Research indicates that achievement in both math and science is associated with the child's perception of how much math or science is actively encouraged and supported in the home (Fraser & Kahle, 2007).

### Support for Development in Targeted Areas of Competence

There is a growing literature on the conditions needed to support children's competence in areas such as science, art, music, and athletics (Elliot & Dweck, 2005). Although each area requires that children engage with relevant objects and materials to gain expertise, most research focuses on the kinds of organizational structure

and social encounters children need rather than on objects and materials per se (McPherson, 2009). J. Davidson, Howe, Moore, and Sloboda (1996) found that children's achievement in music was related to having an instrument at home, plus parental involvement in music lessons and practice. Phillips (2003) found that involvement in instrumental music programs depended on the home musical environment, which included access to musical instruments as well as parental investments in music lessons. A similar pattern of findings emerged in study of science proficiency in 15-year-olds. In effect, it was the opportunities to learn available at home, including access to materials connected with science (books, computers, other devices) and parental support that showed strong relations with performance in science (Liu & Whitford, 2011). In overview, the very limited research done on home supports for competence development and activity participation in areas such as music and science indicate that children from homes richer in educational supports (including materials directly connected to performance) tend to more frequently engage in relevant activities and perform better. However, the total canon of research in this area is very limited.

### The Multimedia Universe

The vast majority of American children—and increasingly children worldwide—have access to multiple forms of media (see Calvert, Chapter 10, this *Handbook*, this volume). There are those who applaud this revolution in access, believing it affords new opportunities for learning, recreation, and social networking. Likewise, there are those who voice concerns that children will be exploited and misdirected (Brooks-Gunn & Donahue, 2008). There are age variations in how much time is spent engaged with media, but the amount of time is growing, particularly among young children (Rideout, Hamel, & Kaiser Family Foundation, 2006). Best estimates are that on a typical day more than 80% of children under 6 use some type of screen media and they spend about 2 hours doing so. In about one third of homes, the TV is on most of the time. About half of preschool-age children have some type of console video game player available to them in the home. The majority of American homes have two or more TVs, with many children having TVs in their own rooms. Nearly 9 out of every 10 school-age children in the United States have access to a computer at home, and 3 out of 4 have Internet access. More than half of U.S. children have their own hand-held video games and about the same number now have personal cell phones. Takeuchi (2011) reported that

more than half of U.S. American children routinely use some type of hand-held gaming device and over two thirds play with TV-based video game consoles. These increasing numbers notwithstanding, there is still an economic digital divide as regards access. Part of what the digital divide represents is *how* children are spending time with media (including time with multiple media simultaneously) more so than *how much* time they spend exposed to media per se (Warschauer & Matuchniak, 2010). That said, high accessibility of media to children in their homes (especially in their own rooms) and a lenient attitude of parents toward media use converts to more average hours of access to media in the household (Roberts, Foehr, & Rideout, 2005). A key factor in determining how much media exposure children get is the amount of time their parents spend watching TV, using the computer for recreational purposes, and the like (Roberts et al., 2005). Finally, the patterns of media use documented for children in the United States are not unique to America. Studies done in other developed countries reveal similar patterns (Hardy et al., 2006).

Most of the time preschool-age children spend watching TV, using computers, and playing video games, they do it independent of their parents (Takeuchi, 2011). Even when parents are present, it does not mean that they are carefully monitoring the content (Rideout et al., 2006). Parents voice concerns about children's use of TV and other media, complaining that it reduces the amount of exercise children get and may pose dangers from predators (Takeuchi, 2011). However, the majority also state that their children more often imitate positive than negative behaviors observed on TV. That said, most parents of preschoolers voice that their children seem highly attentive and responsive to commercials seen on TV. Research appears to attest to this latter worry (Calvert, 2008).

A real challenge in understanding the influence of media on children's development is that there is so much diversity in media used by individual children as well as a constantly changing media landscape (Rideout et al., 2006). Additional challenges derive from the fact that children of different ages use media in somewhat different ways and respond to aspects of media differently. In their review, Kirkorian, Wartella, and Anderson (2008) made note of fact that young children do not readily learn from media due to their need to interact with real people to grow cognitively and linguistically. This problem has been dubbed "video deficit."

As children age, different aspects of media become more perceptually salient and cognitively engaging, with some evidence that certain types of early exposures may

lead to downstream problems with attention (Zimmerman & Christakis, 2007). During early childhood, children are able to benefit from educational media productions and access to computers at home, with low-income children appearing to derive particular benefit (Fish, Li, McCarrick, et al., 2008). That said, there is evidence that more than 2 hours of daily exposure to media may result in lower achievement (Rideout et al., 2006). As Schmidt and Vandewater (2008) noted, the "effects" of media consumption depend on whether the content is educational or entertainment in focus. During middle childhood and adolescence children can take advantage of video games, instructional productions on the Internet, and educational content on TV to assist learning in all areas. As yet there is no compelling evidence that exposure to such programming is generally better than exposure to more traditional forms of learning; however, it may afford some children access to content that would otherwise be very hard to obtain. Part of the inconsistency in patterns of results obtained thus far appears to reflect differences in the nature of the learning experience via media students are exposed to (Warschauer & Matuchniak, 2010). Critically, web-based instruction is a rapidly evolving component of the total media landscape for children—a type of mesosystem phenomenon with little available research to indicate precisely what it means for children's development.

In some respects video games, personal digital assistants (PDAs), and websites present experiences with different affordances than TV, radio, and more traditional media; that is, they are interactive. They have features that resemble play and, thus, have potential to assist children's development in ways similar to well-designed play experiences (Bavelier, Green, & Dye, 2010; Lieberman, Fisk, & Biely, 2009). Research indicates that computer-based games can facilitate certain cognitive skills (De Lisi & Wolford, 2002) and achievement (Clements, 2002). As games and activities on media devices have become more like those available in natural and educational settings, recommendations and standards pertaining to quality are emerging to help guide in the production of games that afford children positive learning and recreational experiences.

Perhaps the greatest concern voiced about media pertains to how involvement with various forms of media influences children's social, emotional, and physical well-being. Having more electronic games at home is associated with lower levels of physical activity and higher body mass index (BMI), especially for boys (Escobar-Chaves & Anderson, 2008; Fakhouri, Hughes, Brody, Kit, & Ogden, 2013; Timperio et al., 2008). McHale, Dotterer, and Kim

(2009) highlighted the point that children's engagement with media plays an important role in identity development, social networking, and connecting children to social institutions. There are worries that media technology has increased risky and self-injurious behavior in some youth and made others more susceptible to bullying and predation (Brooks-Gunn & Donahue, 2008). For certain, media have become an integral means of communications between children and their peers and among family members (Subrahmanyam & Greenfield, 2008). Although teens state that use of communications media has improved their social relationships, the evidence is equivocal, and there are indications that some children may be less interested in face-to-face communication as a result (Subrahmanyam & Greenfield, 2008). What seems clearer is that feedback received from network friends affects adolescents' self-esteem (Valkenburg, Peter, & Schouten, 2006) and it has opened up additional avenues for bullying and exploitation (Wolak, Mitchell, & Finkelhor, 2006). Media violence is a risk factor for aggression, and advertisements on popular media increase smoking and drinking (Escobar-Chaves & Anderson, 2008; Huesmann, Moise-Titus, Podolski, & Eron, 2003; Paik & Comstock, 1994; Wallenius & Punamäki, 2008). Media can contribute to children's fears and anxieties as well as increase empathy (Weiss & Wilson, 1996; B. Wilson, 2008). Cross-sectional and longitudinal evidence links watching violence on television to social as well as physical aggression into adulthood (Coyne, Archer, & Eslea, 2004).

Although some of the mechanisms responsible for observed relations between viewing violence and subsequent manifestation of antisocial behavior would seem operative for prosocial behavior as well, there are fewer long-term studies of such relations. There is evidence for short-term impacts, and a meta-analysis conducted by Mares and Woodard (2005) indicated an overall effect of .27 between viewing prosocial content on the media and prosocial behavior in children. These broad associations notwithstanding, part of what determines impact on children is correlated actions on the part of parents (Nathanson & Cantor, 2000). Although parents report having rules about the use of most forms of media (Takeuchi, 2011), research has shown that, even when parents agree that use of social media represents a significant threat, they do not tend to engage in extensive monitoring (Rosen, Cheever, & Carrier, 2008). The precise implications of the low levels of monitoring are not fully clear, but research on use of monitored versus unmonitored chat rooms clearly indicates that children's experiences in unmonitored chat

rooms are more negative (Tynes, Reynolds, & Greenfield, 2004). Moreover, there is a general concern that extensive use of social media may have negative consequences for parent-child relationships, especially for older children (Subrahmanyam & Greenfield, 2008). Although the findings would seem to confirm broadly held suspicions that the use of social network sites is particularly bad for family relationships, interpreting the findings is not straightforward as there are selection biases as regards how adolescents use the Internet and computers more broadly.

There is very little information on exposure to multiple forms of media during the day or over longer time spans (Wartella, Huston, Rideout, & Robb, 2009). Southwell and Doyle (2004) highlighted the importance of better understanding individual motivations for using particular media and better understanding how the affordances of various media versus the affordances of potential alternative activities may play into individual choice. Vandewater and Lee (2009) suggested the use of multiple measurement strategies, including time diaries, monitoring systems, and experience sampling methods. Research on the effects of particular types of media exposure is challenged by confounds that exist between the overall amount of exposure to media children get and the content present in those exposures. It is also challenged by confounds that exist between amount of exposure and other factors present in a child's social context, including parental and peer mediation of various types of exposures (Oakes, 2009). As the engagement model of person-environment interaction (Neufeld et al., 2006) would suggest, there is considerable interplay among the physical and social elements present in one's life, and considerable renegotiation of how to achieve good fit towards different ends.

Electronic media have become deeply insinuated in the fabric of modern home life. They often guide the arrangement of objects and materials within the residence and influence the arrangement of space. G. Johnson (2010) argued for the inclusion of the techno-subsystem into Bronfenbrenner's ecological developmental model. In support of the idea, he compared the amount of variance in language and cognitive development accounted for by Internet use and family SES and found that the former accounts for a greater proportion of variance than the latter. Interesting as the comparison is, it is a bit misleading in that indices of other recreational and learning materials present in the home also account for more variance in child achievement than SES as well. Nonetheless, the idea that electronic media function as a meaningful subsystem of the home physical environment would appear to have merit.

## Summary

Throughout history humans have sought and fashioned objects to increase the chances of survival and productivity, and to enhance overall well-being. As life has become more varied and complex, the construction and use of objects has become ever more deeply insinuated in human experience. There is a substantial literature on how people use objects and how objects are implicated in various behavior patterns and developmental domains. There remains little doubt that having access to various types of material enables children to develop specific forms of competence; but research is clearer about the instrumentality of objects for early development of competence and simple forms of behavior (e.g., the play of toddlers) than it is for higher levels of competence and more intricate forms of behavior. It is often difficult to pinpoint just how engagement with a particular object functions to support a particular pattern of behavior or the enactment of a particular set of competencies. That is not surprising given that behavior patterns tend to be multiply determined, that is, reflective of many experiences over time and the affordances of particular settings. It is also not surprising that we know less about the “influences” of new object forms (e.g., electronic media). What seems clear is that simply having more objects at one’s disposal is not all that matters, as they afford opportunities for harm as well as enhancement and they can direct as well as facilitate paths of development.

## HOUSEHOLD CHAOS

Evans, Gonnella, Marcynyszyn, Gentile, and Salpekar (2005) found that high levels of environmental chaos at home were related to poorer self-regulation, greater stress, and higher learned helplessness during middle childhood. Their findings are consistent with an expanding repertoire of studies showing associations between household chaos and poor children’s social, emotional, and cognitive functioning (Vernon-Feagans et al., 2012). The relation between household chaos and less optimal child functioning seems to occur because chaos produces stress in children and because it degrades the care provided children. For example, Dumas et al. (2005) found that chaos directly contributed to poorer attention focusing and ability to accurately respond to social cues in young children.

The indirect path between household disorder and lower competence and adaptive behavior in children via poorer

quality parenting has received considerable research support (Dumas et al. 2005; A. Johnson et al., 2008). Coldwell, Pike, and Dunn (2006) found that behavior problems in children who lived in more chaotic homes were more pronounced, partly due to increased negative behavior on the part of both parents and decreased positive behavior on the part of fathers. Deater-Deckard et al. (2009) also observed that household chaos was correlated with poor housing conditions and a lower quality literacy environment. It was also correlated with lower child IQ and more conduct problems, even accounting for other limitations in the home environment.

The pathway to poor development through parenting seems especially likely in many households characterized by disorder in that maternal depression is also common in such households (Calam, Jones, Sanders, Dempsey, & Sadhnani, 2012). In similar manner, chaos is also more common in households when parents have addiction disorders, and there are established links between multiple forms of addiction and poor parenting (Haugland, 2005). With these general patterns in relations between home chaos and poor child functioning accepted, the “effects” do not seem the same in all families. In the study by A. Johnson et al. (2008), household disorder was more influential in situations where mothers had greater reading skills themselves; in effect, it seems to disrupt the generally productive involvement of otherwise competent mothers. This likelihood also manifests itself in the findings by Vernon-Feagans et al. (2012) in that household chaos had a stronger impact in terms of reducing positive aspects of parenting than increasing negative ones. It is important to acknowledge that the association between household chaos and maladaptive behavior in children may be partly genetic (Jaffee, Hanscombe, Haworth, Davis, & Plomin, 2012). It also appears to be the case that there can be interplay between the amount of order at home and in the neighborhood as regards when adolescents will engage in some risky behaviors (Roche & Leventhal, 2000).

There is not an agreed on definition of what constitutes family chaos; and it is not clear that all potentially disruptive conditions function to degrade parenting and child development. Consider residential mobility as an example, because it has high relevance for many of the topics discussed here. Frequent movement may create sufficient disturbance that its impacts would likely be detrimental. However, modest residential mobility could have differential impacts depending on whether the move was to a better equipped, more spacious home in a more enriched locale or to a place where accoutrements were

largely lacking (see Murphey, Bandy, & Moore, 2012, for a discussion of the differences).

Wachs and Evans (2009) contend that too much stimulation is disruptive, which raises the issue as to whether homes that contain lots of toys or media devices may present some of the same challenges to parents and children that homes that contain more established forms of chaos. Right now, research on chaos does not address such issues to any appreciable degree. However, findings from several studies in this area, just like studies on media use, suggest that having lots of "good things" may reduce the likelihood of critical positive interactions between household members and potentially lead to nonoptimal realignments of interactions at home. Dynamic systems (chaos) theory suggests the possibility of such realignments and bifurcations in patterns of environment-development relations (Ward, 1995).

## EPILOGUE: THE EVOLUTION OF HABITAT

Throughout most of human history the vast majority of humans lived in small residential facilities that contained very few possessions or amenities and that directly connected to natural surroundings. In developed countries, homes are now more spacious, more complex, and more tightly intertwined with other man-made environments—less so homes in poor countries, but even in poor countries fewer residences connect to natural surroundings (Bradley, 2012). While at home, increasing numbers of children spend less time with others and nature, more time with commercially constructed objects and social networks that lack face-to-face encounters and that may include members vastly different by age, ethnicity, or geography (G. Johnson, 2010). Time while at home or the nearby environment tends to be spent in vastly different types of activities than was the case even a century ago. These differences insinuate themselves into how children think, what they value, and how they form identities.

The physical and connected social conditions now present in daily life also change where family members look for guidance in planning activities and evaluating information. In some ways, the new physical affordances of life have changed social relationships, including parent-child relationships, creating new life niches. Whereas in the past adults have been more expert in how to manage objects and events, there are now increasing instances of children becoming their parents' teachers. Research provides some indication of the consequences of these changes and some

ideas on how best to adapt in the new circumstances. However, research on most issues pertaining to the physical environment is far from adequate and rarely captures the full extent of changes present. What seems clear is that the rapid evolution in human environments requires constant reorganization (Rice, 2012), some of which might be facilitated by access to materials and equipment now more readily available. However, as predicted by dynamic systems theory, some of the changes in affordances may lead to disturbances in patterns of organization present in family life and realignment around new organizational attractors. Just as it seems that the research base to adaptively manage such changes may be lagging the pace of change in our physical and social surroundings, it may also be the case that current theory is not fully up to the challenge of explaining relations between the affordances present in current human habitats and how those are implicated in human development. Thus, extensions of current theory to more precisely address emerging aspects of housing and the physical environment may well be needed to guide productive research and personal agenda. Children's housing and physical environments are now dense with conditions that require more dexterity and precision in the information provided by developmental science if children are to engage in more productive life pathways.

## INTRODUCTION

Several decades of research demonstrate a link between neighborhood residence and human development throughout the life course: literally, from birth until death, and all developmental periods in between. At birth, neighborhood features are associated with newborns' outcomes after individual and family background characteristics are taken into account (e.g., Morenoff, 2003), which may have

---

Tama Leventhal would like to acknowledge the support of the Foundation for Child Development and the William T. Grant Foundation. Véronique Dupéré was supported by grants from Canada's Social Sciences and Humanities Research Council (SSHRC), the Université de Montréal Public Health Research Institute (IRSPUM), and the Fonds de recherche du Québec—Santé & Société et Culture. We are grateful to Margaret Elliott, Natalya Zaika, and Lauren Mims for assistance with this chapter.

lifelong ramifications for health and well-being. In early childhood, neighborhood conditions continue to matter for children in both the short- and long-term (Dupéré, Leventhal, Crosnoe, & Dion, 2010; Wheaton & Clarke, 2003). In later childhood and adolescence, exposure to neighborhoods increases as youth gain autonomy and spend more time outside of the home (Steinberg & Morris, 2001). During these developmental periods, neighborhoods remain associated with children's functioning, but have unique importance for peer group affiliations, engagement in risky behaviors, and initiation of sexual activity (Leventhal, Dupéré, & Brooks-Gunn, 2009). Continuous exposure to neighborhood disadvantage during the childhood and adolescent years compromises development (Wodtke, Harding, & Elwert, 2011). The potential influence of neighborhood conditions extends beyond these first two decades of life, playing a role in adult health, well-being, and mortality (e.g., Diez-Roux & Mair, 2010) and may

be transmitted to the developmental outcomes of the next generation (Sharkey & Elwert, 2011).

The goal of this chapter is to go beyond enumerating studies that have found connections between neighborhoods and development; we focus on synthesizing findings from methodologically rigorous research to lay a foundation of what we know about *how* and *why* neighborhoods matter for children during the first two decades of life to make recommendations for moving the field forward in both the research and policy arenas. We begin the chapter with an overview of the history and context of neighborhood research, with special attention to the intersections of research and policy. We next turn our attention to defining the neighborhood context for children; broadly, we conceptualize neighborhoods as a proximal social context in which children and families engage in a range of daily activities and interactions with individuals and with institutions that control access to opportunities and resources. By addressing issues of theory and measurement in neighborhood research, we provide a framework for the third section on approaches to studying neighborhood influences on children's development. The fourth section presents a review of the current state of research in the field, integrating multiple aspects of the neighborhood context and synergies with related contexts and individual characteristics. The fifth section then considers the neighborhood as a unit of intervention. Finally, we offer a dynamic framework for the study of neighborhoods and child development before presenting our conclusions.

## PROGRESSIVE ERA TO PROMISE NEIGHBORHOODS

During much of the 20th century, scholarly attention to neighborhoods outpaced policy attention to neighborhoods. Historically, however, this situation was not always the case: Neighborhoods as a target of policy intervention can be traced back to public health and safety efforts launched by social reformers during the Progressive Era (1890s to 1920s). During this era of industrialization and urbanization, attention was given to “slum” or “ghetto” neighborhoods, which were poor areas, often with large immigrant concentrations. This period was marked by advocacy and reform around issues for children, leading to the passage of such protections as child labor regulations and such benefits as the provision of public education. The focus on children was in many ways tied to the real and perceived effects of neighborhood conditions: Concern

over the spread of disease and inadequate housing in poor neighborhoods came into public consciousness, and reformers mounted maternal and child health campaigns in response. Moreover, juvenile delinquency arose as another area of concern, leading to states' creation of juvenile courts, and spurring research on links between neighborhoods and crime and delinquency.

The sociology department at the University of Chicago became a hub for the study of urban sociology and ecology; notably, researchers Robert Park and Ernest Burgess began to use empirical methods to study urban social changes and related problems, focusing on crime and delinquency, with adolescent peer groups featuring prominently (Park & Burgess, 1925). Their work in the 1920s and subsequent work of others from the Chicago School identified factors such as economic disadvantage, ethnic heterogeneity, and residential instability as neighborhood conditions associated with elevated rates of crime and delinquency. In a seminal book for the field of neighborhood research, Shaw and McKay (1942) empirically demonstrated that high rates of delinquency persisted over time in certain neighborhoods despite concurrent residential turnover; this finding suggested that delinquency could be transmitted at the neighborhood level, and was therefore not solely an individual-level problem (see Sampson & Morenoff, 1997).

Policy interest in neighborhoods waned after the Progressive Era, but sociologists continued neighborhood research over the next decades of the twentieth century, albeit with less explicit attention to adolescents or children. Further, policies not directly targeting neighborhoods (e.g., housing, school districting) continued to shape neighborhoods during this period. Changing demographic patterns, notably rising concentrations of unemployment and poverty and growing economic and racial segregation in urban centers throughout the 1970s and 1980s, once again ignited policy interest in neighborhoods (e.g., Massey & Denton, 1993). Much of the focus was, and continues to be, on the types of neighborhoods identified by William Julius Wilson in his 1987 landmark book, *The Truly Disadvantaged*: geographically isolated, urban neighborhoods that are high in poverty (over 40% of residents living below the poverty threshold), with high concentrations of minorities. Shaw and McKay's (1942) book suggested a neighborhood-level focus for delinquency decades earlier, but it was Wilson's (1987) book that shifted academic and policy discussions on poverty from the individual to the neighborhood. These discussions around place and poverty prompted multidisciplinary research initiatives, which have grown substantially since the mid-1990s (Sampson,

Morenoff, & Gannon-Rowley, 2002). Further, research attention moved beyond simply studying neighborhood poverty or more general disadvantage to include questions about a broader set of neighborhood economic and social conditions and their links to children's development (Leventhal & Brooks-Gunn, 2000).

As neighborhood research grew exponentially, neighborhood policies evolved incrementally, continuing to focus primarily on poverty. Particular interest in the "broken windows" theory, which suggests that signs of social and physical disorder in neighborhoods lead to increases in antisocial behaviors and crime (J. Q. Wilson & Kelling, 1982), contributed to policy changes in many municipalities: Order-maintenance policing was a major initiative in many cities throughout the 1990s (Harcourt, 1998). Such policies were not clearly supported by empirical evidence (e.g., Cerdá et al., 2009), but they reflect a reinvestment in neighborhoods as a focus of policy during the 1990s. Although order-maintenance policing typically targets young men (Braga, Kennedy, Waring, & Piehl, 2001) and as such is relevant for developmental scientists, these initiatives were not shaped by research from a child development perspective.

Other major initiatives also were undertaken at the federal level during this era, largely through the auspices of the U.S. Department of Housing and Urban Development (HUD). Neighborhoods are tightly linked to housing. The presence of public housing projects frequently concentrates poverty in a neighborhood, and beyond this practice, affordable housing is generally not equally or randomly distributed in neighborhoods (Schwartz, 2010). Thus, housing policy plays a critical role in shaping neighborhood contexts. While the United States saw a renewed interest in socially mixed neighborhoods as an explicit goal of affordable housing policy during the 1990s, these policies were already in place in one form or another since the 1970s in many European countries (e.g., Andersson, Musterd, Galster, & Kauppinen, 2007). In the United States, many HUD initiatives focus primarily on tax incentives for economic development, but others, such as Housing Opportunities for People Everywhere (HOPE) VI, have been more directly tied to children and families. The HOPE VI program began in the early 1990s with the goal of improving severely distressed public housing and reducing the concentration of poverty in neighborhoods with assisted housing by creating mixed income communities. Notably, the United States Congress commissioned research initiatives to understand the impact of the program on residents (Popkin, Levy, & Buron, 2009).

Aside from this major federal initiative that began in the 1990s, local community-based initiatives, with roots in the Progressive Era, have been ongoing, both within and beyond the United States. In fact, predating many of the U.S. efforts, during the 1980s France initiated policies to improve economic opportunity and education in targeted Critical Urban Areas—neighborhoods where unemployment was disproportionately high (Debrand, Pierre, Allonier, & Lucas-Gabrielli, 2012). Japan introduced "hometown-making" policies in the 1980s with the goal of building social connections in urban neighborhoods (Wissink & Hazelzet, 2012). Many of these policies, including these two examples, do not have children's development as a core feature.

In contrast, one community-based initiative that received extensive media coverage, the Harlem Children's Zone (HCZ), made child development its centerpiece. HCZ began in 1990 as a pilot project in just one block of Harlem, but grew to cover a 100-block area in Harlem and became the model for President Obama's federal Promise Neighborhoods initiative (Komro, Flay, & Biglan, 2011). It was not until the announcement of the Promise Neighborhoods initiative in 2009 that a clear focus on neighborhood composition, child development, and policy action garnered national attention in the United States. Promise Neighborhoods is administered through the U.S. Department of Education and evaluation of how program strategies relate to children's outcomes is one of its goals. Further, the National Institute on Drug Abuse funded a Promise Neighborhoods Research Consortium to ensure these initiatives have access to research-based knowledge on community change and child outcomes (Komro et al., 2011).

Clearly, the relation between neighborhood-based research and policy has ebbed and flowed over the years. The policy demand for such research stems, in part, from historical and demographic factors and, in part, from the growing quantity and quality of the research. In the remainder of this chapter, we conceive of the relation between neighborhood-based research and policy as mutually influential (Dowsett, Huston, Imes, & Gennetian, 2008). With this overview in mind, we now turn to the conceptual and methodological framework guiding this chapter.

## DEFINING THE NEIGHBORHOOD CONTEXT FOR CHILDREN

In recent decades, the study of children and adolescents has placed greater attention on the dynamic interactions

between individuals and their contexts. Bronfenbrenner's seminal writings on the ecology of human development (Bronfenbrenner & Morris, 2006) were a clear departure from the strict psychological study of development, which focused on the individual and his or her immediate context, typically the family. More recently, relational developmental systems theories (Lerner, 2006; see also Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1) have come to the forefront in the study of human development, providing a useful framework for understanding the complexities of individuals embedded within contexts from time to culture, and including neighborhoods. These theories emphasize the mutual influences of individuals and contexts on one another (i.e., their bidirectional nature), and reject the premise that it is possible to separate the various levels in the developmental system (Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1).

For the study of neighborhoods, these theories help to understand how the neighborhood context influences child development, but also how these influences are affected by other contexts such as families, peers, schools, and the like as well as interactions with individual characteristics such as gender, race/ethnicity, and personality. Further, the emphasis of these theories on developmental as well as historical timing underscores the importance of examining neighborhood contexts as potentially having different associations with developmental pathways at different points in the life course (see Elder, Shanahan & Jennings, Chapter 2, this *Handbook*, this volume). For example, very young children's interactions with their neighborhood contexts may be controlled largely by their parents, whereas adolescents may engage more closely with the people, institutions, and physical aspects of their neighborhoods, and potentially have a direct influence over neighborhood features through their actions and behaviors. Thus, in defining the neighborhood context for children, we focus on the elements of neighborhoods that help describe and explain features of development beyond the family unit, while recognizing that neighborhoods and families are interactive parts of the developmental system.

One of the challenges in understanding the importance of neighborhoods for development is that neighborhoods are collections of individual families. This problem of endogeneity (or selection bias) can be summed up by the fact that people are not randomly assigned to neighborhoods, but rather have varying degrees of choice regarding where they live. For children, it is typically parents who

are responsible for making locational decisions. Parental characteristics and family circumstances are strongly related to neighborhood of residence, and these parent and family background characteristics also are strongly related to children's development. Moreover, throughout the life course neighborhood and family characteristics may shift together, and earlier features of the developmental context are predictive of later features (Elder et al., Chapter 2, this *Handbook*, this volume). Younger families are, on average, more likely to live in less affluent neighborhoods than families with older children and adolescents, but as children age into elementary school, families are more likely to move from urban to suburban settings (South & Crowder, 1997). Non-normative life events, such as parental divorce or job loss and unemployment, which have clear implications for children in and of themselves (see Ganong, Coleman & Russell, Chapter 4, this *Handbook*, this volume), are also associated with the risk of moving to poorer neighborhoods (Sampson & Sharkey, 2008; South & Crowder, 1997).

It is, therefore, challenging to understand the role neighborhoods play in child development beyond more proximal family effects. Care must be taken both in designing studies to assess these intertwined levels of context, and also in applying statistical techniques to disentangle these overlapping contexts. For these reasons, studies that do not attempt to address the influence of family background simultaneously with neighborhood characteristics when examining children's development are given limited attention or simply excluded from this chapter.

### Neighborhood Boundaries

Before defining the array of neighborhood features that contribute to the study of child development, we must further clarify: What is a neighborhood? Most often, researchers use boundaries identified by the U.S. Decennial Census, or comparable national statistical areas (e.g., Enumeration Areas in Canada and *Îlots Regroupés pour l'Information Statistique* or aggregated units for statistical information in France). In the United States, the units of analysis most frequently used are the census tract (approximately 3,000 to 8,000 people) and census block group (600 to 3,000 people), although some researchers combine adjacent and relatively homogenous tracts or block groups to form neighborhood clusters (e.g., Brody et al., 2001; Sampson, Raudenbush, & Earls, 1997). Others have used geographic information systems (GIS) tools to incorporate information on the neighborhood tracts or block

groups surrounding a participants' own neighborhood (e.g., Hillsdon, Panter, Foster, & Jones, 2006).

Using these neighborhood boundaries for research on child development has both advantages and disadvantages. One of the greatest advantages is the access to consistent, reliable information on the structural characteristics of neighborhoods; that is, the compositional or sociodemographic attributes of the area, such as median income, employment rate, and racial composition. It is important to note that recent changes to sampling in the census and the related American Community Survey (ACS) have raised some concerns about the quality of information available on neighborhood sociodemographics. Census tracts are identified with the advice of local communities working under Census Bureau guidelines to reflect prominent physical and social features that separate neighborhoods, such as highways, railroads, parks, ethnic divisions, and the like, and typically represent meaningful neighborhood divisions. Further, some evidence suggests that residents' perceptions of their neighborhood boundaries are similar in size to a census tract (Sampson, 1997).

Still, these boundaries are selected once every 10 years in the United States, with similar timing in other developed countries, so neighborhood measurements are often asynchronous with measures of children and families. Similarly, despite high levels of stability in neighborhood features (Sampson, 2012), neighborhoods change, with important ramifications for children who live in them (Leventhal & Brooks-Gunn, 2011). Recent changes to the ACS provide ongoing measurement of neighborhood structure in the United States, but require aggregation over several years due to sampling error. Finally, the U.S. Census does not include measures of neighborhood processes. Distinct from neighborhood structure, neighborhood processes entail aspects such as institutional resources and social organization, which are discussed in more detail in the following sections.

### Neighborhood Structure

Neighborhood socioeconomic status (SES)—a combination of social and economic indicators—is the most commonly studied structural dimension of neighborhoods. Other important neighborhood structural characteristics include racial/ethnic composition and residential stability. Despite general consistency across studies, specific definitions of these and other structural dimensions differ somewhat, and often are based on a factor analysis of theoretically relevant indicators.

For example, a factor analysis of 10 census variables for neighborhood clusters in Chicago identified three distinct factors: concentrated disadvantage (rates of poverty, receipt of public assistance, unemployment, female-headed families, density of children, and percentage of African American residents), immigrant concentration (percent Latino/a Americans and foreign-born residents), and residential stability (percent households in same house as 5 years earlier and owner-occupied homes; Sampson & Morenoff, 1997). Although race and ethnicity are strongly linked to other neighborhood structural features in the United States (e.g., poverty), researchers generally separate dimensions of race and ethnicity (i.e., percent African and Latino/a Americans) from other indicators of neighborhood structure to distinguish the relative contribution of neighborhood racial/ethnic composition from these other features (Leventhal, Xue, & Brooks-Gunn, 2006).

Further, researchers often separate measures of neighborhood SES into high SES (e.g., percent high-income residents, percent professionals, and percent college educated), also referred to as affluence or advantage, and low SES (e.g., percent poor residents, percent female-headed households, percent on public assistance, and percent unemployed), also referred to as poverty or disadvantage, because the presence of poor and affluent neighbors may have differential associations with children's outcomes (Jencks & Mayer, 1990). As described in more detail in the next section, it is likely that neighborhood affluence is associated with children's development through different pathways than neighborhood poverty, with neighborhood affluence being different from the simple absence of neighborhood poverty, and vice versa.

Neighborhood structural characteristics are not independent of one another. That is, the percentage of college-educated adults in a neighborhood is correlated with the percentage of employed adults and with the percentage of families living in poverty, and so on. Including only some pieces of information will bias the estimates of neighborhood-level effects, and thus researchers must pay careful attention to which neighborhood characteristics are included in their analytic models. This problem of omitted variables at the contextual level is common, but often overlooked in neighborhood research (Duncan & Raudenbush, 2001), and to some extent in developmental science in general (Elder, 1998). Thus, theory-driven research is critical and supports the use of composite measures of neighborhood structural features when a more fine-grained variable approach is not theoretically warranted.

### Neighborhood Processes

The neighborhood processes most often discussed in the literature revolve around access to high quality local institutions, and around social interactions in less formalized settings. This section briefly presents these two types of neighborhood processes, as well as measurement strategies developed to index these less tangible processes.

### *Neighborhood Institutional Resources*

The quantity, quality, diversity, and affordability of programs and resources at the neighborhood level are an aspect of neighborhoods that is likely to be important for child development, as well as a potential pathway through which neighborhood structural characteristics may influence child development (Leventhal & Brooks-Gunn, 2000). The range of resources that are likely to be important is broad, and includes childcare and preschool programs, schools, after-school and summer programs, libraries, health and social services, parks, recreational and social programs, grocery stores, transportation, and employment opportunities for adolescents and adults. Data to evaluate these myriad resources are not always readily available, at least in forms that correspond to the neighborhood boundaries defined by the census.

Nonetheless, it is possible to capture the availability of institutional resources through a variety of methods. One approach is simply to ask residents about the types of resources available in their neighborhoods (e.g., Sampson, Morenoff, & Raudenbush, 2005). This strategy is advantageous in that it is also possible to ask which of these resources residents use, and what types of resources they go beyond their neighborhoods to access (Jarrett, 1999); evidence suggests that it is important to ascertain not only what is available in the neighborhood, but to whom it is available (Small, 2006). A drawback to survey methods of this type is that respondents are rarely asked how they define their neighborhood boundaries, yielding a relatively subjective perspective on institutional resources. In addition, residents' knowledge of these resources may not reflect the objective reality.

Recent innovations in technology and mapping allow researchers to create more objective definitions of neighborhood boundaries and of the resources themselves than those based solely on participants' reports. Public health research has made numerous contributions to this line of work using GIS mapping techniques, particularly to look at families' access to green space and healthy foods

(e.g., Hillsdon et al., 2006). GIS often can be linked to administrative and public data (e.g., registries of licensed child care providers) to obtain a wide variety of indicators for neighborhood institutional resources. Online mapping tools, notably Google Street View, are another promising approach to quantifying the types of neighborhood institutional resources that are readily visible, particularly parks. To date, only a few studies examine the overlap in these approaches, but some evidence suggests these tools reliably can be used to measure resources that are meaningful for children (Odgers, Caspi, Bates, Sampson, & Moffitt, 2012).

Despite these advances, none of the novel methodologies described here captures the quality of resources available in neighborhoods. However, the quality of the institutional resources should have an important moderating role on how the availability of resources is linked to children's development. For example, a large park may appear to be available in a neighborhood through mapping tools, but if it is often used for selling drugs, it is not likely to be beneficial for children. Similarly, although childcare facilities and schools may be available, if they are of low quality then they are unlikely to promote achievement. Numerous studies document that resources are often of lower quality in more disadvantaged neighborhoods (e.g., Burchinal, Nelson, Carlson, & Brooks-Gunn, 2008), and thus more intensive data collection to understand the quality of resources in neighborhoods remains an important avenue for future research.

### *Neighborhood Social Organization*

Neighborhood social organization is another feature of neighborhoods likely to matter for children, and also may help explain how neighborhood structural features relate to their development (Leventhal & Brooks-Gunn, 2000). Like neighborhood institutional resources, social organization is complex, multifaceted, and not always easy to measure. The elements of social organization most often assessed are collective efficacy and disorder.

Collective efficacy refers to both informal social control and social cohesion at the neighborhood level (Elliott et al., 1996; Sampson et al., 1997), and is measured predominantly through survey items, although expert surveys with key community leaders also can be informative (Sampson, 2012). Informal social control depicts the degree to which residents monitor the behavior of others in accordance with socially accepted practices, and is captured by items such as: "If some children were spray-painting graffiti on a local building, how likely is it that your neighbors would

do something about it?” Social cohesion is the extent of perceived similarities and connectedness among residents, represented by items that ask about how “close-knit” the neighborhood is, and whether people in the neighborhood can be trusted.

Neighborhood disorder can be either physical (e.g., abandoned housing and graffiti) or social (e.g., public drinking and prostitution; Sampson & Raudenbush, 1999). Both aspects of disorder are frequently assessed using surveys, but physical disorder in particular lends itself well to observational measures, known as systematic social observations (SSOs). SSOs involve trained observers using a structured format to characterize neighborhoods through videotaping, rater checklists, or audiotaping (Kohen, Brooks-Gunn, Leventhal, & Hertzman, 2002; Sampson, 2012). Although SSOs also are used for assessing social disorder, signs of social disorder tend to appear sporadically and therefore are more challenging to capture during observations than more concrete signs of physical disorder (Raudenbush & Sampson, 1999), making surveys an appealing option. Despite the advantages of using SSOs to assess disorder objectively (versus surveys) and for clearly defined neighborhoods, they are typically expensive to execute and time-intensive to code. New technologies, as described earlier (Odgers, Caspi, Bates, et al., 2012), provide promising approaches for obtaining cost-effective and timely data on neighborhoods.

Exposure to crime and violence are other neighborhood social processes frequently studied in research pertaining to children. They are evaluated with administrative data such as police records, known as uniform crime reports, or through survey items assessing families’ perceptions of safety (e.g., Molnar, Gortmaker, Bull, & Buka, 2004). Additional constructs that have received somewhat less attention in the developmental literature include the extent of neighborhood social networks, such as close friends and family members, as well as social capital (e.g., Leventhal & Shuey, 2014). Social capital is another multidimensional construct that refers to neighborhood residents’ abilities to achieve various goals, and is defined in numerous ways to include social support, information channels, social leverage, participation in neighborhood organizations, civic engagement, social norms, and informal social control (Coleman, 1988).

### ***Measuring Neighborhood Processes***

A number of approaches to measuring neighborhood processes were described in the preceding sections; however,

a few points merit further attention. First, there are two approaches to obtaining survey data on neighborhood processes: Using individual parents’ or children’s ratings, collected from the same sample as the individual- and family-level data, and using an independent sample of community respondents. Researchers often rely upon the former, but these ratings are problematic because they often are confounded with child outcome measures also obtained by means of participant ratings, leading to problems of shared method variance. Second, the reliability of such measures may be questionable because in most cases it relies on individual rather than ecological data and corresponding methods for handling data. In other words, sampling is not done purposively to obtain large enough samples within neighborhoods to truly measure neighborhood (and not individual) differences in processes. Raudenbush and Sampson (1999) lay out a compelling argument for “ecometric” standards of gathering data from multiple reporters (preferably independent of study families) to enhance reliability of neighborhood measures and to use appropriate statistical tools to generate neighborhood-level reliability indices. This alternative approach to gathering survey data on neighborhood processes consists of conducting a community survey with a sample of nonparticipants in each study neighborhood (ideally at least 15 to 30 respondents per neighborhood), yielding measures of neighborhood processes that are independent from those obtained by study participants. Note that it is possible to generate similar ecometric measures of neighborhood processes for sampled children and families if the study design incorporates neighborhoods as described in the next section.

Third, there are a number of alternative methodologies to measure neighborhood processes in addition to surveys and to SSOs and GIS approaches described earlier. Rather than interviewing a sample of neighborhood residents, neighborhood expert surveys may be conducted, which requires identifying and surveying key community leaders such as prominent religious, political, business, and social leaders about their neighborhoods (Sampson, 2012; Tobler, Komro, & Maldonado-Molina, 2009). Finally, besides the types of administrative data already mentioned, alternative data sources from city, state, and federal agencies may include vital statistics from health departments, school records from education departments, and child abuse and neglect records from human and social service agencies (Coulton & Korbin, 2007). There are also publicly available data sources often produced for commercial purposes.

## APPROACHES TO STUDYING NEIGHBORHOOD INFLUENCES ON CHILDREN'S DEVELOPMENT

Researchers employing the varying methodologies described in the previous section have used nonexperimental and experimental designs to study neighborhood influences on children's development. Each approach is reviewed in turn.

### Nonexperimental Approaches

The first phase of nonexperimental research investigating associations between children's neighborhood of residence and their developmental outcomes used census-based measures of neighborhood structural characteristics (e.g., concentrated poverty, racial composition) in conjunction with data collected on children and their families. This early work was based on two general types of studies. One type was large national data sets, such as the Panel Study of Income Dynamics (PSID; Hill, 1991) and the National Longitudinal Survey of Youth–Child Supplement (NLSY-CS; Baker & Mott, 1989). These studies had substantial variation in neighborhood (and family) types as well as in the age of sampled children and permitted estimation of neighborhood effects based on few children per neighborhood. The second type of study was single-city or regional samples of children, typically school age or older, where the number and types of neighborhoods sampled varied widely across studies. These studies were often composed of primarily urban, low-income neighborhoods, with well-known examples including the Pittsburgh Youth Study (Loeber & Wikström, 1993) and the Beginning School Study in Baltimore (Entwisle, Alexander, & Olson, 1994).

These early studies with appended census data were often cross-sectional. As such, they were primarily useful for documenting associations between neighborhood structural characteristics and children and adolescents' outcomes at a single point in time. A major limitation of this research was that it did not provide much information about the dynamic and bidirectional relation over the course of development between children and their neighborhoods, which also may change through a variety of internal or external processes (Leventhal & Brooks-Gunn, 2011).

The next phase of neighborhood research, which incorporated neighborhoods into the study design, addressed many of these shortcomings. In neighborhood-based studies, a wide range of neighborhood types may be examined (e.g., those from a variety of sociodemographic makeups),

or specific types of neighborhoods may be sampled (e.g., only low- and moderate-poverty neighborhoods). In addition, sampling is done to ensure an adequate number of children per neighborhood (e.g., approximately 10 study participants per neighborhood depending on study design) to permit multilevel (or hierarchical), longitudinal analyses. Multilevel analyses generate estimates of variation in child outcomes both within and between neighborhoods, yielding more reliable estimates of neighborhood effects on children's development.

One well-known example of a neighborhood-based study is the Project on Human Development in Chicago Neighborhoods (PHDCN), in which census data were used to define two stratification variables—SES (three levels) and racial–ethnic composition (seven levels)—that were cross-classified, and then a stratified probability sample of 80 neighborhood clusters was selected for the longitudinal component of the study (Leventhal & Brooks-Gunn, 2003b). Finally, approximately 1,000 children falling within each of seven age cohorts spanning from birth through 18 years of age were sampled from these 80 neighborhoods and followed in three waves of data collection over 6 years; approximately 75 children per neighborhood cluster (at Wave 1) were interviewed. In addition, PHDCN included repeated independent community surveys, systematic social observations, and expert surveys as described previously.

Another example is the Los Angeles Family and Neighborhood Survey (LA FANS), which randomly sampled 65 neighborhoods, defined as census tracts, in Los Angeles County stratified by poverty level (i.e., very poor, poor, and nonpoor). Within each of these neighborhoods, 50 households were sampled across blocks within each tract, and those with children under 18 years of age were oversampled (70% of sample), resulting in a final sample of over 3,000 children. Children and their families were followed over approximately 6 years in two waves of data collection. A unique feature of this study is that an additional sample of new entrants into the sampled neighborhoods was added during Wave 2 of data collection to permit an examination of selection into and out of neighborhoods (Sasstry, Ghosh-Dastidar, Adams, & Pebley, 2006). Sources of neighborhood data include the census, other administrative and public data sources, systematic social observations, and self-reports by respondents that can be aggregated to the neighborhood level to mimic a community survey (though the sample is not independent).

Although neighborhood-based designs offer numerous advantages over earlier studies as just described, they

remain nonexperimental and as such have been criticized for failing to address the problem of selection bias reviewed in the previous section. That is, families self-select their neighborhoods, and factors that determine neighborhood choice also may drive associations between neighborhood residence and children's development. The most common strategy used to minimize this selection problem is to account for child (e.g., gender and age) and family demographic (e.g., income, parent education, family structure) characteristics in analytic models as described earlier. This approach is essential because neighborhood characteristics are defined in part by family composition; however, it does not fully overcome the problem of selection because many important hypothesized omitted variables such as parental depression, motivation, organization, and the like are not included in most nonexperimental neighborhoods studies. In addition, the nature of the bias resulting from the omission of such variables remains unclear. For example, parents who are depressed may be more likely to remain with their children in disadvantaged neighborhoods than parents who are not depressed. Conversely, more motivated parents may be more likely to stay in disadvantaged neighborhoods to conserve funds for children's social and recreational activities than less motivated parents.

Despite potential selection problems due to unobserved variables, a study examining factors associated with neighborhood selection among PHDCN families found that hypothesized omitted variables, such as those mentioned, contributed little to neighborhood selection beyond family socioeconomic characteristics routinely controlled for in neighborhood studies, notably income, parental education, and race/ethnicity (Sampson & Sharkey, 2008). In fact, these same authors, as well as others (Wodtke et al., 2011) have argued that by including too many family background characteristics (e.g., family structure, parent employment) in analytic models, researchers may be overcontrolling for family characteristics that account for neighborhood associations with children's development. In light of this argument, we recommend controlling for key family demographic characteristics (i.e., income, parental education, and race/ethnicity) *at a minimum* for any study of neighborhood effects on children's development and that more extensive covariates be included in a conceptually driven manner as needed.

Beyond simply controlling for background characteristics, researchers have employed a number of analytic strategies designed to more rigorously address selection problems in nonexperimental research. These approaches include comparisons of siblings or first cousins, which

essentially holds family characteristics constant, but not neighborhood exposure (Aaronson, 1997). A related approach is to use fixed effects, which takes advantage of variation in individual's own exposure to different neighborhood characteristics over time, thus holding family characteristics constant; however, sufficient variation in children's life-course exposure to different types of neighborhood conditions is often limited (e.g., Timberlake, 2007). Instrumental variable analyses minimize unmeasured correlations between neighborhood characteristics and children's outcomes by means of a two-stage regression approach (Foster & McLanahan, 1996). Propensity score methods and variants of it use a variety of strategies to match children who are otherwise similar on a wide array of observed background characteristics except for the types of neighborhoods in which they live (e.g., Wodtke et al., 2011); this approach does not address unobserved confounds. Finally, behavior genetics models attempt to distinguish between genetic and environmental influences on children's development (Caspi, Taylor, Moffitt, & Plomin, 2000; Cleveland, 2003). Although these methods are an advance over merely controlling for background characteristics, they have their own inherent limitations, a discussion of which is beyond the scope of this chapter, but most notable: They do not fully overcome the omitted variable problem in neighborhood research; other selection problems may arise if select samples are employed; and they may be limited in the extent to which they can capture developmental processes.

### Experimental and Quasi-Experimental Approaches

Experimental and quasi-experimental studies of neighborhood effects on children's development have used two general strategies. The first and more established approach has been to evaluate housing programs for low-income families that randomly assign families to live in certain types of neighborhoods. Because these programs cannot serve all eligible or interested families, selection of neighborhoods is often random, based on housing availability (i.e., quasirandom), or both. In these studies, a subset of families is typically offered assistance in relocating from high-poverty neighborhoods to less poor areas (e.g., they may receive assistance to rent housing in the private market or be offered housing assistance in nonpoor neighborhoods).

The oldest quasi-experimental study is the Gautreaux Program, which was the result of a 1976 court order to desegregate Chicago's public housing. During its operation from 1976 to 1998, over 7,000 families were given

housing vouchers (or rent subsidies) that were to be used in low-poverty, racially integrated neighborhoods, with a majority of families to be placed outside of the city limits (Rubinowitz & Rosenbaum, 2000). Because of limited housing availability at times, families were placed inside and outside of the city based on housing availability that was presumably random. A more recent example, based on a true experimental design, is the Moving to Opportunity for Fair Housing Demonstration (MTO), sponsored by HUD in 1994, partially in response to favorable findings reported in the Gautreaux Program and renewed interest in socially mixed housing at that time, as discussed earlier. Approximately 4,600 families across five cities were randomly assigned vouchers to move out of public housing in high-poverty neighborhoods into private housing of their choice or into private housing in low-poverty neighborhoods (with special assistance); by design, a subset remained in their original public housing units (Goering & Feins, 2003).

The second strategy for conducting experimental neighborhood studies, which is relatively new, is the use of natural experiments in which some exogenous shock (e.g., policy change, natural disaster) occurs that differentially affects either neighborhoods or individuals' residential location. Examples of the former approach are investigations of the impact of changes in environmental regulations, assessed at either the county or zip code level, on children's health (e.g., Currie & Neidell, 2005) and an evaluation of the impact of a major transit system and local investment in impoverished, isolated communities in Colombia on crime and violence (Cerdá et al., 2012). Examples of the latter approach are a study that examined how changes in neighborhood residence resulting from the devastation of Hurricane Katrina affected inmates' recidivism after they were released from prison (Kirk, 2009), and a study that explored how community characteristics were associated with children's educational outcomes when a sudden influx of Ethiopian immigrants to Israel led to families' random assignment to absorption centers scattered across the country (Gould, Lavy, & Paserman, 2004).

## **A REVIEW OF NEIGHBORHOOD INFLUENCES ON CHILDREN'S DEVELOPMENT**

In this section, we use a relational developmental systems perspective, described previously, to review the current state of knowledge on neighborhood influences on children's development from early childhood to late

adolescence. This perspective serves as the foundation for answering several key questions the field has addressed over the past several decades: (1) Is neighborhood context associated with children's development? (2) How is neighborhood context associated with children's development? And (3) for whom does neighborhood context matter most? At the heart of these three questions are considerations of the relations between individuals and contexts. To address the first question on links between neighborhood context and children's development, we focus on both neighborhood structure and processes and their associations with a broad range of child and adolescent outcomes (cognitive, social, and emotional functioning). In answering the second question on pathways of influence, we consider the interconnections between neighborhoods and other salient social contexts, namely families, peers, and schools, in shaping children's development. The last question on "for whom" centers on what is known about person-context interactions, addressing how individual attributes such as gender, race/ethnicity, immigrant status, and psychological and biological vulnerabilities moderate associations between neighborhood context and children's development.

Because the field of neighborhood research has proliferated during the past several decades (Sampson et al., 2002), this section of the chapter, as in our previous reviews, draws most heavily upon studies that meet certain standards of quality and rigor. Most notably, given the serious problem of selection or omitted variable bias in neighborhood research, as discussed previously, we generally only review studies that account for individual and family characteristics, such as child gender, age, and race/ethnicity, family income and composition, and maternal education, age, and the like, in the analysis. When possible, we highlight longitudinal studies, those using neighborhood designs and methodologies, and those employing alternative analytic methods to address selection. In doing so, our goal is to rely on the strongest evidence possible for making some general conclusions about what we currently know about neighborhood influences on children's development. Finally, in this section, to the extent possible, we review studies beyond the United States to provide evidence of cross-national replication. Addressing the generalizability of research conducted in the United States is critical for documenting the salience of neighborhood context for children's development.

In the following sections, we address how neighborhood structure and processes are associated with children's development. Our framework for this review takes as its

starting point that neighborhood structure, or its compositional characteristics, such as poverty, racial-ethnic makeup, and the like, are distinct from neighborhood processes, such as institutional quality or collective efficacy, which entail social interactions with individuals and institutions within neighborhoods. Distinguishing these aspects is critical because although neighborhood structure and processes are often related (e.g., Cook, Herman, Phillips, & Settersten, 2002), structural characteristics are generally thought to provide the conditions under which processes are facilitated. Thus, for conceptual purposes, neighborhood structure is conceived of as a major driver of neighborhood processes. As a result, these sections highlight studies that incorporate structural measures along with process measures. Neighborhood processes are central for understanding *how* neighborhoods influence children's development, but without addressing structure we cannot rule out omitted variable bias at the neighborhood level.

### Neighborhood Structure and Children's Development

This review builds on our previously published summaries of the neighborhood research (Fauth, Leventhal, & Brooks-Gunn, 2005; Leventhal & Brooks-Gunn, 2000; Leventhal & Brooks-Gunn, 2003a; Leventhal et al., 2009) as well as reviews by others (Burton & Jarrett, 2000; McBride Murry, Berkel, Gaylord-Harden, Copeland-Linder, & Nation, 2011; Nettles, Caughy, & O'Campo, 2008; Sampson et al., 2002). With respect to neighborhood structure, research largely examines three structural dimensions (assessed by the census)—income/SES (high-SES/affluence and low-SES/poverty), racial/ethnic diversity, and residential instability. Because most of this work points to the salience of neighborhood income/SES, we focus primarily on this dimension, but bring in other aspects as relevant.

Before we consider the connection between neighborhood SES and children's development, it is important to highlight several demographic trends that likely bear on these relations. The period from 1970 to 1990—captured in much extant research—was marked by rising economic and racial segregation at the neighborhood level (Jargowsky, 1997; Massey, 1996; W. J. Wilson, 1996). Although much attention was placed on the increasing concentration of poverty during this time, the concentration of affluence grew even more extreme than the concentration of poverty over this period (Massey, Fischer, Dickens, & Levy, 2003). Both factors contributed to rising inequality and racial stratification. A slight reversal

of these trends occurred during the 1990s, particularly in large metropolitan areas where inequality was most pronounced (Ellen & O'Regan, 2008; Jargowsky, 2003), but the overall pattern of economic segregation not only persists into the 21st century, but has continued to expand (Kneebone, Nadeau, & Berube, 2011; Reardon & Bischoff, 2011). As noted earlier, these trends were an impetus for the field of neighborhood research, but also provide a general backdrop for the pattern of results described in the following section.

The extent to which these trends and the resulting implications for children's development generalize to other countries merits mention. Sweeping parallels have been drawn between structural disadvantage in the United States and in Europe (e.g., Wacquant, 2008). Despite such parallels, the isolation and historical marginalization of predominantly African American neighborhoods in the United States (Massey & Denton, 1993; W. J. Wilson, 1987) is distinct from demographic patterns seen in Europe or Canada (Oreopoulos, 2008; Wacquant, 2008); however, immigrant neighborhoods in some European cities are somewhat similar in terms of the lack of access to economic and institutional resources, albeit on a smaller scale (Sampson, 2012). Debate continues over the nature and size of neighborhood effects in Europe (Andersson & Musterd, 2005; see also Galster, 2012), but evidence suggests similarities between neighborhood function in the United States and elsewhere. With this background, we turn in the remainder of this section to a summary of findings on the role of neighborhood SES for children's development first from various nonexperimental strategies, starting with snapshot approaches, then longitudinal studies and ending with experimental work.

### *Snapshot Approaches to Neighborhood SES*

Nonexperimental studies generally take either a cross-sectional approach, as described earlier, or use data from longitudinal studies of child development, but in fact use only a single point in time to measure neighborhood SES. That is, neighborhood SES, and to a lesser extent children's development, are seen as relatively static and thus these studies capture only a snapshot of children's neighborhood experiences (for a similar argument, see Jackson & Mare, 2007; Sampson, 2008). Because this review follows in the footsteps of many others (e.g., Leventhal & Brooks-Gunn, 2000; Leventhal et al., 2009; Sampson et al., 2002), we briefly summarize the conclusions of this body of work. A first conclusion drawn is that the nature of these associations depends on the aspect of SES and the outcome

under investigation. Specifically, neighborhood high SES is favorably associated with children's and adolescents' achievement-related outcomes, such as school readiness, test scores, academic performance, and educational attainment; this pattern was reaffirmed in a meta-analysis (O. Johnson, 2013; but for potential downsides of neighborhood affluence see Luthar, 2003). Conversely, neighborhood low SES is adversely linked to children's and adolescents' social, emotional, and behavioral outcome including behavior problems, depression, delinquency, and deviant peer group affiliation. It is also associated with adolescents' risky sexual behavior and fertility outcomes.

A second conclusion drawn is that the size of neighborhood SES "effects" in this research is small to moderate. Neighborhood SES (high or low) generally accounts for approximately 5% to 10% of the variance in developmental outcomes after covarying for child and family background characteristics. Although few of these studies compared the size of effects within a single sample (e.g., Leventhal & Brooks-Gunn, 2001), associations are quite comparable in magnitude for children and adolescents and across outcomes.

Despite these rather consistent patterns, this research has been criticized on the grounds of selection bias (e.g., Duncan, Connell, & Klebanov, 1997; Manski, 2000). To address this concern, researchers have used more robust analytic techniques as described earlier (see the section "Nonexperimental Approaches") than standard regression with covariates employed in much of this extant work. Across these studies, the general conclusions are not substantially altered; however, effect sizes tend to be reduced in most cases and some studies fail to report any associations.

We view this snapshot approach as an important first step in documenting trends, but it does not reflect a relational developmental systems perspective wherein individuals, contexts, and their relations are construed as dynamic over time. More recent work incorporating a longitudinal perspective, notably with respect to neighborhoods, has emerged.

### *Longitudinal Approaches to Neighborhood SES*

Several descriptive studies employing national longitudinal data examine children's exposure to neighborhood SES. Yet, this small research base does not address the source of shifts in SES that occur over the course of childhood (e.g., mobility versus internal neighborhood dynamics) and the diversity in children's exposure to both neighborhood poverty and affluence during this period (e.g., Sharkey,

2008; Timberlake, 2007). Families' circumstances generally improve over time as their children age (Leventhal & Brooks-Gunn, 2001); however, stability in overall neighborhood conditions—level and rank ordering—is prevalent and driven by race/ethnicity. For example, based on estimates from the 1970s to 1990s, long-term exposure (at least 50% of the first 18 years of life) to high-poverty neighborhoods (defined as poverty rate > 20%) was common among African American children and, to a lesser extent, Latino/a American children, but quite rare among European American children, who conversely were disproportionately exposed to the lowest poverty neighborhoods (defined as poverty rate < 20%; Timberlake, 2007). Neighborhood SES during childhood has implications for later exposure to neighborhood poverty during adulthood, and may extend to the next generation (Sharkey, 2008).

A small body of research links children's history of exposure to neighborhood poverty and affluence with their developmental outcomes. Three general hypotheses arise from this literature; however, they are not always explicitly tested. The first hypothesis, and perhaps least developmental in nature, is that children's cumulative experiences over the first two decades of life may be more important than exposure during a particular developmental period. Several studies based on the PSID demonstrate the power of cumulative measures of SES compared with single point in time estimates. For example, cumulative exposure to neighborhood poverty since birth was more strongly associated with non-marital fertility in young adulthood than a single point in time estimate at 14 years of age (South & Crowder, 2010), and a similar pattern was found for adolescents' odds of high school graduation (Crowder & South, 2011). The effect sizes for cumulative measures were on the order of 25% larger than point in time estimates. It is important to note that these studies only compared cumulative measures of neighborhood SES with those in adolescence (i.e., 14 years).

A second hypothesis that may be conceptually inherent in the studies just described—despite the nature of their findings—is that adolescence is a period of particular sensitivity to neighborhood influences because parents grant their older children greater autonomy, resulting in more exposure to extrafamilial contexts such as neighborhoods than in earlier childhood (Leventhal et al., 2009; see also Steinberg & Morris, 2001). In contrast to this hypothesis, a third hypothesis grows out of the work on family income and poverty which indicates that family economic resources during early childhood, as opposed to other developmental periods, are most salient for adult

achievement (Duncan, Ziol-Guest, & Kalil, 2010); early economic deprivation may lead to impaired functioning, which sets the stage for continued problems into adolescence and beyond (Shonkoff, Boyce, & McEwen, 2009). Thus, like family income, neighborhood SES may be most critical during early childhood too (Sampson, Sharkey, & Raudenbush, 2008). Studies addressing these two hypotheses generally take a more developmental approach than those studies testing the first hypothesis because they consider how exposure at different points in the life course may be linked to children's later functioning.

Although the research base is modest and results are mixed, there is some support for the early childhood hypothesis. For example, a study using nationally representative data indicates that exposure to neighborhood low SES in childhood, compared with exposure in adolescence or early adulthood, had the largest associations with mental health in early adulthood (Wheaton & Clarke, 2003; see also Anderson, Leventhal, & Dupéré, 2014). Other studies have incorporated longitudinal measures of children's outcomes in addition to neighborhood SES to address this issue. For instance, an investigation with a diverse U.S. sample reported that neighborhood high SES in early childhood was associated with children's reading achievement in first grade, but not with subsequent learning rates into adolescence (Dupéré et al., 2010).

A final set of studies that is somewhat distinct from the ones just described, but that takes a developmental perspective, focuses on changes in neighborhood conditions and their implications for children's development. Interest in this topic was fueled, in part, by questions about the effect of gentrification—or reductions in socioeconomic disadvantage—on children. The minimal work on this topic has employed various analytic methods to address the selection issues inherent in studying mobility out of changing neighborhoods. One such study based on the PSID reported that African American youth who lived in neighborhoods with declining concentrated disadvantage benefitted with respect to their adult economic attainment (Sharkey, 2012). However, another study employing PHDCN data found that boys', but not girls', trajectories of internalizing and delinquent behaviors were worse if they lived in neighborhoods that decreased *or* increased in poverty compared with their peers in stable neighborhoods (Leventhal & Brooks-Gunn, 2011). Together, these longitudinal studies taking a broader approach suggest that current estimates of neighborhood SES effects—drawn largely from single point in time estimates—likely underestimate the role of neighborhood SES in children's development.

In addition, the work of others reveals that it may take several years for neighborhood SES effects to even take hold (Sampson et al., 2008; Turley, 2003), but the timing, duration and nature of these experiences are likely to matter for children's development.

### *Experimental Approaches to Neighborhood SES*

In line with the longitudinal nonexperimental research just discussed are the experimental and quasi-experimental studies on neighborhood SES and children's development, which view neighborhoods as dynamic rather than static. As important, they further address concerns about selection bias in this field. As described earlier, most of this work grows out of housing programs for low-income, often minority, families receiving housing assistance or who volunteered to participate in mobility programs, and thus is restricted to this population (see the section "Experimental and Quasi-Experimental Approaches"). In addition, the study of neighborhood SES in this context is typically confounded with residential mobility. Again, the results of these studies are widely reported (e.g., Leventhal et al., 2009), and we only briefly summarize them here.

Among the oldest of these studies is a follow-up of the Gautreaux Program. A study following about 350 families who relocated under this program found that, 10 years after relocating, poor youth who moved to private housing in affluent suburban neighborhoods were less likely to drop out of high school and more likely to enroll in college preparatory classes and attend college than youth who moved to private housing in poor urban neighborhoods (Rubinowitz & Rosenbaum, 2000). Work following a larger sample of Gautreaux families through administrative data sources reports that, 15 years later, youth who moved to the suburbs had established their own households in less poor and segregated neighborhoods than their peers who stayed in the city (Keels, Duncan, Deluca, Mendenhall, & Rosenbaum, 2005). The long-term impacts on educational and economic attainment, however, are unknown, particularly for the larger, more representative sample.

Building on the promising early results of Gautreaux, MTO is the most recent, well-known, and only true experimental study of neighborhood mobility. A 10-year evaluation of MTO revealed that adolescent boys, but not girls, who moved to low-poverty neighborhoods reported worse mental health than their peers who remained in public housing in high-poverty neighborhoods and that some benefits were seen for girls (Kessler et al., 2014). Generally, no program effects on youth education, crime, or physical health were reported (Gennetian et al., 2012).

Finally, another court-ordered desegregation effort in Yonkers, New York, in 1985 entailed the construction of 200 units of low-rise publicly funded townhouses in eight primarily White middle-class areas of the city. A quasi-experimental study followed approximately 220 low-income, minority families 7 years after relocating. Unlike the Gautreaux, it found uniformly unfavorable outcomes in both the schooling and behavioral domains for youth who moved to the new housing compared with their peers from the old neighborhood, about half of whom had families who were on the waitlist for the new public housing (Fauth, Leventhal, & Brooks-Gunn, 2007).

Given the rather consistent pattern in the nonexperimental literature regarding links between neighborhood SES and children's development, these mixed results from mobility programs have been rather puzzling. A number of factors may contribute to the mixed results, but the underlying reasons likely vary somewhat across the programs. To begin, moving likely disrupted children's existing social networks, which could have offset any benefits associated with more advantaged neighborhoods (see also the section further on in the chapter, "Synergies Between Neighborhood and Peer Contexts"). For example, qualitative work on MTO suggests that boys' access to fathers and father figures was curtailed by moving, which might account for the unfavorable program effects seen for them (Clampet-Lundquist, Edin, Kling, & Duncan, 2011). In addition, boys in MTO were more likely than girls to return to their old neighborhoods to access social networks. Both factors might have mitigated the benefits of lower poverty neighborhoods for boys.

At the same time, income and/or racial/ethnic differences between mover youth and their new neighbors may have been another challenge. These differences may have precluded the formation of close ties, subjected movers to experiences of racism and discrimination, and engendered resentment. For instance, families who moved to less poor neighborhoods were more likely to report experiences of discrimination in Gautreaux and less informal socializing with neighbors in Yonkers, at least in the short-term, than their respective counterparts in higher poverty neighborhoods (Fauth, Leventhal, & Brooks-Gunn, 2004; Rubinowitz & Rosenbaum, 2000).

Another factor explaining the mixed results involves schools. If school quality was not improved by moving, educational benefits were unlikely to accrue (see also the section "Synergies Between Neighborhood and School Contexts"). For example, in Yonkers, children remained in the same city and school district. In MTO, the situation was

more complicated. Families who moved to low-poverty neighborhoods remained in urban areas and in predominately racial and ethnic minority neighborhoods (i.e., did not move to the more affluent suburbs like in Gautreaux). As such, children often remained in the same urban school districts as prior to the move, and many even attended the same schools because of school choice policies allowing them to do so (see Sanbonmatsu, Kling, Duncan, & Brooks-Gunn, 2006).

Finally, we should note that, in all of the programs, families remained poor despite their improved neighborhood conditions. Many economic, social, and personal challenges that children and their families faced—beyond neighborhood poverty and related conditions such as safety—likely remained in place after they moved and may have been heightened or made more salient with the move to a more advantaged neighborhood. These mixed results are perhaps not surprising given that mobility programs do not directly target child outcomes and given that neighborhood socioeconomic composition influences children's development largely indirectly, a topic we turn to in the remainder of this section.

### **Neighborhood Processes Linking Neighborhood Structure and Children's Development**

This section highlights potential pathways for explaining observed links between neighborhood structure, notably SES, and children's development reviewed in the previous section. We focus on two central vehicles, institutional resources and social processes.

#### ***Institutional Resources***

One major pathway through which neighborhood socioeconomic characteristics might influence children's development is the quality of local institutional resources (Leventhal & Brooks-Gunn, 2000; Sampson et al., 2002). Children spend a large share of their waking hours in neighborhood institutions that reflect local realities. Child-care centers, preschools, and schools are examples of such local institutions at the core of children's daily routines (see Burchinal, Magnuson, Powell & Soliday Hong, Chapter 6, this *Handbook*, this volume, Crosnoe & Benner, Chapter 7, this *Handbook*, this volume).

This section discusses how the neighborhood context may shape these local institutional resources. Other resources, such as afterschool programs (see Vandell, Larson, Mahoney & Watts, Chapter 8, this *Handbook*, this volume) and health care (see Zuckerman & Keder,

Chapter 15, this *Handbook*, this volume), are also relevant, but fall beyond the scope of this chapter (for a discussion of a wider set of local institutional resources, see Leventhal et al., 2009).

The children attending local child care centers, preschools, and schools typically come from families who mirror the neighborhoods in which they are embedded. Most children attend their neighborhood's school, and even those who participate in school choice programs usually attend nearby schools within their own school districts (Ryan, 2010). In terms of young children's early care and education, for whom no corresponding districting constrains choice (in most cases), a convenient location close to home often is cited by parents as a leading reason underlying the selection of care (e.g., Raikes, Torquati, Wang, & Shjegstad, 2012). As such, childcare centers, preschools, and schools located in disadvantaged neighborhoods will mostly serve disadvantaged families, and vice versa. Given increasing neighborhood inequality in the United States, many local institutions, beyond educational settings, are likely to be composed uniformly of either disadvantaged or affluent participants (as opposed to average), limiting the types of institutions available to families in their neighborhoods (Reardon & Bischoff, 2011).

A sizeable body of research reveals that a higher concentration of disadvantaged children within institutions is independently associated with adverse developmental outcomes beyond children's own family disadvantage (e.g., Levine & Painter, 2008). This pattern may arise because teachers and child care providers serving disadvantaged populations typically have to manage comparatively large proportions of children with learning, emotional, and/or behavioral problems (Dinkes, Forrest Cataldi, & Lin-Kelly, 2007). Such a context makes it challenging to create a learning environment that supports high-quality instructional activities.

Neighborhood composition determines not only who attends a certain care or educational setting, it also influences who works there. Institutions located in affluent neighborhoods often have more financial resources because institutions such as public schools are largely funded by local tax revenues based on property values and business activities, both of which increase with neighborhood SES. In addition, affluent parents can and do invest more financial resources in their children's education than more disadvantaged parents (Conger, Conger, & Martin, 2010). Thus, institutions located in affluent areas can tap these pooled resources to finance both infrastructure development and competitive salaries for teachers. These resources allow institutions in affluent neighborhoods to hire and

retain more qualified and effective teachers, as compared with those with large enrollments of poor (often minority) students, which are disproportionately represented in urban areas (Guarino, Santibañez, & Daley, 2006). These institutional dynamics may be moderated by the broader policy context: In contrast to the United States, countries such as Sweden and Canada have policies to allocate more resources to schools in disadvantaged than affluent areas (Andersson & Musterd, 2005; Oreopoulos, 2008).

High-quality child care in the United States is more accessible in advantaged than disadvantaged neighborhoods, despite the presence of high-quality publicly funded programs in poor neighborhoods (e.g., Burchinal et al., 2008; see also Burchinal et al., Chapter 6, this *Handbook*, this volume). A study using national data reflects the lack of quality options available to low-income families, even when they receive subsidies to assist with the cost of care in the private market (A. D. Johnson, Martin, & Brooks-Gunn, 2013). The relative scarcity of high quality care in disadvantaged neighborhoods is problematic, given that the benefits associated with it may be greatest among disadvantaged children (e.g., Tucker-Drob, 2012).

Likewise, the quality of schools is tied to neighborhood SES (Crosnoe & Benner, Chapter 7, this *Handbook*, this volume). Affluent, highly educated parents typically expect educational services of high quality for their children, and they exert pressure on their local institutions to get them (Lareau, 2003). For instance, the level of parent participation in school-related activities, such as parent-teacher associations (PTAs), is higher in advantaged than disadvantaged neighborhoods (e.g., Greenman, Bodovski, & Reed, 2011), thus raising the level of connections and social capital among parents. Increased connectivity and social capital also has other ramifications such as supporting the flow of information about whom the good teachers, tutors, coaches, and so on, are and where they are located. Such exchange of information is likely to support the growth and preservation of well-functioning services, which benefits all neighborhood children.

Some empirical evidence supports the premise that the quality of local institutions is key for understanding why children from comparatively advantaged neighborhoods tend to have more favorable outcomes than their peers from less advantaged ones. For instance, a natural experiment in which Ethiopian immigrants were relocated in a quasi-random fashion throughout Israeli communities revealed that the quality of local primary schools was associated with student's long-term educational success (Gould et al., 2004). A nonexperimental study found that

the observed quality of child care and school advantage partially explained the link between neighborhood affluence and children's achievement (Dupéré et al., 2010). Studies of youth behavioral outcomes also report that the quality of local educational institutions matters (e.g., Eitle & McNulty Eitle, 2004). In short, the composition and quality of early care and educational institutional settings serving children is central for their development and appears to be a function of neighborhood socioeconomic composition.

### *Social Processes*

Another means through which neighborhood structural characteristics may influence children's development is neighborhood social processes. As described earlier, neighborhood social processes include collective efficacy, physical and social disorder, exposure to violence and safety, and the extent of social networks. Although all of these processes are linked to children's development (Leventhal & Brooks-Gunn, 2000), we focus here on the large bodies of research on collective efficacy and the overlap of social disorder and exposure to violence as pathways that are especially informative for understanding how neighborhoods matter for children's development.

As with neighborhood institutional resources, social processes may help to explain *how* neighborhood structural characteristics, notably poverty and affluence, influence children's outcomes. Whereas institutional resources are probably most informative for understanding children's achievement-related outcomes, and to some extent their opportunities to avoid the problematic behavioral outcomes associated with unstructured time (Gottfredson, Gottfredson, & Weisman, 2001), neighborhood social processes may be more useful for addressing neighborhood influences on children's behavior outside of structured settings. Theoretically, we expect that neighborhoods high in collective efficacy limit children's opportunities to engage in deviant behaviors, in contrast to neighborhoods high in crime and disorder that offer more opportunities to engage in such behaviors.

**Collective Efficacy.** Collective efficacy is embedded in the larger neighborhood context and can be understood as an engine for community action and organization, operating through formal and informal community institutions, and stemming from neighborhood structural characteristics, including low SES, racial/ethnic diversity, residential instability, and single parenthood (Sampson et al., 1997). An important distinction is that collective

efficacy is broader and more diffuse than neighborhood social networks; collective efficacy does not require strong ties or associations within neighborhoods (Sampson, 2003). Rather, it is trust among neighbors that there are shared norms and expectations for behavior and a collective willingness to enforce such norms, even in the absence of close personal ties. Empirical studies focusing on collective efficacy specifically related to community exchange on issues relevant for children indicate that it is highest in neighborhoods of concentrated affluence and low residential mobility (Sampson, Morenoff, & Earls, 1999).

Growing research has taken collective efficacy from its initial roots in criminology and urban sociology to demonstrate its relevance for developmental science. The bulk of this research focuses on links between low collective efficacy and problematic and risky adolescent behaviors (e.g., Browning, Leventhal, & Brooks-Gunn, 2005), but other work reveals the importance of collective efficacy during early childhood, and for a range of outcomes such as verbal ability and mental and physical health (e.g., Kohen et al., 2002; Xue, Leventhal, Brooks-Gunn, & Earls, 2005). The range of outcomes associated with neighborhood collective efficacy in early childhood suggest there are likely many pathways by which the neighborhood social context comes to matter for young children, which are given greater attention in subsequent sections on cross-context and person-context interactions. Moreover, these multiple pathways are likely to be part of broader developmental trajectories that have some continuity across development and contribute to the associations observed between neighborhood collective efficacy and adolescent outcomes.

The focus on adolescents in this literature stems largely from the argument that with greater autonomy than younger children, teenagers are more likely to have direct exposure to neighborhood social conditions (Leventhal et al., 2009). This relatively rich body of research enables us to focus this section of the review on only methodologically strong studies. Greater collective efficacy, particularly community social control, is associated with adolescents' fewer externalizing (delinquency and violence, affiliation with deviant peers, and carrying a concealed weapon) and internalizing (depressive symptoms) behaviors (e.g., Dupéré, Leventhal, & Vitaro, 2012; Roosa et al., 2010; Sampson et al., 2005). Neighborhood social cohesion and collective efficacy also are associated with adolescents' body mass index and frequency of physical activity (e.g., Cohen, Finch, Bower, & Sastry, 2006; Utter, Denny, Robinson, Ameratunga, & Milfont, 2011). Further, collective efficacy is associated

with more private adolescent behaviors including sexual debut and number of sexual partners (e.g., Browning, Burrington, Leventhal, & Brooks-Gunn, 2008; Browning, Leventhal, & Brooks-Gunn, 2004).

Conversely, greater neighborhood informal social control is linked to favorable adolescent outcomes, including prosocial competence and conventional friends (Elliott et al., 1996). As with results from studies with younger children, findings with adolescents suggest that collective efficacy may at least partially explain the connection between developmental outcomes and neighborhood low SES. Overall, strong theoretical and empirical support exists for the link between neighborhood collective efficacy and adolescent outcomes.

Again, given the breadth of young child and adolescent outcomes associated with collective efficacy and its components (social control and social cohesion), understanding when and for whom this feature of neighborhoods matters most is an important direction for developmental scientists. Individual, family, and neighborhood-level factors are all likely to be relevant, including other social processes, such as exposure to violence and social disorder in the neighborhood.

**Exposure to Violence and Social Disorder.** Higher collective efficacy is associated with lower rates of neighborhood violence, both concurrently and over time, and even partially explains the association between neighborhood concentrated disadvantage and crime (Sampson, 2003; Sampson et al., 1997). Although collective efficacy may contribute to the link between structural disadvantage and violence and disorder, exposure to violence and social disorder, in particular, have independent relations with children's development beyond that of low social control and a lack of neighborhood cohesion (e.g., Roche, Ensminger, & Cherlin, 2007). We examine exposure to violence and social disorder together in this section because both are related to criminal activity, are likely to co-occur, and are often considered in tandem.

Exposure to violence is typically assessed at the individual level. Individuals' perceptions of danger and violence may have profound implications for their social and emotional functioning beyond more objective rates of community crime and violence (Cammack, Lambert, & Ialongo, 2011). It is important to acknowledge, however, that individual reports may reflect individual biases as well as objective neighborhood conditions and are methodologically problematic for this reason.

Results from experimental evaluations of housing programs offer insight into the role of parents' perceptions

and fears of community violence: Parents applying for two such programs reported that getting away from drugs and gangs was their primary motivation for wanting to move away from public housing in high-poverty neighborhoods (Briggs, 1997; Goering & Feins, 2003). Initial and longer-term follow-ups of these programs found that children who moved to more advantaged neighborhoods were less likely to be exposed to violence and danger than were peers who remained in poor neighborhoods (Fauth et al., 2007; Kling, Liebman, & Katz, 2007; Popkin, Leventhal, & Weismann, 2010). These results, again, point to the importance of considering neighborhood socioeconomic conditions simultaneously with neighborhood social processes, as well as the importance of parents' perceptions of the ways in which they select neighborhoods.

Across development, neighborhood safety is linked to children's overall physical health (Fan & Chen, 2012). This association begins with lower birth weights among babies born to mothers residing in neighborhoods with high levels of violent crime (Morenoff, 2003) and persists throughout childhood. Parents may be less likely to allow their children to spend time outside in neighborhoods that are less safe, restricting their options for out-of-school-time physical activity (Schreier & Chen, 2012). In fact, parents' perceptions of neighborhood safety and social disorder are associated with the amount of time children engage in physical activity and are associated with their risk of obesity (Bacha et al., 2010; Molnar et al., 2004).

As with collective efficacy, theory implies that exposure to violence and social disorder are likely to have the largest links with adolescents' behavior as youth gain independence and develop strategies to navigate their neighborhoods. Studies examining how community violence and social disorder are associated with young children's outcomes are sparse. However, disorder and crime assessed using systematic social observations and by official crime records, respectively, were adversely associated with preschool children's intellectual development (Caughy, Hayslett-McCall, & O'Campo, 2007; Kohen et al., 2002). Another neighborhood-level study found an association between residents' fear of victimization in their neighborhoods and young children's internalizing symptoms (Caughy, O'Campo, & Muntaner, 2004). These divergent findings may be related to the different neighborhood features assessed: Objective and visible disorder versus neighborhood residents' fear. The former may influence availability of and access to early education opportunities, whereas the latter may be more reflective of parents' behaviors, thereby showing stronger connections

with young children's achievement and psychological outcomes, respectively.

Among older children and adolescents, evidence more clearly points to a link between neighborhood disorder and violence and behavioral outcomes specifically. Overall, youth who are exposed to greater community violence and disorder have lower self-efficacy, more externalizing problems, earlier age of sexual debut, display more anti-social behavior and severe behavior problems, and are more likely to commit acts of violence themselves than peers who are exposed to less violence (Cummings et al., 2011; Dupéré et al., 2012; Gonzales et al., 2011; Singh & Ghandour, 2012). Neighborhood danger may account for links between neighborhood low SES and adolescent outcomes, including emotional problems and timing of first intercourse (e.g., Pettit, Bates, Dodge, & Meece, 1999; Upchurch, Aneshensel, Sucoff, & Levy-Storms, 1999). In addition, a body of qualitative research suggests that social disorder and exposure to violence may be particularly relevant for girls' sexual initiation, in part due to coercive sexual environments in high poverty neighborhoods (Popkin et al., 2010) and individual fears of death (Choby, Dolcini, Catania, Boyer, & Harper, 2012). In sum, growing evidence points to the salience of neighborhood disorder and violence as key social processes that comprise children's development.

### Cross-Context Interactions

As discussed, developmental science has long acknowledged that successful and healthy child development requires interactions between an active individual and his or her environment (Elder et al., Chapter 2, this *Handbook*, this volume; Lerner, 2006; Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1). This environment is composed of a complex web of embedded and overlapping contexts with the potential to shape and influence individual trajectories. These overlapping contexts are likely to exert joint influences, mitigating, exacerbating, supporting, nullifying, or counterbalancing one another. Such cross-context interactions occupy a central place in relational developmental systems theories (e.g., Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1) because they help to fully make sense of human development's successes and failures. This section looks at such cross-context interactions between the neighborhood and the family, peer, and school contexts.

### *Synergies Between Neighborhood and Family Contexts*

To at least some degree, families select and shape the neighborhoods in which they live. In addition, children are not alone in how they are influenced by neighborhood structural and social features: Parents also experience and adapt to their neighborhood contexts. Thus, in addition to direct links between neighborhoods and child outcomes, there are multiple ways in which parent and family characteristics are likely to intersect with neighborhood features relevant for children. Accordingly, this section is divided into two parts: First, the ways in which neighborhoods might shape parenting are considered, and second, the potential for parenting to matter differently in different neighborhood contexts is examined.

**Neighborhoods Shaping Parenting.** Consistent with findings that neighborhoods matter for children, research also shows that neighborhood characteristics matter for adults in general, and parents in particular (e.g., Franco, Pottick, & Huang, 2010; Guterman, Lee, Taylor, & Rathouz, 2009; see also Bornstein, Chapter 3, this *Handbook*, this volume). Notably, links between neighborhood features and adult psychological well-being suggest that parents in more disadvantaged neighborhoods may experience greater depression, more stress, and worse physical health—all of which are associated with less warm and consistent parenting behaviors (Conger & Donnellan, 2007; Elder, Eccles, Ardelet, & Lord, 1995). In addition, it is likely that parents who are more overwhelmed and stressed by their neighborhood contexts may be less adept at shielding their children from the negative aspects of their neighborhoods. In this way, parenting may act as an indirect pathway for the effects of neighborhoods on children, and also a contributing factor in children's direct experiences of their neighborhoods.

Experimental evidence from MTO indicates that parents who moved from high poverty to low poverty neighborhoods experienced psychological and physical health benefits, including lower rates of diabetes and extreme obesity, compared with parents who stayed in high poverty neighborhoods (Ludwig et al., 2011, 2012). Nonexperimental research partially supports links between neighborhood socioeconomic disadvantage and parents' greater depressive symptoms, lower overall parenting quality, and higher family stress and conflict (Conger & Donnellan, 2007; Paschall & Hubbard, 1998). However, some work, including quasi-experimental studies,

reveals that neighborhood SES associations with parenting may be more complex, such that greater neighborhood affluence may be associated with parents' lower social support and higher alcohol use (e.g., Briggs, 1997; Chuang, Ennett, Bauman, & Foshee, 2005; Fauth, Leventhal, & Brooks-Gunn, 2008).

In terms of specific parenting behaviors, findings from the Yonkers Project suggest that compared with families who stayed in low-income neighborhoods, parents who moved to middle-class neighborhoods used less stringent monitoring with their children, and less restrictive control and discipline because they were "not struggling to isolate their kids from neighborhood risks" (Briggs, 1998, p. 208). In contrast, in the New York MTO sample, compared with parents who remained in high poverty neighborhoods, parents who moved to low poverty neighborhoods were observed to use harsher parenting with girls, and no differences emerged between the groups in terms of parents' monitoring practices or family routines (Leventhal & Brooks-Gunn, 2005). The authors suggest this counterintuitive finding related to harsh parenting may be related to the short-term strain of moving, with increasing conflict between girls and their parents as a normative component of adolescence; however, it remains unclear whether these experimental findings persist over time.

Net of neighborhood SES, neighborhood social processes also are associated with parents' well-being and parenting behaviors. Consistent with findings that affluent neighborhoods may not always optimize parent well-being, associations with neighborhood social processes and parenting are nuanced and potentially moderated by neighborhood structure, notably SES. For example, lower neighborhood social cohesion is associated with greater parental depression (Kohen, Leventhal, Dahinten, & McIntosh, 2008), but higher neighborhood informal social control may exacerbate the negative association between parenting strain and parents' feelings of personal control (Carpiano & Kimbro, 2012).

More general measures of neighborhood quality also may be linked to parents' well-being, but a majority of this work has not used methodologically rigorous assessments of neighborhood social processes. Not surprisingly, reports of parenting stress are higher and ratings of general psychological and physical well-being are lower in neighborhoods that parents rate more negatively (e.g., more signs of social disorder and lower perceptions of safety; Franco et al., 2010; Guterma et al., 2009). Although

parents' perceptions of their neighborhoods may affect their parenting behaviors (Rankin & Quane, 2002), it is important to consider whether parents' negative neighborhood perceptions reflect neighborhood conditions per se, or whether negative neighborhood perceptions are simply a marker for a more general constellation of family stress, disadvantage, and/or poor functioning.

The associations between neighborhood context and parental well-being and parenting behaviors are likely to matter for children's development. Robust assessment of these types of mediated pathways typically comes from longitudinal data, which allows temporal sequencing of the proposed pathways to reduce the confounding influence of bidirectional effects. Such studies reveal that diverse parenting behaviors (i.e., parental warmth and monitoring, consistent discipline, and provision of home learning opportunities) help explain links between neighborhood SES and children's behavioral and achievement outcomes (Dupéré et al., 2010; Kohen et al., 2008; Odgers, Caspi, Russell, et al., 2012).

Cross-sectional studies also provide support for parenting as a link between neighborhood SES and children's outcomes (e.g., Chuang et al., 2005; Simons, Johnson, Beaman, Conger, & Whitbeck, 1996), but work examining mediated pathways with other aspects of neighborhoods, aside from SES, is relatively scarce. Some research suggests that parenting behaviors may mediate the links between both neighborhood social cohesion (Kohen et al., 2008) and neighborhood disorder (Mrug & Windle, 2009) and children's outcomes. These studies highlight the potential for different neighborhood and parenting features to predict different outcomes for children, as well as the possibility that different neighborhood social processes may be more or less salient for parents, perhaps depending on children's developmental status. For example, neighborhood social cohesion may be more important for parents when their children are young because of the parenting demands, but parents may become more focused on neighborhood disorder as their children age and have greater direct exposure to neighborhoods.

### **Neighborhoods Shaping How Parenting Matters.**

In addition to considering parenting as a potential pathway between neighborhood features and children's outcomes, the next models propose that parenting may simply matter differently in different contexts. That is, parenting and neighborhoods may interact to influence children's

development differently based on the specific combinations of parenting and neighborhood attributes. These models are informed by a risk and resilience perspective (Cicchetti, 2010; Werner, 1995), with both neighborhood and parenting features garnering consideration as risk and protective factors. Most similar to traditional risk and resilience models, the buffering model frames neighborhood context as a risk factor and parenting as a protective factor (Simons et al., 2002). Support for this hypothesis is most abundant in samples of African American and Latin American youth, and suggests parental warmth, monitoring, and engagement in school activities can all act as buffers in the context of neighborhood low SES and high crime and disorder (e.g., Dearing, 2004; Rankin & Quane, 2002; Roche & Leventhal, 2009).

Whereas the buffering model frames parenting as a moderator of the link between neighborhood and child outcomes, the neighborhood context also can be considered a moderator of the link between parenting and child outcomes. In this formulation, parenting and neighborhood context are at odds: One serves a protective role for child development and the other poses risk. That is, neighborhood disadvantage may overwhelm any advantages of typically beneficial parenting behaviors so that parenting effects “evaporate” in high-risk neighborhoods (Simons et al., 2002); or, ineffective parenting behaviors (e.g., low monitoring) might not be as problematic in the context of supportive neighborhoods (e.g., high collective efficacy; Browning et al., 2005).

A complementary hypothesis is that parenting behaviors and neighborhood characteristics work in the same direction, resulting in amplification, for better or for worse. That is, negative, ineffective, or uninvolved parenting strategies may confer greater threats to children’s development in the context of high-risk neighborhoods (Roche et al., 2007). Lower monitoring and permissive parenting were found to be particularly detrimental for children’s behavior in neighborhoods rated as less safe, as well as in neighborhoods with greater residential instability and disorder (Beyers, Bates, Pettit, & Dodge, 2003). Similarly, in more disadvantaged neighborhoods, harsh and inconsistent parental discipline practices are more strongly associated with children’s symptoms of conduct disorder (Brody et al., 2003). On the other hand, parenting strengths (e.g., use of authoritative control strategies) may be even more beneficial for children’s outcomes in neighborhoods where authoritative parenting is the norm or where collective efficacy is high (Fletcher, Darling, Dornbusch, & Steinberg, 1995; Simons, Simons, Burt, Brody, & Cutrona, 2005).

Yet another possibility is that a “goodness-of-fit” between parenting practices and neighborhood characteristics may make some parenting behaviors differentially successful across diverse neighborhoods. This match between neighborhood features and parenting behaviors may depend upon parents’ or children’s individual characteristics, particularly race and ethnicity (e.g., Carpiano & Kimbro, 2012; Dearing, 2004). Research supporting the goodness-of-fit model suggests that more restrictive parenting can be protective, or at least not harmful, in disadvantaged neighborhood contexts. For example, high parental authoritarian control was associated with adolescents’ delayed sexual initiation in low SES neighborhoods, but in high SES neighborhoods this parenting approach was associated with earlier sexual initiation (Roche et al., 2005). Punitive parenting, on the other hand, seems most detrimental for children’s behavior in the context of disadvantaged neighborhoods (Roche et al., 2007; Roche, Ghazarian, Little, & Leventhal, 2011), but restrictive parenting in these neighborhood contexts is associated with favorable academic outcomes (Dearing, 2004). These quantitative findings are consistent with a body of qualitative work that suggests greater parental control may be protective for minority youth in high-risk settings (e.g., Jarrett & Jefferson, 2003).

In sum, family processes and parenting behaviors clearly have multiple roles and meanings in diverse neighborhood contexts. To date, theoretical explanations for specific pathways and directions of associations across the neighborhood and family contexts are weak, and methodologically rigorous studies (e.g., using longitudinal family data in conjunction with independent assessments of neighborhood features) continue to be the exception. Nonetheless, the breadth of existing research highlights the complexities inherent in understanding how different levels of context interact to affect individual children. To further complicate the matter, parents also influence children’s neighborhood peer groups, and their school experiences; interactions between these contexts and neighborhoods are considered next.

### *Synergies Between Neighborhood and Peer Contexts*

Developing positive and meaningful peer relationships is thought to be a vital part of healthy development, perhaps especially so during adolescence, when the larger social world beyond the family is needed to meet the psychosocial needs of adolescents, notably identity formation and autonomy (e.g., Brown & Larson, 2009; see also Rubin, Bukowski, & Bowker, Chapter 5, this *Handbook*,

this volume). The neighborhood context provides a social space for interactions outside of the family, and thus converges with the peer context. After all, a large portion of children's friends comes from their neighborhoods (e.g., Dolcini, Harper, Watson, Catania, & Ellen, 2005). As friends play an important role in development (e.g., Rubin et al., Chapter 5, this *Handbook*, this volume), peer relations represent a major pathway through which neighborhoods could influence children and adolescents. There are at least three different ways in which the neighborhood context could shape the peer context: (1) determining the pool of potential friends; (2) shaping the larger normative context; and (3) constraining unstructured peer group activities through collective resources. We discuss each in turn with a focus on adolescence because of the central role peers play during this period of development and because of the dearth of research on childhood.

**Neighborhoods as Determinants of the Pool of Potential Friends.** The most obvious and direct way in which neighborhoods might influence the peer context and in turn children's development is by determining the pool of available peers with whom one can form friendships. A long research tradition in social psychology shows that mere physical proximity to someone, notably living nearby, increases the likelihood of friendship formation (e.g., Back, Schmukle, & Engloff, 2008). Moreover, availability may influence who children spend their free time with even more so than similarity (Siennick & Osgood, 2012). These proximity effects suggest that children's social worlds are at least in part bounded by their neighborhoods, as they typically spend their structured time in neighborhood institutions (e.g., preschools/schools or after school programs), or unstructured time in their neighborhoods (e.g., playing in parks or hanging out in the streets).

Nonexperimental research reveals that youth living in disadvantaged neighborhoods are more likely to have deviant friends than their peers in more advantaged communities, even after taking into account individual and family background characteristics (e.g., Brody et al., 2001). This increased tendency to affiliate with problematic peers partly explains why youth in disadvantaged neighborhoods are at an increased risk for various unfavorable developmental outcomes such as delinquency and risky sexual behaviors (e.g., Chung & Steinberg, 2006; Dupéré, Lacourse, Willms, Leventhal, & Tremblay, 2008).

Findings from a study using a natural experiment reveal how the neighborhood context influences one's immediate peer group and, in turn, behavior (Kirk, 2009). As

described earlier, this study took advantage of changes in offenders' residential location after release from prison in the aftermath of Hurricane Katrina and found that not returning to one's former place of residence was associated with inmates' reduced chances of recidivism and re-incarceration because it likely disrupted deviant peer networks. In a somewhat similar vein, qualitative research suggests that some of the disappointing findings following mobility in the context of the MTO program arose because young males in the program were not effectively separated from their peers in their old neighborhood because of the proximity of their new neighborhoods to their original ones (Clampet-Lundquist, 2011). In addition, nonexperimental work with PHDCN found that mobility within or outside the city of Chicago had differential implications for youth experiences and outcomes, presumably in part because of connections to peers (Dupéré et al., 2012; Sharkey & Sampson, 2010). Clearly, more research is needed to sort out the processes underlying the effect of different kinds of mobility and its associations with the maintenance of peer relationships in the context of neighborhood research.

**Neighborhoods Shaping the Larger Normative Context.** The neighborhood context has the potential to influence the characteristics of children's close friends, but more generally, it also can shape the larger peer normative context to which they are exposed. Even without cultivating intimate relationships with neighborhood peers, children are likely aware of consequential events of those who share the same general neighborhood-based social milieu. For example, news of conspicuous events such as going to college or having a baby can spread widely in loose networks through hearsay, well beyond one's immediate network of close friends (e.g., Tyler, 1980). Through such channels, children perceive the setbacks and successes inflecting the pathways of other neighborhood youth. To describe the potential role of this larger normative context, two general models are proposed.

The first general model is based on the premise that children's behavior will be affected by their larger normative context in a manner that mirrors behaviors and attitudes that are common around them. This approach incorporates epidemic models (Crane, 1991; Jencks & Mayer, 1990), which propose that negative outcomes such as school dropout or teenage childbearing are "contagious," in the sense that they propagate through contacts with peers exhibiting problematic behaviors and who are thus "infected." The model stipulates, for instance, that when a behavior reaches a critical threshold, it spreads like

an epidemic, but remains under control when this critical threshold is not attained. As disadvantaged neighborhoods are composed of more individuals at risk of developing a behavioral “sickness” due to their individual and family circumstances, “outbreaks” are more likely in these contexts.

The spread also could be complicated by the fact that fewer individuals are “inoculated” with protective factors. Harding’s (2009, 2011) model of cultural heterogeneity can be included under this approach as well. This model suggests that disadvantaged neighborhoods are far from monolithic cultural entities. Rather, it proposes that children living in such neighborhoods are exposed to a wide range of cultural scripts, mostly mainstream ones, but also to many unconventional variants, such that youth in disadvantaged neighborhoods have a wider set of models to choose from than their peers in more advantaged neighborhoods, creating confusion and opening the way for suboptimal or deviant choices. The epidemic and heterogeneity models stress different processes, but they both propose that behaviors and attitudes spread and reproduce themselves within a neighborhood, so that the proximity of peers engaging in problematic behaviors increases the chances that other youth from the same community will do the same, and vice versa. Empirical support for these models comes from studies showing that unfavorable outcomes such as low achievement and risky sexual behaviors are more likely for youth when they are surrounded by low achieving or risk-taking peers in their neighborhoods than when they are not (e.g., Harding, 2009, 2011).

The second general model proposes that peers influence youth’s motivation and behavior through a comparative process of redefining one’s relative standing in the immediate social context (e.g., neighborhood). In the neighborhood literature, this process is generally known as “relative deprivation” (Jencks & Mayer, 1990) and is referred to as the “big fish little pond” or the “frog pond” effect in the education literature focusing on school effects (e.g., Crosnoe, 2009; see Crosnoe & Benner, Chapter 7, this *Handbook*, this volume). For instance, the academic self-concept of a high-achieving youth may be higher if the youth lives in a neighborhood where the youth excels compared with neighborhood peers than if the youth performs the same but lives in an exclusive neighborhood comprised of other high achieving children who are exposed to strong pressures to distinguish themselves both in school and in other domains (Luthar & Barkin,

2012). Thus, according to this perspective, growing up in a relatively disadvantaged neighborhood may lead to comparatively positive outcomes in some domains such as achievement. Supporting this view, disadvantaged youth were more likely to feel inadequate when they were exposed to a relatively advantaged neighborhood contexts, as compared with their respective peers in more disadvantaged settings, and this experience had developmental consequences (e.g., Clampet-Lundquist et al., 2011). A particularly telling example comes from the evaluation of the Yonkers Project: Seven years after relocation, youth who moved to middle-class communities had similar scores on standardized tests to youth from comparable backgrounds who did not move (Fauth et al., 2007). Even though their achievement scores were indistinguishable, movers reported worse academic performance and lower school engagement as compared with stayers, consistent with the relative deprivation hypothesis.

These two families of models lead to contrasting hypotheses regarding the connection between the presence of disadvantaged peers in children’s neighborhoods and their developmental outcomes: The first set of normative models lead to the prediction of worse outcomes, whereas relative deprivation models anticipate better outcomes, in particular for struggling or disadvantaged children (e.g., Crosnoe, 2009). In fact, both could operate in parallel and somewhat cancel each other’s effect. For this reason, considering both simultaneously may be necessary to fully understand how the influence of the neighborhood context plays out. Recent efforts have tried to do just that in the school effects literature, with mixed results (see Crosnoe & Benner, Chapter 7, this *Handbook*, this volume). One factor that complicates the picture is that the relative importance of these competing processes could depend on the specific outcome considered. In theory, the adverse effect of school or neighborhood disadvantage should be felt more acutely in terms of actual performance, whereas the beneficial effects stemming from social comparison should be most evident in perceptions of abilities and motivation (Crosnoe, 2009). This interpretation could help to explain the discrepant results of the Yonkers Project, where differences between those who moved to more advantaged neighborhoods were observed on self-perception outcomes but not on standardized-tests outcomes (Fauth et al., 2007). In short, the ways in which neighborhoods shape the larger normative peer context is likely to be complex and vary as a function of neighborhood, peer, and individual factors.

### ***Neighborhoods Constraining Youths' Unstructured Peer Group Activities***

The previous sections describe ways in which neighborhoods can shape the characteristics of peers who comprise children's social world, be it intimate friends or the backdrop of acquaintances who create the local normative ethos. A third way in which the neighborhood context can affect young people's peer relationships is not so much by influencing *who* is in their social worlds, but rather by defining *what* activities they can engage in with their peers. Indeed, some neighborhoods have less tolerance for youth's unstructured and disorderly activities than others, and more collective resources to curtail them (Sampson, 1997). In addition, some neighborhoods have comparatively more institutional resources than others, facilitating children's participation in structured activities that reduces time left for "hanging out" or loitering around in the neighborhood as described in the previous section (see also Vandell et al., Chapter 8, this *Handbook*, this volume). These neighborhood processes and resources help define the opportunity structure for youth's delinquent and risky behaviors, as these behaviors typically take place in the context of unsupervised, unstructured activities with peers (Osgood, Wilson, O'Malley, Bachman, & Johnston, 1996). Research supports the hypothesized linkages between the neighborhood context, time spent in unstructured, unsupervised activities with peers, and both youth delinquency and victimization (e.g., Maimon & Browning, 2010).

Thus, there are a number of ways in which the neighborhood context can shape children's peer context. Rather than operating in isolation, these components are likely to reinforce one another's influence on behavior. If we take delinquency, for instance, it is likely that youth in more disadvantaged neighborhoods will be exposed to more deviant individuals in their peer groups, and live in a larger context where delinquent activities are more frequent and where opportunities to spend time in unstructured, unsupervised activities with peers are greater. These conditions can reinforce one another leading to youth's enhanced risks of engaging in problematic behaviors. Along these lines, Maimon and Browning (2010) found that spending time in unstructured activities with peers was more strongly associated with violent behaviors among youth living in neighborhoods with fewer social resources. In the same manner, Pettit et al. (1999) found that adolescents who lived in a disadvantaged neighborhood context and who

had deviant peers were especially at risk, thus supporting the idea of cross-context interactions, in this case between the smaller world of the peer group and the broader context of the neighborhood.

### ***Synergies Between Neighborhood and School Contexts***

Concentrated neighborhood disadvantage has implications for schools as well, with schools in disadvantaged neighborhoods often facing numerous challenges that are thought to adversely affect learning and other developmental outcomes (see the earlier "Neighborhood Institutional Resources" and "Institutional Resources" sections in this chapter). Thus, the ways in which these two contexts intersect have ramifications for children's achievement.

One way in which this issue has been studied is through school reform initiatives for children living in disadvantaged neighborhoods. Some evidence suggests that when children from impoverished neighborhoods receive high quality educational services on par with those available to their peers in more affluent communities, they can thrive (e.g., DeLuca & Dayton, 2009). One example is the Promise Academy, a charter elementary and middle school located in a disadvantaged neighborhood, which was part of the HCZ described earlier (Dobbie & Fryer, 2011). Other charter schools have been found to improve children's achievement too, especially among disadvantaged youth (see Abdulkadiroğlu, Angrist, Dynarski, Kane, & Pathak, 2011; Gleason, Clark, Tuttle, & Dwyer, 2010), suggesting that charter schools may be particularly effective in comparatively disadvantaged neighborhoods, where local schools are more likely to struggle.

In addition to public charter schools, school choice voucher programs offer another way to improve access to high quality schools among children from disadvantaged neighborhoods. Charter schools are alternative public schools, whereas voucher programs allow parents to use public funds to pay tuition in a private school of their choosing. Evaluations of various school choice vouchers programs report mixed, often disappointing results (for a review see DeLuca & Dayton, 2009). Many explanations are proposed for these findings, but one relevant from a neighborhood perspective is that improving schools without improving other potentially problematic aspects of children's lives, such as their neighborhoods of residence, may be insufficient. Yet this argument is at odds with the favorable results of charter school evaluations for disadvantaged children. Clearly, studies specifically designed

to address the added value of community investments are needed to settle this issue.

Although school improvement can benefit the achievement of children living in disadvantaged neighborhoods, the reverse is not necessarily true. That is, neighborhood improvement without school improvement appears insufficient to significantly benefit children's achievement. Notably, results from the MTO experiment showed that more advantaged neighborhood conditions without corresponding changes in school conditions yielded no achievement benefits (Gennetian et al., 2012; Sanbonmatsu et al., 2006). It is important to note, however, that favorable achievement results were observed in two of the MTO sites, Baltimore and Chicago, two cities with serious problems of poverty concentration and crime (Burdick-Will et al., 2011). This finding raises the possibility that getting out of extremely disadvantaged neighborhoods might, in and of itself, be enough to make a difference for children's achievement.

This section outlined how various contexts intersect with the neighborhood context to create the complex, interrelated settings in which child development takes place. However, as covered in the next section, further complexities emerge from the fact that individual children also interact with these contexts, thus shaping their own environments as well as their exposure and responses to them.

### Person-Context Interactions

In addition to the web of contexts in which children develop (Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1), each of these contexts has its own internal complexity. Notably, Harding's work (2009, 2011) illustrates that neighborhoods are culturally heterogeneous entities, exposing children to a range of subcultures and alternative scripts. Individual children thus can choose among these models according to their backgrounds and preferences. They can even influence the range and salience of alternative subcultures available to them by eliciting responses from others via their own actions. Such a multi-faceted, ever evolving system leaves room for a lot of individual variation as to how the neighborhood context is experienced, with individual children bringing into the mix their own individual strengths, vulnerabilities, and filters (Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1). Thus, the neighborhood context likely influences development in different ways and at different degrees for different children. A growing set of studies examines this notion by considering how the link between neighborhood

characteristics and children's development is moderated by individual characteristics such as gender, race/ethnicity and biological/psychological vulnerability. The next section presents the result of neighborhood research investigating moderation along these lines.

### Gender

The moderating role of gender on "neighborhood effects" erupted in the field in part because of MTO results showing favorable effects on girls' mental health and risk behaviors, but null or negative effects for boys (Kling et al., 2007; Gennetian et al., 2012). Why did girls and boys react so differently when they moved from a very poor neighborhood to a lower poverty one? In-depth interviews with MTO participants provide interesting explanations. One such study revealed that social integration was easier for girls, in part because boys' activities and demeanor departed from the norm in their new neighborhoods, prompting negative reactions from neighborhood adults including the police (Clampet-Lundquist et al., 2011). As a result, many of these boys were drawn towards local marginalized delinquent groups or continued their involvement with peers from their old, disadvantaged neighborhoods. Given the strength of peer influences during adolescence (see the previous section in this chapter, "Synergies Between Neighborhood and Peer Contexts"), this study provides a powerful explanation for the unfavorable results observed among boys. In terms of the favorable results observed among girls, another MTO-based study revealed that issues related to safety were pivotal. In this domain, girls reported major improvements that were specific to them, notably around themes of sexual violence and victimization (Briggs, Popkin, & Goering, 2010; Popkin et al., 2010). In short, many boys experienced significant setbacks after they moved, whereas girls felt free from serious threats that loomed in their neighborhoods of origin.

These MTO findings highlight that gender may have profound implications when it comes to the direction and strength of associations among neighborhood characteristics and children's development, particularly during adolescence (see Leventhal et al., 2009, for further discussion). Clearly, the generalizability of these findings is limited to the specific case in which youth from very disadvantaged neighborhoods moved to more advantaged ones. Nonexperimental studies including diverse samples living under more typical circumstances (where neighborhood characteristics are fairly stable over time despite residential mobility) are needed to evaluate the extent to which the

MTO findings with regard to gender generalize to a wider range of contexts and situations.

The few studies tackling the question of how gender moderates associations between neighborhood characteristics and children's development generally rely on the following premise: Boys should be more sensitive to their neighborhood context than girls because they tend to receive less parental oversight and more freedom to spend time outside of the home (e.g., Kroneman, Loeber, & Hipwell, 2004). For this reason, boys living in disadvantaged neighborhoods with more crime and less social control may have greater exposure to violence and deviant peers and other negative role models as compared with girls. This exposure, in turn, may result in stronger associations between neighborhood conditions and problem behaviors among boys than girls. About a decade ago, a review of gender differences in neighborhood associations with children's and adolescents' delinquency and conduct problems, came to this conclusion, although the authors advised caution due to the small number of studies addressing the question as well as methodological issues and inconsistencies across studies (Kroneman et al., 2004). Since then, additional studies using various samples were published, but inconsistencies remain (e.g., Drukker, Kaplan, Feron, Van Os, & Korebrits, 2010; Fagan et al., 2012).

The argument for problem behaviors may not apply to mental health outcomes. That is, girls could be more adversely influenced by disadvantaged neighborhood circumstances for at least two reasons. First, as described, the MTO results revealed that in disadvantaged neighborhoods, many girls fear for their physical safety, with consequences for their well-being. Second, MTO results as well as other nonexperimental work (see this chapter's section "Synergies Between Neighborhood and Family Contexts") also suggest that neighborhood disadvantage and related conditions take a toll on maternal mental and physical health (Ludwig et al., 2011, 2012), a situation that potentially strains family relationships (see Leventhal & Brooks-Gunn, 2005). Girls may be more strongly affected by this strain than boys, as interpersonal stress has a stronger association with their mental health (e.g., Rudolph, 2002). The research base addressing this debate is very small. A study conducted in rural Iowa in the early 1990s found that neighborhood SES was associated with boys' emotional distress but not girls' (Simons et al., 1996). In contrast, several studies of predominantly minority youth find a stronger link between neighborhood conditions and girls' depressive symptoms than boys' (e.g.,

Fitzpatrick, Piko, Wright, & LaGory, 2005; Gutman & Sameroff, 2004).

With respect to achievement, the quality of institutional resources, notably child care, preschool, and schools, could be expected to play an important role (e.g., Dupéré et al., 2010; see also this chapter's section "Institutional Resources"), and there is no reason to expect that exposure to local educational opportunities will vary as a function of gender. Nevertheless, other processes may be operative. Although the strength and direction of gender differences in achievement are unclear, most studies point to stronger associations with neighborhood socioeconomic characteristics among boys than girls (Leventhal et al., 2009); however, some studies find the reverse may be true among certain subgroups (e.g., Crowder & South, 2003). Thus, the extant research on achievement is consistent with work on problem behaviors, suggesting that boys may be more sensitive to neighborhood socioeconomic conditions than girls.

The potential role of other individual characteristics, notably age, urbanicity, and race/ethnicity, to explain some of the discrepant findings in gender differences is hard to ascertain in a context where the empirical base is composed of a small number of studies that differ along multiple dimensions. As the literature continues to grow, so too will new opportunities for systematic reviews and meta-analysis, thus allowing for a better understanding of the moderating role played by gender in the link between the neighborhood context and children's development.

### ***Race/Ethnicity and Immigration Status***

There are a number of reasons why neighborhood characteristics may be differentially associated with children's development as a function of racial/ethnic or immigration status. Some researchers propose that minority children should be more strongly influenced by their local circumstances than nonminority children, as they are more likely to be embedded in dense neighborhood-based social networks (Crowder & South, 2003; Jarrett, Jefferson, & Kelly, 2010). This argument rests on the observation that such networks often are found in minority neighborhoods and may be particularly influential in a context where local ties are reinforced by the sense of a shared ethnic/racial group identity (see McBride Murry, Hill, Witherspoon, & Berkel, Chapter 11, this *Handbook*, this volume). Although the strength of the relation between neighborhood context and children's development may be generally stronger among minority children than among their European American peers, the nature and direction of the link may vary as

a function of the specific history and circumstances of different minority groups.

Among African American families, living in a disadvantaged, unsafe neighborhood takes a heavy toll on both parents and children (e.g., Crane, 1991; Crowder & South, 2003), perhaps because neighborhood crime and violence reach particularly high levels in disadvantaged, predominantly African American neighborhoods. This potential vulnerability is not limited to crime and violence, as disadvantaged African American neighborhoods are host to other social problems, including high rates of joblessness, incarceration, and family dislocation (W. J. Wilson, 1996). The challenges faced by many poor African American neighborhoods are at least in part the legacy of a long history of segregation and isolation (Massey & Denton, 1993; W. J. Wilson, 1987). As a result of this history, African American neighborhoods often cluster together in certain areas within a given city. Due to spatial contiguity and shared borders with high-poverty African American neighborhoods, even middle-class African American neighborhoods have to struggle with inner-city violence “spill overs” (Pattillo, 1998; Sampson, 2012). This situation has consequences for exposure to violence and crime: Exposure to neighborhood violence is more prevalent among African American youth as compared with other racial/ethnic groups, particularly so for those living in disadvantaged urban neighborhoods (for a review see Buka, Stichick, Birdthistle, & Earls, 2001). In addition, predominantly African American neighborhoods confront the stigma associated with ingrained negative perceptions of their neighborhoods held by individuals of all races (Sampson, 2012).

Segregation and isolation in disadvantaged neighborhoods also have ramifications for social networks by contributing to local networks that do not cut across socioeconomic or neighborhood lines (e.g., Small, 2009). Networks composed of others living close by in such neighborhoods may not lead to helpful supports and levers, but rather to increased obligations, hassles and negative outcomes (Portes, 1998). For instance, Caughy, O’Campo & Muntaner (2003) found, in a sample of African American families living in Baltimore, that greater parental social capital within the neighborhood was associated with young children’s better mental health outcomes, but only among those living in comparatively advantaged neighborhoods. Other studies find the reverse to be true in disadvantaged neighborhoods: Strong links with neighbors were associated with worse mental health outcomes (e.g., Dupéré & Perkins, 2007). Thus, the role of protective factors such as social support may be undermined in the

highly challenging neighborhood contexts that many poor African Americans children live. Conversely, weakened protective factors may result in the pronounced role of risk factors known to jeopardize children’s development. For example, one study based on the nationally representative Add Health sample found that neighborhood disadvantage amplified the link between girls’ early puberty and their substance use, but only among African American girls (Tanner-Smith, 2012). In short, the fact that disadvantaged African American neighborhoods struggle with particularly difficult conditions may undermine protective factors and amplify risk factors at other levels, individual or familial. Such interactions could generate unique situations of vulnerability among African American children living in disadvantaged African American neighborhoods.

There are signs that for Latino/a American children, living in a poor, predominately Latin American or immigrant neighborhoods (i.e., enclaves or “barrios”) may not be associated with such challenges as in the case of African American children, and may, on the contrary, have some protective effects. This proposition is linked to the literature on the so-called Latino paradox. This paradox refers to the observation that despite high levels of poverty and disadvantage, Latino/a Americans in the United States tend to have outcomes that are as good as or better than that of European Americans, notably in terms of physical health, such as birth outcomes and mortality (Mason et al., 2011), possibly behavioral outcomes, such as violence (e.g., Sampson et al., 2005), but not necessarily achievement outcomes (e.g., Gonzales, Germán, & Fabrett, 2012). This relative advantage is especially pronounced among those living in co-ethnic neighborhoods characterized by high Latino/a American concentrations and traditional collective values oriented around the family (Bécares et al., 2012; Gonzales et al., 2011).

It is important to note though that this protective function is not observed unilaterally, with the benefits associated with residence in a co-ethnic neighborhood varying according to immigration status and among subgroups within the Latino/a American population (Osyuk et al., 2012; Estrada-Martínez, Caldwell, Schulz, Diez-Roux, & Pedraza, 2013). Thus, caution is warranted to avoid overgeneralization (Leventhal & Shuey, 2014).

Various explanations are proposed as to why living in a Latino/a American enclave may confer benefits for Latino/a American youth, despite the fact that these neighborhoods are typically poor. One major explanation revolves around the observation that although poor, these neighborhoods do not experience many of the other

challenges confronting predominantly African American poor neighborhoods. Specifically, many have relatively high levels of employment and married families, along with low levels of crime and violence (Sampson, 2012). In addition, these neighborhoods are thought to be socially cohesive around a set of traditional values associated with familism (e.g., Gonzales et al., 2012; Estrada-Martínez et al., 2013). Among Mexican American families in a southwestern metropolitan area, these neighborhood characteristics served a buffering role for children's social, emotional, and behavioral functioning (Gonzales et al., 2011; Nair, White, Roosa, & Zeiders, 2013). But again, national data reveal that these links may not generalize to Latin American groups of all origins (Estrada-Martínez et al., 2013). Additional studies are needed to further examine these findings and the extent to which they apply to various subgroups and outcomes.

For Asian Americans, the role of neighborhood characteristics in children's development may parallel more closely that observed among Latino/a Americans than among African Americans, due to the unique historical roots of segregation among the latter and the larger share of recent immigration among both Latino/as and Asians (Mason et al., 2011). The handful of studies investigating neighborhood associations with Asian American children's development lends some support to this notion (Mason et al., 2011), although there are notable inconsistencies (e.g., Perreira, Harris, & Lee, 2006). As with Latino/a Americans, differences among subgroups (i.e., country of origin) within the Asian population exist in the connection between neighborhood characteristics and children's outcomes (Janevic et al., 2010), again calling for additional studies to document these trends.

Native American children represent another group that has been understudied in the field of neighborhood research, reflecting a broader neglect in the child development literature (Sarche & Whitesell, 2012). Their near total absence may be due to the fact that Native Americans are more likely to live in rural areas that are generally underrepresented in a field that mostly concentrates on urban areas (Burton & Jarrett, 2000). In addition, research with tribal communities presents unique challenges (Sarche & Whitesell, 2012). No matter the reasons, this absence is problematic. Native Americans have a special history and status in the United States, so that findings from other groups cannot be assumed to generalize. In particular, almost one-quarter of Native Americans live on reservations, underscoring their exceptionality in terms of neighborhood life (Norris, Vines, & Hoeffel, 2012).

The concentration of multiple problems on reservations, including poverty, unemployment, and substance abuse, raises many important questions that await answers from developmental scientists interested in neighborhood context.

There is some research to suggest that residence on a reservation may confer benefits in terms of adolescents' mental health (LaFromboise, Albright, & Harris, 2010), although other findings indicate that residence on a reservation may be associated with both early onset and intensity of drug use (Yu & Stiffman, 2007). Among Native American youth living off-reservation, neighborhood characteristics had no relation with their drug use (Yabiku, Dixon Rayle, Okamoto, Marsiglia, & Kulis, 2007). In line with research on other racial/ethnic groups, neighborhood disadvantage was adversely associated with a composite score of successful functioning (including being alcohol- and drug-free) in a sample including Native Americans youth both on- and off-reservation (Silmere & Stiffman, 2006). Interestingly, improving economic conditions on a reservation following the opening of a casino were associated with adolescents' improved behavioral trajectories (Stiffman, Alexander-Eitzman, Silmere, Osborne, & Brown, 2007). Even this small number of studies demonstrates the complexity of the situation, raising the possibility that links between neighborhood conditions and Native American children's development may depend on the place of residence (on- or off-reservation) and vary as a function of outcome. Moreover, as is true among other groups, Native Americans include a wide variety of subgroups with their own history and circumstances, highlighting the need for studies sensitive to this complexity.

Despite its shortcomings, the research base reviewed clearly indicates that racial/ethnic/cultural differences matter in terms of neighborhood associations with children's development. As such, this theme deserves more attention, especially among conspicuously understudied groups, such as Asians and Native Americans, as well as Latino/a Americans. The complexities of racial/ethnic differences within the United States also encourage circumspection when it comes to extrapolating an overwhelmingly U.S.-based neighborhood literature to other national contexts (e.g., Musterd & Ostendorf, 2005; Oreopoulos, 2008; Wacquant, 2008). Cross-national comparisons will become increasingly possible as the collection of studies from outside the United States continues to grow. A considerable research base in Western Europe was sufficient to support transatlantic comparisons in a review of neighborhood effects

(Galster, 2012). With neighborhood studies accumulating from developing countries as well (e.g., Kabiru, Beguy, Undie, Zulu, & Ezech, 2010; Villareal & Silva, 2006), new possibilities for cross-national studies will emerge. Such studies are needed to establish the generalizability of “neighborhood effects,” and the extent to which they are conditioned by national institutions and social structures rooted in particular historical contexts as relational developmental systems perspectives would suggest (Blossfeld, 2009).

### ***Individual Biological/Psychological Vulnerability***

In addition to gender and race/ethnicity, biological or psychological characteristics could interact with neighborhood characteristics and moderate associations with children’s development. Most of the theoretical and empirical work on this topic focuses on adolescence and on problem or risky behaviors. Theoretically, two opposing positions have been proposed (see Lynam et al., 2000 for details). The first, the “social push” perspective (Raine, 2002) argues that neighborhood disadvantage should attenuate the etiological role of biological/temperamental risk factors in the genesis of antisocial behaviors. The premise is that genetic predispositions are likely to play a central role in a benign milieu with few environmental risks (e.g., deviant peer groups, unstructured opportunities). In such an advantaged context, individual risks would *have* to be present, in all likelihood, to motivate youth’s violent or antisocial behaviors. In contrast, in very disadvantaged neighborhoods where the social risks may be numerous and where the opportunities to engage in delinquent activities are conspicuous, one would not need to have strong biological or temperamental dispositions to exhibit problem behaviors. Rather, the social push is powerful enough in these contexts to drive antisocial behaviors even among those with low to moderate levels of biological/temperamental risks.

This position can be seen as a variation on the theme of the “strong situation hypothesis” (Cooper & Withey, 2009). This hypothesis, based on the work of Mischel (1977), proposes that personality differences are especially likely to be outwardly expressed in “weak” situations offering no clear situational cues and a wide range of possibilities as to how to behave. Conversely, individual differences are expected to have less room for expression in “strong” situations where the choice of behavioral outcomes is severely limited and where everyone is bound to behave in a similar way. Highly disadvantaged neighborhoods are thought to be one example of a strong situation that severely limits the possibilities for conventional behavior (Lynam et al.,

2000); however, this proposition is at odds with Harding’s (2009, 2011) work on cultural heterogeneity, which suggests that the variety of alternative behavioral scripts is wider in more disadvantaged neighborhoods as compared with less disadvantaged ones, where one pathway often clearly dominates all others. Less disadvantaged neighborhoods arguably could be described as a social context offering strong situational cues encouraging conformity and limiting the expression of individual differences. Thus, individual risks could play a magnified role in highly disadvantaged neighborhood contexts.

In line with this latter prediction, the second theoretical position rests on an amplification or synergetic perspectives as described earlier (see this chapter’s section “Synergies between Neighborhood and Family Contexts”), where the combination of risks at the individual level, along with situational incentives, creates the right mix for problematic behaviors to emerge (see Lynam et al., 2000). This view is consistent with general theories of child development highlighting the interactions between nature and nurture (see Lerner, Lerner, Bowers, & Geldhof, Chapter 16, this *Handbook*, Volume 1). It is also consistent with specific theories in criminology proposing that an individual’s propensity for antisocial behavior is more likely to translate into actual criminal behavior for those exposed to crime-prone environments (Agnew, Brezina, Wright, & Cullen, 2002; Wright, Caspi, Moffitt, & Silva, 2001). So far, the empirical neighborhood literature generally supports this amplification perspective over the social push hypothesis (e.g., Schonberg & Shaw, 2007). In most studies, neighborhood disadvantage interacts with individual risk factors in a manner amplifying problematic outcomes. For example, the link between impulsivity or self-control and delinquency-related outcomes was strongest in disadvantaged neighborhoods in both city-based and national samples (e.g., Gibson, 2012; Jones & Lynam, 2009; Meier, Slutske, Arndt, & Cadoret, 2008). This conclusion should be considered tentative, because it is based on a small number of studies and discrepant findings exist (e.g., Zimmerman, 2010).

Interactions between neighborhood and individual risks emerged in studies looking at other individual risks aside from impulsivity. Notably, early pubertal development is more strongly associated with girls’ problem behaviors in disadvantaged neighborhoods than in more advantaged ones (e.g., Foshee et al., 2007; Obeidallah, Brennan, Brooks-Gunn, & Earls, 2004). Relatedly, Canadian girls with a history of conduct problems during childhood were found to be more likely to report early sexual debut, but

only if this individual risk was combined with neighborhood disadvantage (Dupéré et al., 2010). This work is also consistent with the amplification perspective.

Thus, a general pattern of results supports the amplification hypothesis, but discrepant findings continue to raise questions regarding its role relative to the social push perspective. Many possible explanations have been proposed for these discrepancies, such as the different ways in which individual vulnerabilities and neighborhood characteristics were measured in different studies, as well as the different developmental periods considered (e.g., Zimmerman, 2010).

In sum, this section highlighted the ways in which individuals contribute to their development, but most of the research falls short of considering the bidirectional nature of these influences. That is, individual attributes not only intersect with the neighborhood context in meaningful ways for children's development, but also shape the neighborhood context in which this development unfolds.

## NEIGHBORHOOD AS A UNIT OF INTERVENTION FOR IMPROVING CHILDREN'S DEVELOPMENT

The research reviewed in this chapter thus far suggests that neighborhood context is associated with children's development, though clearly the nature, scope, and magnitude of these associations remain debatable. Nevertheless, interventions aimed at improving neighborhood conditions hold some promise for promoting children's health and well-being and remain better positioned than ever to build off of a growing research base than previous efforts described at the beginning of this chapter (see the section "Progressive Era to Promise Neighborhoods"). With this goal in mind, two types of interventions are addressed: (1) "people-based," which move residents out of poor neighborhoods to nonpoor ones; and (2) "place-based," which invest locally in communities to improve living conditions for current residents (see also "Neighborhood SES" in this chapter).

### People-Based Interventions

The goal of people-based interventions is to expand the residential options of low-income families. Because of limited economic means, low-income families' housing choices are constrained, often restricting them to more affordable housing located in disadvantaged neighborhoods. Subsidies partially covering the cost of rent are one way to help poor

families afford housing. However, unless special assistance with relocation is provided or restrictions on relocation are placed, it is unclear if families given subsidies locate in more advantaged neighborhoods, though they often avoid the most distressed neighborhoods where public housing is located.

MTO is a prime example of this policy approach and represents both its successes and failures. It was successful in the sense that many of the families in the experimental treatment group took advantage of the opportunity to move to safer, less poor neighborhoods than their original neighborhoods. Yet, it failed because more than half of these same families did not relocate because they were unable to find a new unit in the private market, among other reasons. Even among those families who moved to lower poverty neighborhoods, exposure to favorable neighborhood condition was relative, and in many cases short-lived. True, the new neighborhoods were more economically advantaged at the time of the move, but many destination neighborhoods were either on a downward economic slope, or not racially diverse, or both. Moreover, the moves were not associated with noteworthy improvements in school conditions (Gennetian et al., 2012). In addition, after the initial MTO move to better neighborhoods, many families returned to disadvantaged areas. In any case, mobility programs such as MTO necessarily serve only a small fraction of eligible families and may engender some public resistance both from receiving neighborhoods where families relocate as well as from origin neighborhood where others are left behind. Thus, alternative approaches to improve disadvantaged neighborhoods themselves are needed.

Before we move on to discuss place-based strategy, it is important to note one important alternative strategy to the use of vouchers for subsidizing private rental housing in nonpoor neighborhoods. This alternative consists of building new public or affordable housing units in such neighborhoods. This strategy may lead to more stable placement in nonpoor areas than vouchers where problems with landlords can arise, for example, thus potentially avoiding some of the challenges encountered in MTO (though other types of challenges arise; Fauth et al., 2008). However, just as was the case for MTO, mixed results suggest that the effectiveness of this strategy might depend on the general context of mobility. That is, mobility within a city and with no corresponding change in school quality may not lead to favorable outcomes, as was observed in the Yonkers case (Fauth et al., 2007). Still, quasi-experimental evidence emerging from another project entailing the construction of affordable housing units in an affluent

suburb in Mount Laurel, New Jersey, suggests that this strategy has the potential to lead to favorable economic, educational and emotional outcomes (Casciano & Massey, 2012). These findings converge with the generally positive outcomes for Gautreaux families, who largely relocated to suburban areas, and with more recent nonexperimental studies in which mobility from disadvantaged urban neighborhoods to more affluent suburbs was associated with beneficial outcomes, as compared with mobility from one disadvantaged city neighborhood to another (Dupéré et al., 2012; Sharkey, 2012).

### Place-Based Interventions

Placed-based interventions offer an alternative to mobility where the goal is to address neighborhood conditions themselves. Earlier efforts targeting crime prevention in the “neighborhood watch” tradition had some success (Bennett, Holloway, & Farrington, 2008). Building on these efforts, new and broader approaches focusing explicitly on children and families have emerged, with promising results.

A notable example is HCZ (Harlem Children’s Zone, 2009). As described earlier, the program’s explicit goal is to improve the life chances of all children living in a targeted disadvantaged section of Harlem. The program is based on the premise that to lift children out of poverty, they have to graduate from high school and go to college, so that they can successfully integrate into a knowledge-based job market. To achieve this ambitious goal, HCZ proposes a “pipeline” approach, spanning the life course from before birth to college, and involving coordinated community-based services in the educational, health, and social domains. As noted, the program is favorably associated with children’s achievement; however, it remains unclear whether the complete bundle of HCZ services is necessary, over and above the charter schools, to achieve these results (Dobbie & Fryer, 2011; see also this chapter’s section “Synergies between Neighborhood and School Contexts”). In any case, HCZ’s success has been well received and replication efforts are occurring in many communities through Promise Neighborhoods.

Communities that Care (CTC) represents another form of community investment shown to foster healthy child development (e.g., Hawkins et al., 2009). In contrast with the HCZ, CTC does not have any specific program or target. Rather, it proposes a five-step process aimed at mobilizing key community actors towards the selection and implementation of effective programs suited to the

specific needs and circumstances of their local youth. CTC was developed over the past 30 years within a U.S. federal entity, the Center for Substance Abuse Prevention (CSAP). Not surprisingly, given its origin within CSAP, CTC primarily focuses on the prevention of substance abuse problems, although other types of psychosocial difficulties such as delinquency are targeted. CTC was tested in the context of a trial in which 24 communities were randomly assigned to control and intervention conditions, with favorable and cost-effective results (Hawkins et al., 2009; Kuklinski, Briney, Hawkins, & Catalano, 2012). Thus, CTC provides an example of a community-based intervention with demonstrated effectiveness within a randomized controlled trial.

Poverty deconcentration approaches address the problem from a somewhat different angle. Instead of trying to counteract the adverse effects of concentrated poverty, the root of the problem is targeted by supporting the development of mixed-income neighborhoods. HOPE VI, mentioned briefly earlier, is a well-known example of this approach. Infamous housing projects such as the Robert Taylor Homes in Chicago were demolished as part of HOPE VI, with the goal of replacing them with mixed-income communities. Although the effectiveness as well as underlying premise of such efforts have been questioned (Cheshire, 2012), some evidence suggests that HOPE VI had long run benefits for families (Popkin et al., 2009).

The existing options for community-based intervention are not limited to the few examples discussed here. Beyond the varied approaches that already exist, many other potential avenues for community-based interventions are worth exploring, based on neighborhood effect theory and research. Clearly, there is room for innovation in this domain. Policywise, pursuing community-level interventions makes sense, as it could offer more effective options with potentially wider reaching effects than interventions targeting individuals.

### BUILDING THE FRAMEWORK

As the field of neighborhood research moves forward and plays an increasingly important role in policy, we would like to build a more dynamic framework for conceptualizing and assessing children’s development in the neighborhood context—one that takes a truly relational developmental systems perspective. As our review of extant research indicated, we have made some progress in

beginning to think dynamically and developmentally about the link between neighborhood structure and children's outcomes. In addition, our understanding of the features of neighborhoods that matter most has expanded beyond structure, as has our knowledge of how neighborhoods intersect with children's other important social contexts and salient individual characteristics. We begin this section by laying out some of the conceptual issues that need to be considered for a dynamic framework and then move onto the methodological tools that will get us there.

### **Promising Conceptual Directions**

The previous sections of this chapter raised several important theoretical themes that merit further attention. We address them here as promising conceptual directions for a new framework.

#### ***Developmental Timing***

As we discussed in the section "Neighborhood SES," longitudinal research has begun to explore if the role of neighborhood SES varies across development. This issue is fundamental to our understanding of neighborhood influences. Although the existing research reviewed is too limited to adjudicate among the various hypotheses presented (cumulative, adolescence, and early childhood), it points to several related issues with regard to timing that merit attention. It may be that no single hypothesis prevails because the role of neighborhood influences varies by the aspect of neighborhood and the outcome under consideration. Given general variation in patterns of associations among neighborhood SES and children's outcomes, such an expectation is reasonable. Further, the manner in which neighborhoods influence children is also likely to shift across development. For instance, when it comes to achievement outcomes, economic and institutional resources during early childhood, including at the neighborhood level, are thought to be particularly important. For behavioral functioning, neighborhood poverty and collective efficacy during adolescence may be especially relevant, because monitoring of unstructured time with peers is critical during this period. Thus, it remains a question of not only when neighborhoods matter, but how they matter at different points in the life course and even for whom.

#### ***Dynamic Models***

Although longitudinal models are an important development in the field because they help to capture a broader

picture of children's neighborhood experiences, they often ignore the dynamic nature of neighborhood influences. Beyond issues of developmental timing, as just discussed, neighborhood contexts change over the course of development through both mobility and internal neighborhood dynamics (e.g., gentrification). New research in this area from nonexperimental studies as well as policy experiments suggests that these changes have implications for development (e.g., Leventhal & Brooks-Gunn, 2011). Thus, we should not ignore the meaning of smaller time units of exposure determined by the changing neighborhood circumstances in which children develop.

Another dynamic aspect of neighborhoods is space. In this chapter, we generally advocate for using census definitions of neighborhoods; however, many have argued for and against their use (e.g., McBride Murry et al., 2011). One promising approach for dealing with concerns about artificial boundaries is to employ GIS techniques that incorporate features of surrounding neighborhoods into estimates of neighborhood influences. Research along these lines has generated mixed results (e.g., Caughy et al., 2007; South & Crowder, 2010), but it merits additional attention for conceptualizing a range of issues such as how the spatial embeddedness of one's neighborhood or how larger spatial dynamics matters for development (see also Sampson, 2012). In addition, it can contribute to our understanding of more specific issues, such as the extent of overlap between home and school neighborhoods or how the distance of a move from one neighborhood to the next influences children's development. In short, researchers should think more broadly about what constitutes the neighborhood context rather than viewing it as an isolated geographic unit as in most existing research.

#### ***Bidirectionality***

This chapter focuses on the meaning of neighborhoods for individual children, but individuals also influence their neighborhoods as we discussed at some length already (see the section "Person-Context Interactions"). Yet, most research does not truly address how individuals select and shape their exposure to neighborhood influences despite much speculation about the bidirectional nature of neighborhood effects. For example, a study on parenting reported that increases in collective efficacy were associated with increases in authoritative parenting, but the reverse was not true (Simons et al., 2005). This study as well as others suggests that we need to frame our expectations regarding bidirectionality more explicitly rather than implicitly.

Along these same lines, little attention has been given to how neighborhood social processes arise and the role of residents, both individually and collectively, in the development of these processes. Clearly neighborhood structural characteristics, such as affluence, facilitate neighborhood processes, but nonetheless, neighborhoods can be cohesive and collectively efficacious even in the face of disadvantage. Small (2011), for example, argues that it is individuals' "organizational embeddedness" that allows for individuals within a neighborhood to become a community—that is, the institutions through which people interact are more or less successful in promoting networks that can function at both the individual and neighborhood levels. Related work has begun to identify characteristics that make neighborhoods resilient in the face of risk, including the presence of social networks and supports, infrastructure and support services, sense of purpose, and leadership (Buikstra et al., 2010; Maton, 2005). We see this area as one that will push the field forward conceptually and provide a stronger foundation for policy and practice.

### *Expanding the Scope*

A major goal of this chapter was to move beyond documenting links between neighborhoods and children's development and to address *how* and *why* neighborhoods matter. That being said, our understanding of these basic relations is limited in several important ways. For one, despite the rather widespread use of national data, we need to shift our conceptual focus away from urban, often poor areas, to consider a broader range of neighborhoods in terms of geographic locale and demographic makeup. In addition, much of the work on neighborhood processes is based on PHDCN, which was conducted in Chicago in the 1990s, and we need to understand if findings replicate in other locales and during different historical circumstances (Elder et al., Chapter 2, this *Handbook*, this volume).

A related point is that we should explore how wider city dynamics such as segregation, state policy contexts, and population dynamics play a role in neighborhood influences on children's development. Likewise, as we called for earlier, addressing the generalizability of research conducted in the United States is critical for documenting the salience of neighborhood context for children's development. Like other areas of child development, the field of neighborhood research would benefit from more replication studies across time and space (Duncan, Engel, Claessens, & Dowsett, 2012).

Finally, another way in which we need to expand the scope is by moving away from taking a deficit approach to

our study of children's development in the neighborhood context. Given the roots of neighborhood effects research in urban sociology, an emphasis on concentrated poverty, and with it, a focus on problematic behavior, has prevailed. We would like to see a shift towards considering the ways in which neighborhoods support children's development. The research mentioned earlier on neighborhood resilience is a promising direction, but should not be limited to disadvantaged contexts.

### **Promising Methodological Directions**

To incorporate such a developmental, dynamic framework in neighborhood studies, various methodological advances are needed to move the field forward. The following sections briefly review some methodological innovations that are promising with regards to this goal.

#### *Longitudinal Studies*

To allow for developmentally informed studies that take into account neighborhood dynamics, longitudinal studies following both neighborhoods and children and families are needed. In this respect, PHDCN is a prime example where both neighborhoods and individual children and their families were assessed at multiple time points and using multiple informants (see "Approaches to Studying Neighborhood Influences on Children's Development" section earlier in the chapter for details). Moreover, if interactions across contexts, including with families, peers, and schools, have a growing place in the neighborhood literature, it is essential that we give the same attention to assessing the neighborhood context that researchers have paid to these other contexts.

#### *Measuring Neighborhood Characteristics*

In terms of innovative neighborhood measurement strategies, PHDCN again stands out. An explicit goal from the start was to investigate links between neighborhood conditions and children's development (for a history of the PHDCN study, see Sampson, 2012), which contrasts with many other longitudinal developmental studies where the neighborhood context typically was considered post-hoc and restricted to census data. In the "Measuring Neighborhood Processes" section, we described these innovative methods in detail (community survey, systematic observation, administrative data, and expert survey) and highlighted them in our review of neighborhood influences on children's development, but their use is still

relatively scarce. However, some promising developments should push the field forward.

For one, a number of international studies modeled after PHDCN incorporated independent community surveys into longitudinal developmental studies (see Sampson, 2012 for details). In addition, new technologies offer interesting and comparatively cost effective options for conducting SSOs more routinely in developmental studies (e.g., Odgers, Caspi, Bates, et al., 2012; Rundle, Bader, Richards, Neckerman, & Teitler, 2011; see also Hoglebe, 2012, for a larger discussion of the role of GIS technologies in the field of neighborhood research). The increasing availability of administrative and public data offers another rich source of information on neighborhoods that has yet to be fully mined by researchers.

We strongly encourage more researchers interested in studying children in neighborhood contexts to consider their measurement *a priori* and to do so in a fashion that is ecologically valid, including making clear distinctions between neighborhood-level measurements and individual-level measurements of neighborhood perceptions. One prime example where such work is needed is in regard to the direct measurement of local institutions' *quality* to tackle the role of institutions in explaining developmental disparities across neighborhoods.

### ***Innovative Research Designs***

As is the case with measuring the neighborhood context, greater attention should be given to study designs. In a field dominated by nonexperimental studies, the MTO experiment was considered a major breakthrough because of its true experimental design. Yet much has been written about its strengths and flaws (e.g., Briggs et al., 2010; Sampson, 2008). The controversy surrounding MTO underscores the need for other experimental studies to tackle the selection bias problem, while avoiding some of its limitations. The prohibitive cost of MTO is one limitation that is relevant here and suggests the need for more affordable approaches that can be used more routinely.

As one such example, a series of experiments in the Netherlands was conducted to test the premise that physical signs of disorder on a neighborhood street can facilitate deviant behavior (Keizer, Lindenberg, & Steg, 2008). In one of the experiments, individuals were more likely to steal an envelope half-inserted in a mailbox and visibly containing money if the mailbox was covered with graffiti than if it was not. Another alternative is the use of natural experiments (see the section "Approaches to Studying Neighborhood Influences on Children's Development" for

additional detail). Clearly, not all of these studies focused on neighborhoods and children's development *per se*, but we see this work as a promising avenue for developmental research on neighborhood contexts to explore. An important point to acknowledge is that many experimental studies lack generalizability, because of their unique populations or circumstances, despite their inherent methodological strengths at addressing selection.

Although many have argued for a stronger adherence to experimental methods in neighborhood research (Ludwig et al., 2008), there is still an important place for non-experimental neighborhood research, particularly in the case of children's development (Sampson, 2008). Because nonexperimental research is likely to continue to play a central role in neighborhood research—and should—we encourage researchers to use research designs and analytical strategies meant to limit potential selection bias in the context of this work.

In terms of nonexperimental study designs, if assessing the role neighborhoods play in children's development is a primary study goal, then neighborhoods need to be incorporated into the study design (e.g., PHDCN and LA FANS) to generate desired variability in neighborhood contexts, to permit more robust analytic methods, and to allow for the construction of neighborhood-level measures (absent a community survey). Even in the case of neighborhood-based designs, selection bias remains an inherent problem. We reviewed various analytic methods for addressing this problem earlier (e.g., propensity score matching, sibling designs, instrumental variable analyses, and behavioral genetics; see the section "Approaches to Studying Neighborhood Influences on Children's Development" for a description), and are encouraged that such techniques are gaining popularity. The field will need to continue to push itself further in ensuring that researchers incorporate these more rigorous methods, and in a manner that addresses the dynamic interplay of neighborhoods with other contexts and individual characteristics.

### ***Mixed Methods***

The research designs just described all attempt to identify "true" neighborhood effects that are not confounded by other factors that influence neighborhood selection. This focus on the identification of causal relations has consumed much of the field in recent decades, overshadowing efforts to understand *how* the neighborhood context influences children's daily lives (Small & Feldman, 2012). Thus, a paucity of research takes a long, deep look at the lived realities that underpin the observed statistical links. In this

vein, researchers argue that to move forward, the field need not accumulate more studies trying to isolate neighborhood effects and instead call for new approaches to generate ideas and make sense of previous results (e.g., Harding, Gennetian, Winship, Sanbonmatsu, & Kling, 2011; Small & Feldman, 2012).

Mixed-methods studies combining quantitative and qualitative approaches offer one interesting avenue to attain such goals (Tolan & Deutsch, Chapter 19, this *Handbook*, Volume 1). One oft-cited exemplar case of a successful mixed-methods approach is, again, the MTO study. The qualitative work was instrumental in understanding major and unexpected results because elements not included in the survey emerged as central for understanding this disparity. Other notable examples combining interviews conducted in contrasted neighborhoods with surveys include the work of Small (2009) on child care services and that of Harding (2009, 2010) on violent confrontations. Again, we encourage neighborhood researchers to expand their existing set of tools to push the field forward.

## Conclusions

The evidence from a growing body of research and policy initiatives is clear: Neighborhoods matter for children's development, but much debate remains about the manner in which neighborhoods matter. Addressing this debate will entail better integration of neighborhood research within a relational developmental systems framework. We have tried to address the theoretical underpinnings of moving towards this goal and the methodological approaches that will help get us there.

## INTRODUCTION

Socioeconomic status (SES) refers to one's access to economic and social resources and the social positioning, privileges, and prestige that derive from these resources (Entwisle & Astone, 1994). The connection between one's starting position in the SES distribution, child experiences, and later life outcomes has been a stubborn feature of life. Scholars from a wide variety of disciplines have theorized about and attempted to assess the extent to which SES influences developmental processes and outcomes as well as the processes by which this happens. Taken together, this knowledge of SES and child development is both voluminous and incomplete. The purpose of this chapter is to guide readers through the theoretical perspectives and empirical studies linking family SES to children's development and highlight points of consensus within the field, and areas in need of more research. The salience of SES in children's lives is seen early in life when considering

difference in child well-being. In the fall of 1998, the Early Childhood Longitudinal Study (ECLS-K) collected nationally representative data on kindergarten children's test scores and more general development, and followed the children through eighth grade. The ECLS-K also asked children's parents about their own schooling, occupations, and household incomes. Combining these elements into a single socioeconomic status index and comparing children with different SES index values demonstrates the nature of SES gaps in children's school readiness and later achievement. For reading achievement—skills such as recognizing letters and associating letters with sounds at the beginning of words—the difference was 1.25 standard deviations between children in the bottom and top 20% of the SES distribution (Figure 14.1). For math achievement—skills such as recognizing numbers and geometric shapes, counting, recognizing patterns—the same SES gap was slightly larger. Although one might hope that formal schooling would reduce these skill gaps,

**Figure 14.1** Achievement, behavior, and health gaps between low- and high-SES kindergarteners and eighth graders.

*Source:* Authors' calculations based on data from the ECLS-K. Bars show differences between children in the top and bottom quintiles of socioeconomic status. Higher values on the externalizing scale represent better behavior.

both were larger in eighth grade than they had been at school entry.

SES-based differences in children's behavior and health were also apparent, although considerably smaller than differences in math and reading achievement skills. The teachers of children in the top compared with the bottom 20% of the SES distribution reported less aggressive behavior in kindergarten, and parents of higher-SES children reported that their children were healthier as well. These differences early in life portend differing levels of educational attainment and success in the labor market as well as differing levels of involvement in the criminal justice system and patterns of family formation. The transmission of SES advantage from parents to children is found both historically and internationally (Ermisch, Jäntti, & Smeeding, 2012; Smeeding, Jäntti, & Erikson, 2011).

The fact that children's skills, health, and behavior differ so much across the SES distribution leads many to conclude that SES itself must be shaping children's experiences and opportunities. Our review points to both theoretical frameworks and empirical evidence that support a causal pathway. Children from higher-SES families are afforded many advantages. Compared with their lower-SES peers, they are more likely to be raised by two biological parents and less likely to have mothers who experience mental health difficulties such as depression (Lee & Burkam, 2002). They tend to experience high-quality early education, schools, and health care. They reside in safer neighborhoods and engage in more after-school enrichment activities (McLoyd, 1998). Finally, children from higher-SES families tend to experience warmer, more responsive and

stimulating parenting and are exposed to more varied and complex language and conversation (Hart & Risley, 1995; McLoyd, 1998). Nevertheless, there are reasons to believe that socioeconomic circumstances are not as consequential for children's development as one might think (Sobel, 1998). Our review of the empirical evidence for this chapter seeks to sharpen the understanding of how and to what extent SES shapes the life course of children.

The chapter begins by providing a review of how scholars define and measure family SES, as well as some stylized facts about its three component parts: income and poverty, parental education, and parental occupation. In the next section, demographic and economic trends in SES components are reviewed, with specific attention devoted to increasing inequality. Following this important descriptive information, three theoretical approaches are presented: the family and environmental stress perspective, the resource and investment perspective, and cultural perspectives. Before reviewing the empirical literature on the connections between household SES and children's development, we describe the multiple challenges that researchers face when trying to establish causal connections between SES and outcomes. Finally, we discuss the implications of the research findings for policy. We conclude by identifying theoretical and empirical work that would improve our understanding of how household SES affects children and families.

## DEFINITIONS OF SES-BASED RESOURCES

SES refers to one's access to economic and social resources and the social positioning, privileges, and prestige that derive from these resources (Hauser & Warren, 1997; Mueller & Parcel, 1981). Some social scientists lump many indicators of financial and social resources under the umbrella of "socioeconomic status" (SES). Others identify the defining features of SES as cultural differences in habits, tastes, linguistic patterns, preferences, and world-views (Entwisle, Alexander, & Olson, 2005; Lareau, 2003). Although these perspectives differ in what they offer as central explanatory constructs of SES, both suggest that proximal environments, particularly family and childrearing environments, are the critical link between a family's SES and a child's well-being.

Researchers' differing conceptual views of SES lead to discrepant approaches to measurement. Because it may be difficult to measure a family's access to economic and

social resources or their position in a social hierarchy, social scientists often use a single indicator, typically occupation or maternal education, or combine indicators (e.g., parental education and income) into scales that proxy for families' SES (Hauser & Warren, 1997; Mueller & Parcel, 1981). The SES gaps shown in Figure 14.1 exemplify the single-indicator approach, in this case by combining education and income. A single indicator may serve as an effective index for other possible indicators because social structures tend to ensure that education, income, and occupation are strongly related. Most scholars using SES indexes recognize that SES is multidetermined, consider social stratification to be a powerful organizing force in individuals' lives, and presume that one's overall social standing (or social class) is more important than the particular combination of economic and social resources that determine or measure it.

This holistic approach argues that a household's social and economic resources are not additive pieces, but rather, when taken together, constitute a single social ecological phenomenon. Additional scholarship focuses on broader SES constructs, especially neighborhood and community SES, and this work is not included here because it is reviewed thoroughly elsewhere in this volume (Leventhal, Dupéré, & Shuey, Chapter 13, this *Handbook*, this volume).

An alternative view of SES is based on the premise that distinct types of socioeconomic resources contribute to social inequality and stratification along differing economic and social dimensions (Bollen, Glanville, & Stecklov, 2001). This standpoint does not prescribe how each dimension interacts or relates to the others, but it does argue that they can be understood better when identified individually rather than as only part of a larger superordinate construct. For example, although parents' educational attainments, incomes, and occupations are correlated, each may affect children in different ways (Duncan & Magnuson, 2003). It is perhaps not surprising that individual SES components often explain more variation in family processes than aggregated SES indexes (Callahan & Eyberg, 2010).

A related construct—social class—is sometimes used interchangeably with SES because it refers to one's social status as determined by their access to valuable social and economic resources. Social class differs from SES, however, because it is typically assessed by an individual's subjective categorical rating of their social position rather than by indicators of the social and economic resources from which their position is derived (Liu et al., 2004). In these assessments, study participants either place

themselves on a scale or ladder or they indicate which social class they belong to or identify with (e.g., working class, middle class, upper class). Most often, social class measures are used when collecting specific information is difficult, for example when asking for retrospective accounts of childhood SES, and when the subjective aspects of social status are thought to be more relevant than the actual resources and conditions.

Given the moderate-to-high correlations among SES components, it is sometimes difficult to empirically sort out their separate effects, especially in school or community samples with restricted ranges of SES variation. Yet, even with sufficient variability, an attempt to estimate the contribution of distinct SES components fails to account for importance of the constellation and accumulation of household resources, as such additive models may fail to identify how each component part contributes to the functioning of an organized system of parts.

Nevertheless, scholars using surveys drawn from diverse or national samples of children have concluded that components of SES have differential effects on parenting and children's development, and recommend that for many purposes they not be combined into a single scale (Bornstein, Hahn, Suwalsky, & Haynes, 2003; Duncan & Magnuson, 2003). For this reason, much of our discussion is organized around the specific components of family SES: income (including related constructs of wealth and poverty), education, and occupation. However, we remind readers that these dimensions are contextually defined parts of the larger SES construct.

Although at first glance income, poverty, wealth, education, and occupation may seem easy to define and measure, social scientists have expended considerable energy describing these dimensions and elaborating on how they can be used to measure SES, or more specifically dimensions of SES resources (see Hernandez, 1997, for practical measurement suggestions). In the sections that follow, we provide a discussion of the definitional and measurement issues for these constructs, and provide some important information about how these dimensions of SES are distributed across the U.S. population and experienced by individuals over their life course.

## Income

Household income is the sum of income from all sources received by all members of the household over some time period, typically a calendar year or month. When combined with a measure of household wealth (see below),

a household's income measures its ability to provide its children with food, shelter, a quality home or childcare environment, and a safe and stimulating community setting. As would be expected, there is considerable variation in household income in the United States. In 2012 the median household income was about \$50,000. The bottom 20% of the distribution had household incomes below about \$20,000, whereas the top 20% of the distribution had household incomes of about \$100,000 or higher (U.S. Census Bureau, 2012a).

Adjustments for the inclusion of "near-cash" sources of income such as food and payments from the Earned Income Tax Credit, and subtraction of taxes paid, produce a better approximation to the income that a household can actually use for purchase of goods and services (disposable income). Division of household income by household size or, better yet, the federal poverty threshold, which is based on household size, produces a more refined measure of its per capita command over resources. A family's income divided by its poverty threshold is referred to as its income-to-needs ratio (Citro & Michael, 1995).

Contrary to popular belief, and in comparison to other SES-based measures, family income is quite volatile across a family's life cycle, and across childhood, in particular (Duncan, Brooks-Gunn, Yeung, & Smith, 1998). On average, family incomes increase as children age, but average patterns conceal a great deal of year-to-year volatility, making it important to measure economic resources during the particular childhood stage in which income-based SES influences are sought. Income instability also imparts considerable error to a single year's measure of household income if it is taken as a measure of "permanent" income.

For many nonelderly households, adult earnings from the labor market are the primary source of income. An individual's hourly wage is usually obtained by dividing labor-market earnings received over some time period by the total number of hours worked during that time. Workers paid by the hour have an hourly wage rate that may differ between regular and overtime hours.

Perhaps surprisingly, some economists would nominate the hourly wage rate as *the* best summary measure of individual SES. This is because they conceive of it as a good measure of an individual's stock of skills—the productivity of his or her time either at work or at home. How an individual chooses to allocate time between market work and childcare (and other "home production") activities depends on a host of factors, such as family structure and local-area employment conditions as well as individual preferences. For individuals who spend all of their time on

home production, including childcare, their hourly wage is not considered to be zero, but rather the wage they could receive if they chose to enter the labor market. Thus, the product of the hourly wage and 16 waking hours provides a measure of the total value of those waking hours, regardless of how those hours happen to be divided between paid and unpaid work.

## Poverty

Poverty focuses on variation at the low end of the income distribution and its relation to economic deprivation (Citro & Michael, 1995). Social scientists have proposed many household-income-based definitions of poverty. The official U.S. definition of poverty is based on a comparison of a household's income with an income threshold level that varies with family size, the age of household members, and over time with inflation. In 2012, the respective thresholds for two-, three-, and four-person families with a single parent were \$15,825, \$18,498, and \$23,364 (U.S. Census Bureau, 2012b). For the purposes of poverty calculations, household income is defined as pretax income, and excludes in-kind and near-cash welfare benefits such as childcare subsidies, housing vouchers, or Supplemental Nutrition Assistance Program (SNAP, formerly food stamps). Households with incomes below these thresholds are considered "poor," whereas households with incomes above the thresholds are considered not poor. A household's poverty status is assumed to apply to each household member. Thresholds are adjusted each year for inflation using the general consumer price index, but not for changes in living standards of the general population. These federal poverty thresholds were created in the 1960s primarily for purposes of tracking trends in poverty across the United States, and the U.S. Census Bureau provides annual reports detailing poverty rates across a range of relevant demographic groups.

Though having a consistent measure of poverty across groups and over time has been invaluable to policymakers and scholars, the federal measure of poverty is not without flaws. In 2012, a "Supplemental Poverty Measure" (SPM) was developed to provide a useful alternative measure of economic deprivation. It is not intended to replace the existing federal poverty measure. Following recommendations of a committee established by the National Research Council (Citro & Michael, 1995), the SPM poverty line is set at a fixed percentile of actual expenditures for commodities that all families must purchase: food, shelter, clothing, and utilities as tracked by the Consumer Expenditure Survey.

Thus, in contrast with the existing set of poverty thresholds, the SPM changes with living standards. This is important because some costs such as housing can increase faster than others such as food. Another important point of departure from current poverty thresholds is that the SPM goes beyond cash income to include noncash benefits such as payments from the SNAP program and posttax transfers such as the Earned Income Tax Credit. With many current welfare benefits providing in-kind benefits rather than cash support, this may better reflect a family's ability to purchase needed goods. Finally, work expenses and out-of-pocket medical expenses are subtracted from household income, in an effort to better measure disposable income and purchasing power. Analyses suggest that the SPM generates slightly higher poverty rates than the current federal poverty measure, although poverty rates would be lower for children and higher for working age and elderly adults using the SPM (Short, 2012).

According to opinion polls, official poverty thresholds are lower than the amounts of money—typically around \$30,000 (in 2012 dollars)—judged by Americans as necessary to “get along in their community,” to “live decently,” or to avoid hardship (Vaughn, 1993). A detailed ethnographic study of family budgets identified \$25,680 (in 2012 dollars) as the approximate income level necessary for a thrifty three-person family to live without severe hardship (Edin & Lein, 1997). This figure exceeds the official poverty thresholds by about \$6,000—one-third higher in the United States. Child poverty rates are higher than rates for the adult and elderly populations. In 2011, 21.4% of children, over 15.5 million, lived in families with incomes below the official poverty threshold compared with only 13.7% of adults under Age 65, over 26.5 million. Another 22.4% of children lived in families with incomes between 100 and 200% of the poverty threshold (DeNavas-Walt, Proctor, & Smith, 2012; U.S. Census Bureau, 2012a). Although it is difficult to make international comparisons, research suggests that the United States has one of the highest rates of child poverty among western industrialized nations (Bradbury & Jäntti, 2001). Young children have higher rates of poverty than older children—the 2011 poverty rate for children under Age 5 was 25.1% while it was 20.7% for children Ages 5 to 17 (U.S. Census Bureau, 2012b). Parents of young children do not earn as much as parents of older children because they themselves are younger and have less work experience. It is also possible that the higher cost of childcare for young children reduces parents' employment. Poverty rates are also considerably higher among some racial and ethnic minority children

compared with White children. In 2011, the poverty rate for children under Age 18 was 37.2% for Blacks, 33.7% for Hispanics, 12.6% for Asians, and 18.1% for Whites (DeNavas-Walt et al., 2012). Data from earlier years also suggest that children of immigrants also experience higher rates of poverty than children of native-born parents (24% versus 12%; Fass & Cauthen, 2007). Finally, poverty rates also differ by family structure. In 2011, about 12.1% of children living in married families were poor, compared with 57.2% of children living in unmarried, female headed families (DeNavas-Walt et al., 2012).

How persistent is poverty? These annual poverty rates provide only a snapshot of the number of children in poverty. With child poverty rates remaining relatively stable over time, it would be easy to mistakenly conclude that the population of children experiencing poverty also changes little. We speak easily of “the poor” as if they were an ever-present and unchanging group. Indeed, the way we conceptualize the “poverty problem” or the “underclass problem” presumes the permanent existence of well-defined economic groups within American society. In fact, longitudinal data have always revealed a great deal of turnover among the poor, as events like unemployment and divorce push families into poverty, and reemployment, marriage, and career gains pull them out (Duncan, Corcoran, & Hill, 1984). More than one quarter of the individuals living in poverty in a single year report incomes above the poverty line in the next, and considerably less than one half of those who experience poverty remain persistently poor over many years (Bane & Ellwood, 1986).

On average, children experience 1.8 out of the first 15 years of life in poverty (calculated by Kathleen Ziol-Guest as reported in Magnuson & Votruba-Drzal, 2009; see also Ratcliffe & McKernan, 2012). This average masks considerable heterogeneity (Table 14.1); about 65% of children never experience poverty, whereas 15% of children are poor for at least 5 of 15 years. As with all poverty, persistent poverty is not evenly distributed across ethnic groups. Long-term poverty rates for minority children are especially high, with over one-third of African American children living in persistent poverty (Ratcliffe & McKernan, 2012). African American children are considerably more likely than White children to experience chronic poverty. The average African American child was poor for nearly 5.5 years, whereas the average White child was poor for less than a year. Moreover, only 30% of African American children never experienced poverty compared with 75% of White children. Children born to unmarried mothers and mothers with less than a high school diploma

**TABLE 14.1** Fifteen-year poverty experiences of children in the Panel Study of Income Dynamics born between 1975 and 1987, by race and maternal characteristics at birth

	Average Number of Years Poor	Never Poor	Poor for at Least 5 Years	Poor for at Least 8 Years
Total Sample	1.81	65%	15%	10%
African American	5.53	30%	46%	37%
White	0.93	75%	7%	4%
Unmarried Mother	5.39	24%	46%	33%
Mother Education: < High School Degree	5.03	31%	44%	33%

Notes: Calculations of the Panel Study of Income Dynamics conducted by Kathleen Ziol-Guest, New York University. Figures in this table are based on weights that adjust for differential sampling and response rates.

were also more likely to experience chronic poverty with an average of about 5.4 and 5.0 years spent in poverty during childhood, respectively.

Childhood poverty can also be characterized by the number of poverty spells that are experienced. Most poverty spells are relatively short, ending within 2 years (Gottschalk, McLanahan, & Sandefur, 1994). However, about half of poor individuals who escape poverty, experience another spell of poverty within 4 years (Stevens, 1999). Recurrent poverty spells are also evident among children, more than half of children who are ever experience poverty are poor for more than one spell (Ashworth, Hill, & Walker, 1994). Children who are in poverty for longer periods of time are more likely to experience deep poverty (Ashworth et al., 1994).

U.S. poverty thresholds are not directly applicable in international and comparative work. A common way of measuring poverty in developed countries around the world is to consider the percentage of children or households whose income falls below one-half of the country's median income. Using this metric at the turn of the 21st century, the United States had one of the highest levels of child poverty (over 20%) among developed nations (Heuveline & Weinshenker, 2008). An alternative comparative poverty measure that has been adopted by the World Bank defines global poverty income as income of less than \$2 per day per household member. An examination of 2010 extreme poverty in the United States that did not count the Supplemental Nutrition Assistance Program (SNAP) benefits as income, found that the proportion of poor households with children meeting the World Bank definition was nearly 20% (Shaefer & Edin, 2012). Counting SNAP benefits reduces the estimates of extreme poverty by about half.

## Wealth

Like poverty, wealth is closely related to household income, but somewhat distinct, and typically it focuses attention on

variation among those at the higher end of the income distribution. Wealth is the point-in-time “stock” of a household's financial assets, including both “liquid” (readily accessible) forms such as money in a savings account as well as “illiquid” forms such the net equity tied up in an owned home. Wealth is the *net* amount held in accounts and assets—the difference between the market value of that asset and whatever remaining debt the household owes on that asset. In contrast to income, which consists of a flow of resources over some time period, wealth is a “stock” concept and makes sense only at a distinct point in time.

Assuming no inheritance and a constant return on assets, a family's wealth at any point is the accumulated difference between its past income and past consumption. In other words, if two families have similar income histories but different current levels of wealth, then the family with higher wealth must have saved more of its income. These connections cloud the interpretation of the “effect” of wealth controlling for recent income, because the wealth effect may merely reflect a greater tendency to save income. Of course, our assumptions are also approximations—some families do inherit considerable wealth and some families earn far higher returns on their assets than others.

In 2007, mean net worth in the United States was estimated as \$556,000 and the median \$120,300 (Kennickell, 2009). About 19% of households had zero or negative net worth, the highest level in 24 years (Wolff, 2010). Wealth is highly concentrated among the wealthiest Americans. For example, in 2007 the wealthiest 1% of families held 34% of the total family wealth, with the 9% of families falling below them holding an additional 38%. Families in the lowest 90% of the wealth distribution owned only 29% of total family wealth (Kennickell, 2009). The concentration of wealth is even more pronounced when considering nonhome wealth, 93% of which is held by the wealthiest 20% of Americans (Wolff, 2010). Both the amounts and type of wealth are differentially distributed. The most common assets among poor families are vehicles, whereas homes tend to make up the greatest portion of wealth for

families falling in the middle of the wealth distribution. For the wealthiest Americans, business and financial assets make up the largest proportion of assets.

Income and wealth have a modest positive correlation; there is considerable heterogeneity of wealth within income brackets and vice versa. Using data from the 2007 Survey of Consumer Finances, Kennickell (2009) finds that the most consistent pattern when examining joint distributions of income and wealth is that high income and wealth tend to go together as do very low wealth and income. In between these two extremes, however, the relationship between wealth and income is more diffuse.

### Parental Schooling

Human capital constitutes a second component of SES, and includes the collection of parental skills acquired in both formal and informal ways that are valuable in the labor market and at home (Becker, 1981). Formal schooling is the most familiar and most studied form of human capital, and a large body of literature has demonstrated that obtaining higher levels of education increases a wide range of individuals' academic and cognitive skills as well as their future employment and earnings (Card, 1999). Many longitudinal studies consider parents' education to be fixed during a child's life, and measure it at only one point in time. Yet it has become increasingly common for adults to accrue education in a discontinuous fashion, and to extend their schooling well into adulthood (Astone, Schoen, Ensminger, & Rothert, 2000; Jacobs & Stoner-Eby, 1998). Studies show that attending school during adulthood is particularly common for economically disadvantaged mothers (Rich & Kim, 1999).

Parental education is measured in various ways. Some researchers focus on the highest grade of school completed, which counts years of school attendance even in the absence of obtaining a terminal degree. Others focus on degree completion and distinguish between types of degrees, for example, between vocational and nonvocational degrees. Some also attempt to measure the quality of schooling by assessing, for example, the average achievement level of students within the school or "selectivity" of postsecondary institutions. Focusing on formal education overlooks important skills that are acquired through work experience, including employment-based training, which leads some scholars to characterize job or employment tenure as additional indicators of human capital.

The average education level of Americans has increased dramatically over the past 50 years (Bailey & Dynarski,

2011). Among the most recent cohorts of young adults, nearly two-thirds of individuals have attended at least some college, with over a quarter completing a 4-year college degree. Similar patterns hold for parents. For example, in the early 2000s, about 18% of preschool-age children had mothers with less than a high school education and an additional 24% lived with mothers who had completed only some postsecondary schooling (authors' calculation of the October CPS data).

### Parental Occupation

Human capital also refers to a much broader set of skills than those learned through formal education. Intellectual flexibility as well as verbal communication and decision making skills accumulate throughout a lifetime. In the 1960s and 1970s, social psychologists and sociologists sought to describe how occupations and job characteristics augment or deplete human capital through the life course (Kohn, 1959, 1969; Kohn & Schooler, 1973).

Occupations differ from jobs, in that jobs are specific set of bundled activities and responsibilities, whereas occupations combine roughly similar jobs into a single category. Occupations are a much-studied component of socioeconomic status, with higher-status occupations typically conferring higher earnings, more control, and more prestige on workers holding them (Jencks, Perman, & Rainwater, 1988). Research has focused on occupations as an important aspect of SES because they are closely related to education and earnings and, when compared with single-year income, may better measure a family's "permanent" economic position. On the other hand, considerable research on occupational transitions throughout the life course suggests that career mobility patterns are dynamic (Featherman & Selbee, 1988; Featherman & Spenner, 1988).

Occupational measures of SES include both measures of occupational "prestige" as well as "occupational SES," although some researchers gloss over their differences (Hauser & Warren, 1997). Prestige scales focus on the subjective ranking of occupations whereas Occupational SES scales are typically derived from a weighted sum of the average earnings and education level of particular occupations. The choice of which measure to use is often driven by the specifics of a research question, but Hauser and Warren (1997) argue that when it comes to understanding intergenerational mobility, disaggregated dimensions of occupations, and specifically occupational education, are more useful than indices that combine educational and income features.

Research has found that job conditions appear to shape workers' values and personalities (Kohn, 1959, 1969, 1976; Kohn & Schooler, 1982). High-prestige jobs are characterized by complex tasks and high levels of autonomy. These jobs require self-direction and intellectual flexibility, whereas low-complexity jobs give rise to an orientation toward conformity. Based on correlational evidence, researchers have argued that job conditions shape workers' values and skills on the job and that these generalize to other areas of life (Kohn & Schooler, 1982). Job characteristics also affect employees' cognitive skills and personalities (Menaghan & Parcel, 1991; Parcel & Menaghan, 1994). In particular, low-prestige jobs, with low autonomy, routinized tasks, and little opportunity for "substantively complex work," may erode parents' cognitive skills, whereas high-prestige jobs promote initiative, critical thinking, and decision-making skills.

Other job characteristics have implications for family life as well, including job-related stress and nonstandard work schedules. Job stress encompasses subjective appraisals of interpersonal distress that stem from occupational conditions, such as the workplace social climate, time pressure, job demands, and work/family conflict (Repetti & Wang, 2009). Nonstandard work schedules are commonly defined as work schedules that occur outside the typical daytime hours (6 a.m. to 6 p.m.) or during weekends. Some service and retail jobs combine not only nonstandard hours but also rotating or just-in-time schedules, in which hours of work change from week to week.

In the current labor market, a great deal of attention has been given to the decline of middle class jobs. Yet it is worth understanding that even in the face of differing patterns of growth, most jobs in the U.S. labor market are considered "skilled" jobs. Calculations by Holzer and Lerman (2009) conclude that over half of current jobs are "middle-skill" jobs and another third are "high-skill" jobs as defined by needing some postsecondary or specialized training (Holzer & Lerman, 2009). They do note, however, that some jobs they classify as middle skill may provide low wages and few opportunities for wage advancement, thereby limiting access to resources and amenities that are typically associated with middle class lifestyles.

## MACRO TRENDS IN FAMILY SES

Both socioeconomic status and children's developmental outcomes are products of macroeconomic, political, and cultural influences and can change in different ways

over time (Bronfenbrenner, 1986; Hernandez, 1997). In the United States, the secular trends in individual SES components have led to what McLanahan (2004) refers to as "diverging destinies"—a collection of systematic economic experiences that have changed in differing ways for those at the lower and upper ends of the SES spectrum. We provide a brief discussion of these trends and the economic contexts from which they arise. This discussion is primarily focused on the United States, although many of the economic and demographic patterns found in the United States are also evident in other Western nations, to varying degrees (Brandolini & Smeeding, 2009; McCall & Percheski, 2010).

Key among trends has been an increase in economic inequality. While the incomes of lower SES families have stagnated in the United States since the 1970s, the incomes of high-income families have grown considerably, thus widening SES gaps in income. In recent years, the economic rewards of the growing economy have been concentrated primarily among those in society who were already privileged. Consider, for example, the sharply growing income gaps between high- and low-income families beginning in the 1970s. The bottom line in Figure 14.2 shows trends for children in families with incomes that placed them at the 20th percentile of the income distribution. The middle line shows changes at a high-income threshold—children with family incomes above those of 80% of the nation's families. The top line is for children in very-high-income families—those with incomes higher than 95% of U.S. families. To show relative changes, all three sets of incomes are set equal to 100 in 1970.

Even after adjusting for inflation and population growth, the U.S. economy more than doubled in size between 1970

**Figure 14.2** Family income relative to 1970.

Source: Authors' calculations based on data from the Current Population Survey, U.S. Census Bureau.

and 2010. Despite this growth, compared with 1970, the family income of children at the 20th percentile had fallen by 28% in 2011—from about \$37,000 to \$26,000. The depressed economic conditions (shown in shaded areas in Figure 14.2) in the 1970s, early 1980s, 1990s, and 2000s, and the Great Recession which began 2008, all drove income down more than could be offset by the growth periods in between. In contrast, the incomes at the 80th percentile grew by 22%, from \$98,000 to \$121,000, while the incomes of families at the 95th percentile rose even more. The income stagnation of the families at the lower end of the spectrum is reflected in the nation's child poverty rate, which rose sharply from 15.1% in 1970 to about 22% in 2011.

Over the past 20 years, the distribution of wealth has changed as well. Most notably, the share of total wealth held by households falling between the 50th and the 90th percentiles of the wealth distribution fell by about 4%, with households in the top 5% of the wealth distribution absorbing this shift. Between 1989 and 2007, families in the middle of the wealth distribution experienced modest growth, but wealth grew more rapidly for the very wealthiest families (Kennickell, 2009). Since 1983, there has been a slight, but relatively steady increase in the percentage of households with zero or negative net worth, with rates rising from 16% to 19% in 2007 (Wolff, 2010).

What has caused such changes in income and wealth inequality? There are several important underlying factors, and key among these are changes in the labor market and family structure. First, although there has been some overall decline in middle-skill jobs, and greater projected job growth in low- and high-skill jobs, the more important changes in the labor market have occurred with respect to wages (Autor, 2010; Holzer & Lerman, 2009). For the past three decades wages have stagnated for low-skilled workers. The lack of wage growth at the low end of the SES spectrum is even more striking when contrasted with the remarkable growth of wages for high-skilled workers over the same time period. Many theories have been advanced to explain this unprecedented growth in the inequality of earnings: increased demand for highly skilled workers, stagnating minimum wage, immigration of low-skill workers, globalization reducing the number of high-paid manufacturing jobs, and decline of unions (Autor, Katz, & Kearney, 2006, 2008; Borjas, Freeman, Katz, DiNardo, & Abowd, 1997; Juhn, Murphy, & Pierce, 1993; Katz & Autor, 1999; Katz & Murphy, 1992; F. Levy, 1998; F. Levy & Murnane, 1992; F. Levy & Temin, 2007). Of course, earnings (and employment) continue to be affected by

cyclical changes in the overall growth of the economy. The late 1990s economic boom, in particular, provided some boost to workers at the bottom of the distribution, whose earnings rose in real terms for the first time in several decades (Mishel, Bernstein, & Allegretto, 2007). But, following the economic expansion, low-skilled workers still had lower earnings relative to their median in 1979.

Family income growth may have stagnated not only because of job conditions, but also because of patterns of family formation. Since 1960 the percentage of children born to unmarried mothers has nearly doubled from about 20% of all births to nearly 40% in 2006 (Cancian & Reed, 2009). This is because more unmarried women had children, but also because married women had fewer children. Families headed by single mothers experience poverty rates that are 5 times higher than other family structures, and because the rate of nonmarital births is concentrated among low-SES families, all else equal, this trend would contribute to lower income growth at the low end of the SES spectrum (Cancian & Reed, 2009).

At the same time, demographic trends in the United States related to other dimensions of SES have offset the downward pressure on family income. Women have increasingly delayed childbearing, families have gotten smaller, and women's education and employment levels have risen (Cherlin, 2005). In the absence of these changes, growth in inequality might have been much worse. For example, over the past four decades, teenagers have accounted for a decreasing share of women giving birth for the first time (36% in 1970 compared with 21% in 2007). The average age at which women first gave birth in 2007 was 25, compared with 21 in 1970 (U.S. Department of Commerce, 2011). Delays in marriage and childbearing over the past several decades are associated with a reduction of about one child per mother by the end of the childbearing years (U.S. Department of Commerce, 2011). The drop in fertility rates has been especially apparent among non-Hispanic Black women, who saw their rate decrease from 91 births per 1,000 women aged 15 to 44 in 1980 to 67 births per 1,000 women aged 15 to 44 in 2005. Fertility rates among non-Hispanic White women decreased from 62 to 58 (Child Trends Databank, 2006). As a result, families with large numbers of children have become far less common, with a drop in the proportion of families containing four or more children from 17% in 1970 to 6% in 2000 (Lofquist, Lugaila, O'Connell, & Feliz, 2012).

Delayed marriage and childbirth have also been associated with increased educational attainment and employment among women over the past 40 years. Undergraduate

enrollment at colleges grew rapidly in the 1970s, especially for women; correspondingly, the share of women aged 25 to 34 with at least a college degree has more than tripled since 1968, from about 11% to about 35% (U.S. Department of Commerce, 2011). A higher share of women than men completed high school and earned a bachelor's degree in 2009 compared with 1971. Finally, women's employment also increased significantly during this time period and low-skill women experienced greater wage growth than low-skill men. In 1970 about 50% of women aged 30 to 34 worked, but by 1990s this number had risen to nearly 80% (Cancian & Reed, 2009).

A key question is whether the growing income inequality has affected the developmental fortunes of children, as would be suggested. Reardon (2011) examines this question using data from achievement tests administered to national samples of children over the past 60 years. In interpreting the income-based data, it is helpful to begin with more familiar trends in the Black–White test score gap. Figure 14.3 presents smoothed data based on the National Assessment of Educational Progress—the NAEP. Among children born in the early 1950s, shortly before *Brown v. Board of Education*, Black children scored one and a quarter standard deviations below White children when tested in the ninth grade. Over the next two decades, as the quality of schools attended by Blacks improved, these gaps narrowed—by a remarkable half a standard deviation—but have changed little since then (Magnuson & Waldfogel, 2008).

Income-based gaps have evolved differently. Figure 14.3 also shows gaps in test scores between children at the 10th and 90th percentiles of the family income distribution

(Reardon, 2011). As with the race gaps, the line is smoothed in order to focus on trends. Among children born around 1950, test scores of low-income children lagged behind those of their better-off peers by a little over half a standard deviation. For children born 50 years later, this gap was twice as large. Bearing in mind that middle-school children's achievement grows by between one-quarter and one-third standard deviations per year (Hill, Bloom, Black, & Lipsey, 2008), this implies that in the past 30 years low-income eighth graders have lost more than a year's worth of learning relative to high-income children.

Given the importance of cognitive skills in determining educational success, it is not surprising that there has also been a growing gap in the rate of college completion. Bailey and Dynarski (2011) calculate that the fraction of children raised in affluent families who completed college jumped by 18 percentage points—from slightly more than one third to more than one half—for students entering high school in the mid-1990s relative to their counterparts in the mid-1970s. Among children from low-income families, in contrast, the graduation rate was only 4 percentage points higher for the later cohort than for the earlier one (see Figure 14.4). Among OECD countries, 38% of 25- to 34-year-olds have completed tertiary education (OECD, 2012). Although the U.S. rate (42%) is above this average, it is well below the 68% rate in Korea and below that of 13 other countries as well.

In sum, in the United States, the past four decades have witnessed a simultaneous increase in both family income gaps and income-based achievement and attainment gaps for children. Tempting as it might be to infer causal connections between these income and attainment gaps, it is

**Figure 14.3** Achievement gaps by race and income, by birth year.

important to consider how the constellation of changes in family SES and other factors may be involved in the diverging skills of very low- and high-income children. Although the increasing income inequality may be influential, the rising number of children growing up in single-parent households probably matters as well. Single parenthood has risen more quickly among low- than high-SES families and strong associations exist between growing up with a single parent and a host of problematic developmental outcomes (McLanahan & Percheski, 2008). In 1960, about 14% of mothers in the bottom quartile of the education distribution, versus 4% of mothers in the top quartile, were single. By 2000, the percentages were approximately 43% and 7%, respectively. Thus, over four decades, the disparity in single motherhood by socioeconomic background grew from 10 percentage points to 36 percentage points (McLanahan, 2004). On the other hand, increasing parental education and reduced family sizes should have improved more rapidly among low-SES children than their higher SES counterparts. An important next step in this line of inquiry is better understanding how these various facets of social inequality have interacted to affect children's well-being and life chances.

In summary, there have not been uniform trends in household SES in the recent past. Along some SES dimensions, inequality has been increasing. In particular, gaps in household income, wealth, and the prevalence of single-parent families have increased. At the same time, however, gaps in parental education and family size have equalized across the SES spectrum. How this constellation of demographic and economic changes has affected the contexts in which children develop and their life chances is not yet fully understood. Nevertheless, the diverging destinies of low-SES and high-SES children deserve further study and attention (McLanahan, 2004).

## THEORY

Three main theoretical frameworks describe the pathways through which family socioeconomic resources may affect children's development: family and environmental stress, resource and investment, and cultural theories. In this section, we summarize each of these approaches and the type of research questions they generate.

Each framework is grounded in a different disciplinary background and each differs in the extent to which it focuses on socioeconomic status in general rather than a particular component or indicator of SES. In all of these

theories, families and parents are central to the transmission of socioeconomic advantage across generations. The theories differ in the family and developmental processes that are identified as being most important to the intergenerational transmission of SES and in the sources of these differences. Finally, although each of these theories recognizes the role of broader communities play in SES processes, these theories are limited in the extent to which they differentiate SES at the individual level from the broader community or neighborhood context (for a more detailed discussion of neighborhood SES, see Leventhal, Dupéré, & Shuey, Chapter 13, this *Handbook*, this volume). Although developed primarily in the U.S. context, each theory has cross-national and cross-cultural applications. Despite some important points of departure, the three theories can be best understood as overlapping and complementary, in that each perspective generates different types of research questions. Taken together, the larger body of work conveys a more complete understanding than any one standpoint alone.

### Family and Environmental Stress Perspective

The family and environmental stress perspective focuses on how experiences of material scarcity and economic hardship affect parental psychological well-being and cognitive capacities, which in turn negatively affect parenting and then children's development. Although parenting quality is commonly considered the central explanatory process in these models, this perspective is broader and encompasses other sources of environmental stress related to economic hardship that may affect children's stress levels directly, such as pollution, noise, and low-quality housing and neighborhood conditions. This perspective is built on the understanding that experiences of lower quality parenting and stress then are linked to compromised development among children.

According to family and environmental stress perspectives, economically disadvantaged families experience higher levels of stress in their everyday environments, and these disparities in environmental stress may affect development processes. The family stress model was developed first by Elder to document the influence of economic loss during the Great Depression (Elder, 1974; Elder, van Nguyen, & Caspi, 1985, see also Elder, Shanahan, & Jennings, Chapter 2, this *Handbook*, this volume). According to this perspective, poor families face significant economic pressure as they struggle to pay bills, purchase important goods and services, and are forced to cut back on

daily expenditures. This economic pressure, coupled with other stressful life events that are more prevalent in the lives of poor families, create high levels of psychological distress, including depressive and hostile feelings, in poor parents (Kessler & Cleary, 1980; McLeod & Kessler, 1990). Psychological distress spills over into marital and coparenting relationships. As couples struggle to make ends meet, their interactions become more hostile, conflicted, and they tend to withdraw from each other (Brody et al., 1994; Conger & Elder, 1994). Parents' psychological distress and conflict, in turn, are linked with parenting practices that are on average more punitive, harsh, inconsistent, and detached as well as less nurturing, stimulating, and responsive to children's needs. Such lower-quality parenting is likely to elevate children's stress responses, and ultimately harm children's development (Bornstein, Chapter 3, this *Handbook*, this volume; Conger et al., 2002; McLoyd, 1990).

This perspective has been broadened by recent behavioral economic work that argues that conditions of poverty and scarcity not only create psychological distress, but also deplete important cognitive resources, specifically attention processes. Studies primarily in developing countries find that making economic decisions under conditions of scarcity reduces adults' subsequent behavioral self-control, rendering them less able to regulate their own behavior to pursue goals (Mani, Mullainathan, Shafir, & Zhao, 2013; Spears, 2011).

Stressful experiences are typically conceptualized as the result of insufficient income and financial resources, yet they may be exacerbated by the working conditions of low-wage workers. Difficult job conditions, including changing or rotating job schedules, nonstandard hours, and low complexity jobs, characterized by little autonomy, high levels of supervision, and routinized tasks, are associated with higher levels of psychological distress and lower levels of self-esteem, which in turn have negative implications for parent-child interactions (Couter & McHale, 2005; Menaghan & Parcel, 1991; Rapoport & LeBourdais, 2008; Tausig & Fenwick, 2001; Wight, Raley, & Bianchi, 2008).

Extant literature has uncovered associations between job stress and family functioning (for a review, see Repetti, 2005). Job stress spills over into the home environment via compromised parental psychological well-being, diminished marital quality, greater irritability, impatience, and withdrawal in the home environment. All of these factors compromise parenting (Bumpus, Couter, & McHale, 2006; Repetti & Wang, 2009; Repetti & Wood, 1997). On the other hand, higher levels of cognitive skills may buffer

children and families from stresses related to employment by improving parents' problem-solving skills and enabling parents to better meet their family's needs and goals (Johnson, Kalil, & Dunifon, 2012).

Although relationships are central to these stress models, a complete understanding of environmental stress as a pathway incorporates the broader contexts and experiences of low-income children's and family's lives. Compared with their more affluent peers, poor children are more likely to live in housing that is crowded, noisy, and characterized by structural defects (e.g., leaky roof, rodent infestation, inadequate heating) (Evans, 2004; Evans, Saltzman, & Cooperman, 2001). Poor families are more likely to reside in neighborhoods characterized by high rates of crime and neighborhood risk factors, such as boarded-up houses, abandoned lots, and inadequate municipal services (Evans, 2004). The schools that low-SES children attend are more likely to be overcrowded and have structural problems (e.g., with noise, lighting, and ventilation) compared with the schools more affluent children attend (Evans, 2004). Economically disadvantaged children also tend to be exposed to greater air pollution from parental smoking, traffic, and industrial pollution (Evans, 2004). Any one of these environmental conditions may create physiological and emotional stress in the lives of low-income children, which, in turn, may have harmful effects on socioemotional, physical, cognitive, and academic development. For example, childhood poverty heightens children's risk for lead poisoning, which has been linked to health, behavior, and neurological problems that may persist into adolescence and adulthood (Cecil et al., 2008; Shonkoff & Phillips, 2000).

The field of cognitive neuroscience provides related evidence that chronic elevated stress may harm the development of poor children's stress response system, health, and regions of the brain responsible for self-regulation. This perspective also argues for greater attention to the timing of the experiences of poverty and related stress, as early experiences are especially likely to influence brain architecture and neurochemistry, which in turn have implications for learning and health throughout the life span (Knudsen, Heckman, Cameron, & Shonkoff, 2006). Researchers have documented the harmful effects of stress on animal brain development. Stress exposure and the elevation of stress hormones, such as cortisol, negatively influences animals' cognitive functioning, leading to impairments in brain structures such as the hippocampus, which is of central importance for memory (McEwen, 2000).

For obvious ethical reasons, these studies have not been replicated in humans. However, nonexperimental studies

have found low-SES children do have significantly higher levels of stress hormones than their more advantaged counterparts (Lupien, King, Meaney, & McEwen, 2001; R. J. Turner & Avison, 2003) and that early childhood poverty is associated with increased allostatic load, a measure of physiological stress. These increased levels of physiological stress have been linked to both cognitive functioning as well as immunological functioning, which has long-term implications for inflammatory diseases later in life (Chen & Miller, 2013). Specifically, recent work has linked the hypothalamic-pituitary-adrenal (HPA) axis to the functioning of the prefrontal cortex and related cognitive skills, such as executive functioning and self-regulation. Recent work by Blair et al. (2011) has found that heightened salivary cortisol, and indicators of elevated stress response system, partially accounts for the association between poverty and parenting on young children's executive functioning. Thus, disparities in stress exposure and stress hormones may partially explain why poor children have lower levels of cognitive ability and achievement and higher rates of poor health later in life (Farah et al., 2006). Although this explanation is compelling, and evidence is accumulating, to date studies have not established a clear causal sequencing of these associations or isolated the role of SES per se in these processes.

In summary, the family and economic stress perspective focuses on how conditions of low family income, economic hardship, and low-wage work generate psychological distress and physiological stress. Experiences of stress negatively affect the quality of family relationships, and specifically reduce the quality of parenting that children receive. Recent behavioral economics work has also argued that the conditions of scarcity affect adult's cognitive self-control by reducing their attention to other matters. Considerable work has found that the basic associations proposed by these theories hold across diverse contexts and populations (Conger et al., 2002; McLoyd, 1990). Current theoretical work is focusing on greater specificity on how low-quality parenting and stress affects individual developmental processes and cognitive functioning. An important next step will be to think about how responses and experiences of economic hardship and scarcity are related to other possible mechanisms by which SES advantages are transmitted across generations. For example, this theoretical model clearly better explains differences in development between poor and nonpoor families, but would appear to be less compelling an explanation of differences between

children in middle- and upper-middle-income families, for whom economic hardship is not prevalent.

### Resource and Investment Perspective

The resource and investment approach differs from other approaches in that it focuses on the ways in which SES resources can buy or create material goods and experiences that enhance children's development. The origin of this perspective is in economics, specifically household production theory. Becker's (1981) *A Treatise on the Family* posits that child development is "produced" from a combination of endowments and parental investments. Endowments include genetic predispositions and the values and preferences that parents instill in their children. Parents' preferences, such as the importance they place on education and their orientation toward the future, combined with their resources, shape parental investments.

Economists argue that time and money are the two basic resources that parents invest in their children. Because these resources differ markedly across the SES distribution, this theory suggests that such differential investments explain SES differences in children's development. For example, investments in high-quality childcare and education, housing in good neighborhoods, and rich learning experiences enhance children's development, as do nonmonetary investments of parents' time.

Links between endowments, investments, and development likely differ by the domain of development (e.g., achievement, behavior, health) under consideration. Characteristics of children also affect the level and type of investments that parents make in their children (Becker, 1981; Foster, 2002). For example, if a young child is talkative and enthusiastic about learning, parents are more likely to purchase children's books or take the child to the library (Raikes et al., 2006). Indeed, one of the more important insights from this model is that parental investments are likely to differ across children, in part, because children need and benefit from different things, be it experiences or goods.

Household production theory suggests that children from poor families lag behind their economically advantaged counterparts because their parents have fewer resources to invest in their children (Becker, 1981). Compared with more affluent parents, poor parents are less able to purchase inputs for their children, including books and educational materials at home, high-quality childcare

settings and schools, and safe neighborhoods. Economically disadvantaged parents may also have less time to invest in children, due to higher rates of single-parent families, nonstandard work hours, and less flexible work schedules (Smolensky & Gootman, 2003). This too may have negative consequences for children.

An obvious advantage of a higher family income is that it provides more resources to buy books, computers, high-quality childcare, summer camps, private school tuition, and other enrichments (Kaushal, Magnuson, & Waldfogel, 2011). Forty years ago, low-income families spent about \$850 (in 2011 dollars) per year on variety of possible child enrichment expenditures, while higher-income families spent more than \$3,500, already a substantial difference (see Figure 14.5). By 2005–2006, low-income families had increased their expenditures to over \$1,300 (in 2011 dollars), but high-income families had increased theirs much more, to more than \$9,000 per child. The differences in spending between the two groups had almost tripled in the intervening years. The largest spending differences were for activities such as music lessons, travel, and summer camps. Differences in parental expenditures on child investments are also found by maternal education, though these differences likely reflect the differing economic standing of more or less highly educated parents.

The provision of cognitively stimulating and enriching home environments reflects familial investments of time and money into the materials and experiences that promote learning. Children from poor households tend to experience lower quality home environments than advantaged peers and these differences, in turn, explain some of the influence of poverty on child educational

achievement (Duncan & Brooks-Gunn, 2000). It is perhaps not surprising that home environments play such a central role in explaining poverty's effects, given the well-established effects of environmental enrichment on the structure and functioning of the brains of animals (van Praag, Kempermann, & Gage, 2000). Disparities in the cognitive development of low- and middle-SES children are most pronounced in brain regions that are important for language, memory, and cognitive control (Farah et al., 2006; Noble, McCandliss, & Farah, 2007). These differences may, in part, stem from differences in exposure to enriching environments and corresponding effects on brain development (Farah et al., 2008).

Studies of parental time use provide strong evidence that maternal education also shapes investments in children. Guryan, Hurst, and Kearney (2008) documented the educational gradient in parents' care for their children. Despite also spending more hours working outside of the home, more highly educated mothers spent approximately 4.5 more hours a week than less educated mothers directly caring for their children. SES predicts not only the time that mothers care for their children, but also the developmental quality of that time. More highly educated mothers engaged in more developmentally appropriate care of their children, spending more time in play with younger children and more time in child management tasks for older children (Kalil, Ryan, & Corey, 2012).

Other studies also suggest that parents with higher levels of education promote their children's achievement by holding higher expectations for their children, providing more stimulating learning materials and activities, engaging in higher quality instruction, using more varied and complex language and speech patterns, as well as by supporting their children's learning (Davis-Kean, 2005; Hoff, 2003; Raviv, Kessenich, & Morrison, 2004; Richman, Miller, & Levine, 1992). Finally, how mothers allocate their time also seems to depend on children's characteristics. More highly educated mothers spend more total time and more educationally oriented time with lower birth weight compared to higher-birth-weight children, whereas less educated mothers spend more time with higher- than lower-birth-weight children (Hsin, 2012). The compensating effects of more highly educated families are substantially larger than the reinforcing effects in low-education families (Hsin, 2012).

The SES resource and investment perspective focuses attention on the instrumental nature of SES resources and how parents deploy them to the benefit their children.

**Figure 14.5** Enrichment expenditures on children.

Source: Authors' calculations based on data presented in Duncan and Murnane, 2011.

In particular, this perspective highlights the potential of research to fail to find one explanatory mechanism that will account for the full effect of higher SES on children's development, because these explanations may be as diverse as parents' resource use. Nevertheless, some general patterns suggest that parents' investment of time and money in experiences and activities that are cognitively stimulating and enriching are one pathway by which SES affects children.

Current theoretical work focuses on better understanding how parents' investments interact with children's own skills and traits and investments from other contexts to affect development. Compared with the family and environmental stress perspectives, this approach is better able to explain differences in children's outcomes across the entire SES spectrum, as differences in development are attributed to parents' differential levels of investments. Most empirical efforts to test the family stress and family investment perspectives have conceptualized them as competing explanatory pathways to be parsed out, but more attention should be given to how they may interact and synergistically affect family and individual developmental processes.

### Cultural Perspectives

Sociological and anthropological approaches to explaining SES-based differences in children's development focus primarily on a more complete understanding of why family and community patterns of behavior differ. Though they share this focus with other theoretical perspectives, the cultural perspectives argue that differences in aspects of culture are central to understanding SES differences in parenting practices and parental investment (Lamont & Small, 2008). Early cultural perspectives emphasized socioeconomic variability in norms, values, and behaviors that were shared by individuals with similar SES, whereas more recent perspectives draw on a broader range of cultural constructs to explain heterogeneity in behaviors within and across groups based on SES. Given the cultural and behavioral emphasis of these perspectives, there is a tendency to focus on SES as a unidimensional concept of social standing or social class, although the most recent work in this area aims to identify dimensions of culture that explain heterogeneous responses and outcomes to the same material and economic conditions (Small, Harding, & Lamont, 2010).

Sociological theories about how the norms and behavior of the poor affect children began with the "culture of poverty"

theory put forth by Lewis (1969). Based on his fieldwork with poor families in Latin America, he argued that the poor were economically marginalized and had no opportunity for upward mobility. Individuals responded to their marginalized position by adapting their norms and values, which guide behavior. The resulting culture of poverty was unitary and shared by members of the marginalized group. It was characterized by little impulse control and inability to delay gratification, as well as feelings of helplessness and inferiority. These adaptations manifested in high levels of female-headed households, sexual promiscuity, crime, and gangs. Although Lewis (1969) acknowledged that these behaviors emerged in response to structural factors, he argued that over time, these shared values and behaviors were transmitted to future generations, and therefore became causes of poverty. He writes: By the time slum children are age six or seven they have usually absorbed the basic values and attitudes of their subculture and are not psychologically geared to take full advantage of changing conditions or increased opportunities. (Lewis, 1966, p. xlv)

Cultural explanations for the effects of poverty on children were prevalent in the mid-1980s through the 1990s and continued to be grounded in the notion that poor families shared norms, beliefs, and behaviors that differed from those shared by middle- and upper-income families and placed them at a distinct disadvantage. These aspects of culture were found across multiple generations and thus supported an intergenerational transmission of poverty. Behaviors associated with cultural perspectives during this time include high levels of nonmarital childbearing, joblessness, female-headed households, criminal activity, and welfare dependency among the poor.

Theorists tended to agree that behavioral differences exist, but they disagreed on the origins of these differences. For example, Mead (1986) emphasized the role of individual characteristics and the liberal welfare state's perverse incentives that reward single-mother households and joblessness among men. Massey (1990) and Wilson (1987, 1996) stressed the importance of structural and economic factors: the concentration of neighborhood poverty, the social isolation of poor inner city neighborhoods, and the deindustrialization of urban economies. They contended that these structural factors negatively influence the behavior of inner-city adults and their children.

These early notions of a culture of poverty have come under fire for several reasons. First, these perspectives are often criticized for the basic assumption that differences in norms and values drive differences in behavior (Lamont & Small, 2008). Evidence suggests that disadvantaged individuals hold many middle class values and beliefs.

However, unlike the middle class, circumstances make it difficult for the poor to behave in accordance with their values and beliefs. For example, Edin and Kefalas (2005) show that poor women value marriage and recognize the benefits of raising children in a two-parent household. However, their low wages as well as Black men's high rates of unemployment and incarceration lead poor women to conclude marriage is out of their reach. Traditional notions of a culture of poverty do not account for this sort of disconnect between values and behaviors.

Today, cultural sociologists generally reject the notion that a unitary set of norms, values, and behaviors (culture) shared by economically disadvantaged families can explain disparities in children's development. Instead, sociologists have developed increasingly sophisticated approaches to examine the intersection of culture and poverty drawing on cultural concepts, including repertoires, frames, narratives, as well as social and cultural capital, to understand how poor adults experience, perceive, and respond to their economic position (Lamont & Small, 2008; Small et al., 2010).

From this new approach emerges a portrayal of the heterogeneity that characterizes individual responses to socioeconomic disadvantage. For example, Small (2004) highlighted variability in community involvement among low-income Latino/a residents of a housing project in Boston. He found that differences in cognitive framing of the neighborhood were central to explaining this heterogeneity. In particular, residents who talked about the neighborhood as a housing project tended to show low levels of community involvement, whereas those who recognized the neighborhood as a community with a shared history of social and political involvement tended to continue this tradition by taking part in community activities.

Among cultural approaches, some seminal work in the field explicitly focused on understanding childrearing. Early research focused on the occupational conditions faced by workers suggests that differences in occupational complexity may contribute to the variability in childrearing values, beliefs, and behaviors seen between middle- and low-income families. It suggests that parents tend to socialize their children in ways that emphasize the values and behaviors that are effective in their own workplace (Kohn, 1976; Parcel & Menaghan, 1994). Middle-class workers in higher complexity jobs are more likely to stress self-direction, autonomy, flexibility, and reasoning in their child rearing practices (Lareau, 2003). In contrast, parents in low-complexity occupations tend to emphasize conformity to rules, constraint, discipline, and control

(Luster, Rhoades, & Haas, 1989). These differences in values give rise to variability in parenting practices that may have implications for children's development. Yet, work by Weininger and Lareau (2009) points out that this description is complicated by the fact that, whereas middle-class parents try to instill self-direction in their children, they nonetheless exert subtle forms of control. Likewise, although working-class and poor parents command conformity from their children, they also provide their children with large amounts of autonomy in some aspects of their lives.

Lareau (2003) identifies other differences in cultural childrearing repertoires of high- and low-income families, including the degree to which middle-class parents "managed" their children's lives, whereas working-class and poor parents left children alone to play and otherwise organize what they did. She summarizes her findings as follows:

In the middle class, life was hectic. Parents were racing around from one activity to another. In families with more than one child, parents often juggled conflicts between children's activities. . . . Because there were so many activities, and because they were accorded such importance, child's activities determined the schedule for the entire family. . . . [In contrast], the limited economic resources available to working class and poor families make getting children fed, clothed, sheltered and transported time-consuming and tedious. Parents tend to direct their efforts toward keeping children safe, enforcing discipline, and, when they deem it necessary, regulating their behavior in certain areas. . . . Thus, whereas middle-class children are often treated as a project to be developed, working class and poor children are given boundaries for their behavior and then allowed to grow. (pp. 35, 66–67)

Lareau calls the middle class patterns "concerted cultivation," which involves the provision of stimulating learning activities and social interactions that parents believe will promote their children's social and cognitive development. According to this approach to child rearing, children's skills are projects to be managed, built, and honed through focused parental efforts. In contrast, the "natural growth" perspective of working-class and poor parents often stops at providing basic supports (e.g., food, shelter, comfort). These differences in cultural repertoires provide a distinct advantage to middle-class children as the skills they develop are valued by institutions they experience, such as schools and work places, and this in turn contributes to the intergenerational transmission of social class.

A growing body of quantitative research has tested Lareau's findings. Roksa and Potter (2011) identify social class variation in the use of parenting practices, including concerted cultivation, but do not find parenting behaviors to be exclusive to any particular class. Other researchers have explored whether concerted cultivation is associated with better child outcomes. Two studies have suggested that indicators of Lareau's idea of "concerted cultivation" are linked with academic advantage in kindergarten and subsequently through third grade. So while distinctive patterns of parenting have been identified that are linked to children's achievement, questions still remain about the extent to which patterns are distinct across SES and shared within SES.

Beyond a family's own SES, the SES of prior generations may also be important in shaping family processes, evidence suggests. This has been considered most directly in discussions of how African American middle-class families compare to White middle-class families. In particular, it is argued that although African American families may have similar levels of income and parental education, these parents are often the first of their families to have achieved such status (Hardaway & McLoyd, 2009). The SES of prior generations may be important in shaping family and social networks such that families who have been of lower SES for generations are likely to be embedded in social networks that are more economically heterogeneous (Heflin & Pattillo, 2006), and thus may transmit fewer advantages to their children. The importance of generational SES has not been studied extensively, in part because of the difficulty of collecting the necessary data, but studies suggest a small to moderate prediction from grandparents' education to their grandchildren's academic skills, holding constant parents' SES (Ferguson & Ready, 2011; Phillips, Brooks-Gunn, Duncan, Klebanov, & Crane, 1998).

Cultural and sociological approaches have been important for understanding how structural and social conditions interact to affect individuals' behaviors. Focusing on holistic conceptualizations of SES rather than particular SES dimensions, these approaches have described how patterns of behavior are organized differently across the SES continuum. Whereas early work discussed unified cultural beliefs and behaviors that perpetuated the very poverty that gave rise to it, new scholarship rejects the notion of a unified culture, and does not conceptualize behavior as derived primarily from values. This work complements and rounds out other theoretical approaches by drawing attention to the fact that responses to economic conditions, and more generally one's social standing and strategies of coping with it, are

socially constructed and thus involve cultural repertoires, frames, narratives, as well as social and cultural capital as found in social networks. Thus this approach offers one means to understand differential responses to similar economic resources and social positions, and infuses an important emphasis on social processes, rather than only individual or intrafamilial processes.

## CORRELATION AND CAUSATION IN STUDIES OF FAMILY SES AND CHILD WELL-BEING

Researchers seeking to identify the causal influences of family SES face formidable challenges. They must take seriously threats to internal validity from a variety of sources, including bias from simultaneous causation and potential omitted variables (Sobel, 1998). Duncan (2006) describes a continuum for evaluating the methodological rigor of studies aimed at estimating poverty and income's influence on child development. On one end are correlational studies that analyze associations between concurrent measures of family income and child outcomes, with few adjustments for confounding factors. These studies are common, but likely plagued by biases. On the other end are experiments in which families are randomly assigned to receive additional income, without any strings attached. If implemented correctly, experiments provide unbiased estimates of income effects, but such studies are exceptionally rare. Between these two extremes, ranging from less to more rigorous, are natural experiments, studies that employ econometric techniques to reduce omitted variable bias (e.g., fixed effects, instrumental variables regression), and longitudinal studies. We describe these common problems in studying SES and children's outcomes, and then provide a brief description of research methods and analytic statistical approaches that provide more rigorous evidence of the effects of SES on children (see also Duncan, Magnuson, & Ludwig, 2004).

### Simultaneity Bias

Despite the abundance of research documenting correlations between family socioeconomic status and outcomes, it is difficult to determine whether these outcomes are consequences or causes of low family income. For example, consistent associations have been found between childhood poverty and a wide range of health outcomes (Case, Lubotsky, & Paxson, 2002; Currie & Stabile, 2003). At the same time, mothers of children who have poor health

status are less likely to be involved in the paid labor force, tend to work fewer hours, and have a greater likelihood of experiencing job loss (Earle & Heymann, 2002; Gould, 2004; Kuhlthau & Perrin, 2001; Powers, 2001, 2003). Did the family poverty cause the poor child health or did emerging child health problems limit family income? Researchers face considerable challenges in ruling out this type of simultaneity bias, with the failure to do so resulting in an overestimation of poverty's effects.

### Omitted Variable Bias

A second challenge involves isolating the effects of socioeconomic status from other disadvantages that poor families face. A first issue is that socioeconomic characteristics tend to cluster together, so that children who live in poverty are likely to have parents with lower levels of education, which makes it difficult to isolate the unique influence of any one indicator of SES. A second problem is that family income or low parental education are linked with several other family circumstances such as greater prevalence of single-parent families, low levels of parents' cognitive skills, and poor parental mental health. Each of these factors may have an independent negative effect on children. Thus, to ascribe a causal effect to poverty or parental education requires ruling out other explanations for the associations between socioeconomic factors and children's development.

Some researchers have argued that income effects are largely the spurious result of unmeasured differences that are correlated both with SES and child outcomes (Mayer, 1997). In other words, unmeasured characteristics such as parental mental health or motivation that contribute to greater education and earnings may also enhance child development, leading to a spurious correlation between SES and child development. This threat of omitted variable bias is an important concern in most nonexperimental research. Studies that use rigorous statistical techniques to address bias issues tend to uncover smaller effect sizes than studies that do not (Duncan, 2006; Holmlund, Lindahl, & Plug, 2011).

Some researchers argue that attempting to isolate the causal effects of one dimension of SES, in particular income, is misguided because it is difficult to know the extent to which related disadvantages, such as low levels of education or mental health, are themselves caused by income (Gershoff, Aber, & Raver, 2003). In this view, parsing out the effects of a particular dimension of SES from other dimensions of advantage or disadvantage is

likely to present a distorted or incomplete view of the extent to which SES and economic disadvantage affect children. Though these indicators are strongly related, they are affected by different policies and may operate to affect differing family processes, and potentially different domains of child well-being. Thus, while it is important to recognize that parental income and education are closely related, it is also valuable to understand the unique contribution of each dimension of family SES.

### Random Assignment Experiments

Although there are no fail-proof methods to generate unbiased estimates of family SES on children, some studies are able to minimize the threats of bias by using research designs that eliminate or reduce simultaneity and omitted variable biases. The most rigorous approach to these problems is reliance on data gathered in an experiment in which families are randomly assigned to some kind of SES-improving program. Income supplementation is the most obvious kind of experimental SES manipulation, although one could also imagine assigning parents to opportunities to complete more schooling. Although experiments can suffer from problems of generalizability, such as Hawthorne effects (Shadish, Cook, & Campbell, 2002), their virtue is that they eliminate omitted variable bias by forcing their treatment and control groups to have virtually identical measured and unmeasured characteristics.

### Change Models

Lacking experiments, researchers seeking to identify the causal influences of child SES face formidable challenges. One potentially useful approach is to use longitudinal data to estimate change models. Suppose one has reason to believe that SES effects on a given child outcome occur quite quickly. With longitudinal data on SES and child outcomes, one might be able to relate *changes* in child outcomes to *changes* in family SES. The equation-based intuition behind this approach is shown in Equation 14.1, where child *i*'s outcome in period *t*,  $y_{it}$ , is a function of family SES effects in that period ( $SES_{it}$ ), unmeasured parent and child variables that are constant over time ( $par_i$  and  $child_i$ ), and unmeasured variables that vary over time ( $par_{it}$  and  $child_{it}$ ), and an error term ( $e_{it}$ ):

$$y_{it} = \beta SES_{it} + par_i + child_i + par_{it} + child_{it} + e_{it} \quad (14.1)$$

In this case, unmeasured parent and child characteristics will bias estimates of  $\beta$  to the extent that they are correlated with both *SES* and *y*. To avoid these sources of bias, one can first-difference the data, a procedure in which each child's observation in period *t* is subtracted from his or her observation in period *t* + 1. These are sometimes called individual fixed-effects models. Subtracting Equation 14.1 at time *t* + 1 from Equation 14.1 at time *t* eliminates the biasing effects of time-invariant parent- and individual-level unmeasured variables from the right-hand side of the regression equation.

Fixed-effects models are still subject to bias from time-varying parent or child-level unmeasured variables, because first-differencing does not eliminate these variables from the estimating equation. However, with sufficiently long panels, more elaborate methods may be used to control for unmeasured variables whose values change over time in specific ways. For example, looking at how changes in the rate at which family or contextual variables change affect the rate at which children's outcomes change (obtained by twice-differencing the data) can help control for unmeasured parent or child-level variables that change over time at a constant rate. All of these change models rely on the assumption of short-run SES impacts.

### Within-Family Variation

Another set of methods for reducing bias exploit within-family variation. Sibling models (sometimes referred to as family fixed-effects models) provide an example of using within-family variability to eliminate bias, in this case from omitted parental (*par<sub>i</sub>*) factors. In these approaches, each sibling's score on the dependent and independent variables is subtracted from the average scores of all siblings in his or her family. In the case of two siblings per family, the deviation-from-family-means model becomes a simple sibling-difference model. If we replace the subscript *i* in Equation 14.1 with 1 (for Sibling 1) and 2 (for Sibling 2), and assume that there is sufficient cross-sibling variability in family and contextual conditions to reference *SES* with the sibling subscripts, the sibling-difference model takes the following form:

$$y_2 - y_1 = \beta(SES_2 - SES_1) + (par_2 - par_1) + (child_2 - child_1) + (e_2 - e_1) \quad (14.2)$$

In estimating this regression model, sibling differences in the outcome of interest are regressed onto sibling differences in observed family and contextual characteristics. Note that coefficient  $\beta$  has an identical interpretation in

Equations 14.1 and 14.2; both reflect changes in outcomes associated with key changes in SES. Observed parental factors that are the same for all siblings in a family are differenced out of a sibling difference regression.

A key advantage of sibling models is that persistent *unobserved* elements of *par<sub>i</sub>* are differenced out as well, thus eliminating the omitted-variable bias caused by the unmeasured persistent family factors shared by siblings. The sibling-difference model thus “automatically” eliminates bias from all permanent family factors, observed or not, if the effects of these factors do not differ between siblings. Time-varying family factors, especially those that might be producing the sibling differences in the context (e.g., divorce, income changes), are a potential source of bias in Equation 14.2 and should be controlled explicitly in the regression if possible. A disadvantage of sibling models is that change measures are more often error ridden than level measures, which can bias parameter estimates toward zero. In order for the model to work, SES has to vary sufficiently between siblings to support the estimation of  $\beta$ .

### Natural Experiments

Another alternative to random assignment is to generate estimates of the causal effects of SES on child outcomes with “natural experiments.” In this case, one wants some kind of event that generates changes in income that are beyond the control of the families and children under investigation. Though the change to SES is not randomly assigned, the event that brings it about may be as good as randomly distributed across those observed in the study. Often these studies exploit variation over time, sometimes within the same families, other times across similar cohorts of families. One example included in the following section consists of income increases generated by increases in the generosity of the U.S. Earned Income Tax Credit program in the mid-1990s (Dahl & Lochner, 2012) and the Canadian Child Benefit program around 2000 (Milligan & Stabile, 2011). Tracking changes in child well-being before and after the changes among eligible families can generate estimates of income effects that are not biased by the kinds of parent and child measures included in Equation 14.1. More details on these studies are provided below.

### Instrumental Variables

A strong, although often difficult to implement, approach to causal inference is instrumental variables. Consider Equation 14.1 and its implied task of producing unbiased estimates of the effects of family SES on child outcomes.

Suppose we can find some variable—call it  $Z$ —that affects family SES but only affects child outcomes by operating through family SES. In this case, a two-stage estimation procedure can be employed to generate unbiased estimates of SES impacts. In the first stage, family SES is regressed on  $Z$  and the estimated regression coefficient is used to generate predicted levels of family SES based on  $Z$ . In the second stage, a regression like Equation 14.1 is estimated, but instead of including  $SES_{it}$  one uses the *predicted value* of  $SES_{it}$  generated from the first stage. Because SES variation in this case is generated completely by  $Z$  rather than any potentially confounding influence on SES arising from omitted family- or child-specific characteristics, the coefficient estimated on SES in the second stage should be free from omitted-variable bias. The challenge with instrumental variables is in finding an appropriate  $Z$  variable (Gennetian, Magnuson, & Morris, 2008). This method is sometimes used in combination with random assignment studies and with natural experiments, and we describe in our literature review several studies that use instrumental variables in the context of experimental work support programs to estimate the effects of increased family income on children.

## EMPIRICAL RESEARCH ON THE EFFECT OF FAMILY SES ON CHILDREN

Despite these challenges of identifying causal connections between SES and child development, empirical research on this subject is abundant. In the following sections we focus on the research that links each component of family SES to children's outcomes during childhood as well as in adulthood, primarily in the U.S. context but also in nations with similar SES contexts. Given the difficulty of identifying causal effects in many research studies, we highlight the most rigorous studies available. For both family income and parental schooling we organize our reviews by developmental outcome, and then provide detail when available about moderating factors such as developmental age when clear patterns emerge in the literature. For parental occupation, we organize our review around the dimension of occupation being studied, because these are more varied and this structure better characterizes the current knowledge base.

### Income, Poverty, and Wealth

Of the three SES components, the effects of family income and poverty on children have been researched most

thoroughly. Numerous studies provide correlational evidence, but a far smaller set of studies use rigorous research designs that increase confidence that the effects are plausibly causal. However, these designs also isolate the effects of income and poverty from other dimensions of SES, and thus do not provide a full picture of how SES affects children. The family stress model argues that poverty in particular may compromise development, and much of the research has taken this perspective. Yet the investment theory suggests that increments to income among middle class and upper class families may also benefit children, and some studies look more broadly at the full income distribution. Most studies focus on children only during childhood, rather than being able to follow them later into the life course. Unfortunately, important theoretical questions about whether some periods of development are more sensitive to income and poverty cannot be answered without such long-run studies. Nevertheless, accumulating evidence suggests that poverty has a causal effect on children's achievement and educational attainment. Less clear are whether income more generally has a causal effect, and the extent to which poverty and income are causally connected to behavior and health.

### *Academic Achievement and Human Capital Attainment*

Income gaps in achievement are present when children enter school and persist during the school years (Magnuson, Waldfogel, & Washbrook, 2012). The magnitude of the gaps between children at the bottom and top fifths of the income distribution are over a standard deviation. Differences between the performance of groups of poor and nonpoor children differ across studies and measures, but typically amounts to about one-third of a standard deviation (Blau, 1999; Smith, Brooks-Gunn, & Klebanov, 1997). Associations with educational attainment are larger, with the mean differences amounting to over a year of schooling (Duncan, Kalil, & Ziol-Guest, 2008). Differential rates in high school completion and college attendance are also large—poor children are one third as likely to complete high school (Corcoran, 2001), and the gap in college attendance between the lowest quintile and highest income quintiles is nearly 50 percentage points (Haveman & Wilson, 2007). Simple associations between income early in life and adult outcomes are striking. Compared with children whose families had incomes of at least twice the poverty line during their early childhood, poor children earn less than half as much, and work 451 fewer hours per year in adulthood (Duncan, Ziol-Guest, & Kalil, 2010).

Despite theoretical predictions and correlational evidence, the extent to which family income and poverty

are causal determinants of children's achievement and education behavior remains a controversial issue. The only large-scale randomized interventions to alter family income directly were the U.S. Negative Income Tax Experiments, which were conducted between 1968 and 1982 with the primary goal of identifying the influence of guaranteed income on parents' labor force participation. Maynard and Murnane (1979) found that elementary schoolchildren in the Gary, Indiana, experimental group (whose families enjoyed a 50% boost in family income from the program), exhibited higher levels of academic achievement and school attendance than the control group. No test score differences were found for adolescents, although youth in the experimental group did have higher rates of high school completion and educational attainment than controls. Maynard (1977) analyzed data from two rural sites—in North Carolina and Iowa—and found test score gains for second through eighth graders in North Carolina but not Iowa. Collectively these results provide some support for the hypothesis that higher income may indeed cause higher achievement in middle childhood, although even in this case it is impossible to distinguish the effects of income from the possible benefits to children from the reductions in parental work effort that accompanied the income increases.

Providing income support to working poor parents through wage supplements has been shown to improve children's achievement, according to data from experimental welfare reform evaluation studies undertaken during the 1990s. One study analyzed data from seven random-assignment welfare and antipoverty policies, all of which increased parental employment, while only some increased family income (Morris, Duncan, & Clark-Kauffman, 2005). Though leveraging experimental data, the analysis itself is not an experiment because families were not randomly assigned across types of treatments. Preschool and elementary schoolchildren's academic achievement was improved by programs that boosted both income and parental employment, but not by programs that only increased employment. The school achievement of adolescents did not appear to benefit from either kind of program. A separate analysis of the data on younger children suggests that a \$3,000 annual income boost is associated with about one fifth of a standard deviation gain in achievement test scores (Duncan, Morris, & Rodrigues, 2011). These findings suggest that income may play a causal role in younger children's achievement, although it should be kept in mind that the beneficial welfare reform programs increased both income and parental employment. Combining these

results with those from the 1970s experiments reviewed earlier, it is apparent that income effects on younger children's achievement emerge when policies increase parental employment as well as when they decrease employment. This suggests that the income boost may have been the most active ingredient in the beneficial impacts.

A set of experimental studies conducted in developing countries and recently implemented in New York City tested the effects of delivering cash assistance through payments that depend on the behaviors of parents and children. Such conditional cash transfer (CCT) programs have been implemented in a number of countries in the developing world. Mexico pioneered this movement, with a program originally called *Progres*a and now known as *Oportunidades*. This program provides direct cash payments that are conditioned in part on children remaining in school and in part on families seeking preventive health care and adopting certain child nutrition practices (S. Levy, 2006). Although poor households in the program did make more use of health and education services, the evidence on improvements for education outcomes is more mixed (Fiszbein, Schady, & Ferreira, 2009). For example, school enrollment improved but achievement test scores did not.

*Oportunidades* inspired New York City's Family Rewards program, which operated in the city's highest-poverty communities. It tied cash rewards to activities and outcomes related to children's education, families' preventive health care, and parents' employment. Results, all of which related to school-aged children, were mixed. The program reduced poverty and hardship and increased savings but did not improve school attendance or achievement overall for its elementary and middle school students (Riccio et al., 2013).

Moving beyond these CCT programs, convincing evidence of the relation between income and child achievement comes from studies employing instrumental variable and natural experiment approaches. One such study, mentioned previously, took advantage of the fact that between 1993 and 1997, the maximum U.S. Earned Income Tax Credit for working poor families increased by more than \$2,000 for a family with two children (Dahl & Lochner, 2012). This generous increase in tax benefits enabled the authors to compare the school achievement of children before and after the increase in the tax credit. They found improvements in low-income children's achievement in middle childhood that coincided with the policy change. A second, Canada-based study found similar results when it took advantage of variation across Canadian provinces in the generosity of the National Child Benefit program to

estimate income impacts on child achievement (Milligan & Stabile, 2011).

These rigorous studies of achievement are more sophisticated than the long line of longitudinal studies that preceded them. Noteworthy examples of the latter include (a) the Duncan and Brooks-Gunn (1997) coordinated analyses of researchers working with 10 different longitudinal data sets seeking to isolate the effects of permanent income from other SES components using covariates; (b) Mayer's (1997) novel longitudinal study design using income measured later in life as a proxy for unmeasured parental characteristics; and (c) Blau's (1999) study of data from the National Longitudinal Survey of Youth, which used family fixed-effect models that relate sibling differences in test scores to sibling differences in the individual children's income histories during middle childhood. Finally, additional studies relating changes in income during childhood to changes in child development further highlight the importance of income in early childhood for children's achievement (Dearing, McCartney, & Taylor, 2001; Votruba-Drzal, 2006).

Taken together, these studies suggest that poverty probably matters for children's achievement and later educational attainment, although not as much as some of the early and less rigorous studies suggested. No study has been able to rule out all sources of bias or threats to internal validity, but taken together, the robust links between early childhood poverty and later achievement and attainment, as well as adolescent income and attainment, suggest that parental economic resources play a modest causal role. Duncan (2006) concluded that the magnitude of the association between income and academic achievement was moderate among poor families, with a \$3,000 annual increment for several years related to between a .05- and a .18-standard-deviation improvement in achievement (an average effect of a .11-standard-deviation improvement).

If poverty, especially early poverty, influences children's achievement, it is not surprising to find that it is also associated with educational attainment. Both Campbell, Haveman, Sandefur, and Wolfe (2004) and Duncan et al. (2008) used regression-based approaches and longitudinal data to relate average household income to completed schooling and find that parental income in early childhood and adolescence are associated with increases in educational attainment, although these studies focus on income rather than poverty status *per se*. Campbell et al. (2004) also found that college attendance is correlated only with income during adolescence, perhaps the result of financial barriers to higher education imposed by increasing college

tuitions and credit constraints (Belley & Lochner, 2007; Kane, 2007). Analyzing a sample of adoptees, Plug and Vijverberg (2005) found that parental income is associated with educational attainment both among adoptees and biological children. Moreover, the estimates are quite similar across these groups, leading the authors to conclude that family income plays a causal role in determining educational attainment.

One final natural experimental study used the oil boom in Norway in the beginning of the 1970s as a source of exogenous variation in family income. Instrumenting childhood family income with being born in the region and cohorts affected by the oil boom, Løken, Mogstad, & Wiswall (2012) find that a simple linear estimator of income is misleading because it assigns little weight to the large and positive marginal effects in the lower part of the income distribution. They estimate substantial positive effects of childhood family income (averaged over Ages 2 to 12) for children living in families in the lower part of the income distribution.

With the exception of Duncan et al. (2010; see also Ziol-Guest, Duncan, Kalil, & Boyce, 2012) work, the prior income literature has not been able to relate family income early in a child's life to adult outcomes, largely because data on both early childhood income and later adult outcomes had not been collected in one study. However, recent research has made this link using data from the Panel Study of Income Dynamics, which has followed a nationally representative sample of U.S. families and their children since 1968 (Duncan et al., 2010). The study is based on children born between 1968 and 1975, for whom adult outcomes were collected between Ages 30 and 37. The study measured income in every year of a child's life from the prenatal period through Age 15. They find that directions of all of the correlations between average childhood income and outcomes are as expected statistically significant—positive for “good” outcomes and negative for “bad” ones. However, their effort to separate income from other related disadvantages and characteristics of poor children by entering controls indicated that a substantial portion of the simple correlation between childhood income and most adult outcomes can be accounted for by the disadvantageous conditions associated with birth into a low-income household, rather than low-income itself.

Some argue that the sensitivity of brain development to early experience would imply that poverty during early childhood may be particularly pernicious. To test this, Duncan and colleagues replaced the average childhood income measure with three stage-specific measures of log

**Figure 14.6** Increase in adult earnings associated with a \$3,000 annual increase in income. “ns” indicates not statistically significant at  $p < .05$ .

Source: Authors’ calculations based on data presented in Duncan, Ziol-Guest, and Kalil, 2010.

income (early childhood, prenatal through fifth year, and middle childhood and adolescence) and an extensive list of background controls. For families with average early childhood incomes below \$25,000, a \$3,000 annual boost to family income was associated with a 17% increase in adult earning (Figure 14.6). Results for work hours are broadly similar to those for earnings—a highly significant estimated impact of early childhood but not later childhood income. In this case, a \$3,000 annual increase in the prenatal to Age 5 income of low-income families is associated with 135 additional work hours per year after Age 25. In contrast, increments to early childhood income for higher-income children were not significantly associated with higher adult earnings or work hours. Further work showed that adult attainment measures—earnings, work, the absence of receipt of welfare income, “on-time” completed schooling—were generally quite responsive to income increases in early childhood for low-income families. Thus, with regard to effects of very low family incomes, early childhood appears to be a much more sensitive period for more adult outcomes than does income in middle childhood or adolescence.

Links between wealth and both academic achievement and educational attainment are well established in the literature, but studies have not yet been rigorous enough to provide evidence of causal associations. Importantly, associations between wealth and achievement and attainment seem to hold even when controlling for household income, which is modestly correlated with wealth. Greater wealth is related to higher reading and math skills in children (Loke & Sacco, 2011; Orr, 2003; Phillips et al., 1998; Shanks, 2007; Yeung & Conley, 2008; Zahn, 2006).

Some evidence suggests that these associations may be selective, with stronger and more consistent relations between wealth and math skills than reading (Shanks, 2007; Yeung & Conley, 2008), and larger associations for school-aged children when compared with preschool-aged children (Yeung & Conley, 2008). Wealth is also linked to higher rates of high school graduation (Destin, 2009; Kim & Sherraden, 2011), college enrollment (Conley, 2001; Destin, 2009; Elliott, 2008; Morgan & Kim, 2006), and college degree attainment (Nam & Huang, 2009; Zhan & Sherraden, 2011). Despite extant literature documenting these associations, it is challenging to draw causal conclusions based on this body of research because few studies have employed research designs or analytic methods that deal effectively with the kinds of threats to internal validity discussed previously.

### **Behavior and Mental Health**

In addition to lagging behind their more advantaged peers when it comes to academic achievement and educational attainment, low-income children are typically rated by their parents and teachers as having more behavior problems than more affluent children. In childhood, this is reflected in elevated levels of externalizing problems, such as aggression and acting out, and internalizing problems, such as depression and anxiety. In adolescence and later adulthood, poverty is related to higher rates of nonmarital fertility and criminal activity. For example, compared with children whose families had incomes of at least twice the poverty line during their early childhood, poor males are more than twice as likely to be arrested. For females, poverty is associated with a more than fivefold increase in the likelihood of bearing a child out of wedlock prior to Age 21 (Duncan et al., 2010). Again, the extent to which these associations reflect causal associations remains uncertain.

A large literature has used longitudinal data from nationally representative and diverse samples and regression techniques to more carefully isolate associations between poverty and dimensions of behavior and mental health in childhood. Links have been found between income and several dimensions of psychological functioning including, internalizing and externalizing behaviors, antisocial behavior, inadequate self-regulation, and poor mental health (Blau, 1999; Mistry, Vandewater, Huston, & McLoyd, 2002; Votruba-Drzal, 2006; Yeung, Linver, & Brooks-Gunn, 2002). For example, 7.8% of poor vs. 4.6% of nonpoor parents rated their children as having difficulties with emotions, concentration, behavior, or getting along with others (Simpson, Bloom, Cohen, Blumberg,

Bourdon, 2005). These associations, however, are not consistently replicated in studies that hold constant confounds, such as family structure and parental education (Duncan & Brooks-Gunn, 1997; Duncan et al., 2008; Mayer, 1997). For example, Dearing, McCartney, and Taylor (2006) examined within-child associations between income and young child behavior and found significant negative effects of lower family income on externalizing behavior, especially for children who live in chronically poor households, but not on internalizing behavior.

A small literature suggests that relations between income and dimensions of behavioral functioning may be nonlinear, with affluent and poor youth showing similar patterns of risk (Luthar & Becker, 2002; Luthar & D'Avanzo, 1999; Luthar & Latendresse, 2005). With data from three cohorts of children and adolescents sampled from more affluent communities and comparison groups from inner-city neighborhoods, Luthar and colleagues have shown that in the case of certain dimensions of behavior, particularly substance use and internalizing problems, children from affluent communities look more similar and sometimes even worse than their counterparts from inner-city schools (Luthar & Latendresse, 2005). For example, in her first cohort study, Luthar found 10th graders attending a suburban high school reported significantly higher use of cigarettes, alcohol, marijuana, and hard drugs when compared with students attending an inner-city high school. Moreover, the advantaged teens had significantly higher anxiety and somewhat elevated depression (Luthar & D'Avanzo, 1999). Two key pathways through which affluence seems to give rise to behavioral maladjustment in children are heightened achievement pressures as well as greater physical and emotional isolation from parents, which is common in dual-career families (Luthar & Latendresse, 2005). It is difficult to know whether these results are generalizable to representative samples of children. Moreover, concerns over omitted variable bias are not addressed adequately in these studies.

Researchers have rarely used rigorous experimental or strong quasi-experimental designs to study children's psychological and behavioral health. An exception is work by Costello, Compton, Keeler, and Angold (2003), who were able to take advantage of the Great Smoky Mountain Study of Youth, which gathered longitudinal data on child outcomes during the introduction of a casino by a tribal government in North Carolina. The casino distributed about \$6,000 each year to all adult tribal members. Akee, Copeland, Keeler, Angold, and Costello (2010) compared Native American children with non-Native American

children, before and after the casino opened, and found that receipt of casino payments increased the educational attainment of poor Native American youth by nearly a year and reduced criminal behavior and drug use. A second exception is a study by Morris and Gennetian (2003) that used data from a random assignment pilot welfare reform program in Minnesota that included wage supplements to examine links between income and child development. The study found that increases in family income were related to higher levels of school engagement and more positive social behavior in children.

Across the broad literature addressing links between poverty and children's social, emotional, and behavioral well-being, it is likely that, to the extent that effects are causal, they are selective. Accumulating evidence suggests that, for example, poverty may be more strongly associated with externalizing problem behavior, such as aggression, rather than internalizing behavior, such as depression. The fact that family income may be more linked with some types of behavior than others is not surprising. However, discrepancies across studies may also be attributable to differences in study design. Studies vary considerably in the ages of children and the timing of the poverty or income measure. There is little evidence to indicate whether current or permanent income is a stronger predictor of children's behavior. Nor is there clear evidence on whether the age at which poverty is experienced or timing of poverty is salient in understanding associations between income and children's behavior.

In recent years, a growing literature has examined relations between timing-specific measures of household income (e.g., early childhood income, middle childhood income, adolescent income) and behavioral and psychological functioning into adulthood. These studies show that children raised in low-income households have higher rates of arrest and incarceration in adulthood than their affluent counterparts (Bjerk, 2007; Duncan et al., 2008). Duncan et al. (2008) found that boys living in poverty during the first 5 years of life were more than twice as likely to be arrested as boys who had family incomes over twice the poverty threshold (28% versus 13%). However, taking into account the variety of ways in which poor families differ from wealthier families reduces the associations to statistical insignificance. Thus, it is questionable whether elevations in criminal activity can be attributed to poverty per se, rather than the range of social disadvantages associated with poverty.

Similarly, nonmarital births are more prevalent among women who experienced poverty as children. More than

half of girls who experienced poverty for the first 5 years had a nonmarital birth by Age 28, compared with 21% for those with family incomes between 100% and 200% of the poverty threshold and only 8% for those with household incomes over 200%. Attempting to isolate a causal effect of income, Mayer (1997) reduces these associations by more than half, but still finds a significant association between income during adolescence and nonmarital fertility. Duncan et al. (2010) have examined whether the timing of poverty matters for dimensions of behavioral functioning and find that income during adolescence, not earlier in childhood, is most strongly associated with adult behavior. In these cases, though, income increments in adolescence were more consistently significant for children in middle- and higher-income (income greater than \$25,000) than lower-income families.

Few studies consider links between wealth and dimensions of emotional and behavioral functioning. The tendency in the wealth literature has been to focus on academic achievement and educational attainment. An exception is a study by Shanks (2007) that uncovers modest relations between wealth and a broad measure of children's behavior problems. A second study by Kaushal and Nepomnyaschy (2009) found significant associations between wealth and children's participation in extracurricular activities, but no association between wealth and suspension or expulsion from school. Far too few studies have explored linkages between wealth and emotional and behavioral development to draw clear conclusions from this literature.

In sum, associations between income and dimensions of children's behavioral functioning tend to be less consistent than are links with achievement and attainment and less robust to more rigorous methodological approaches and analytic techniques. To the extent that there are causal connections between income and behavior in childhood, these influences may be selective, with some evidence to suggest there are stronger associations with dimensions of externalizing than internalizing problems. It is important to note, however, that few studies have been able to differentiate these subtypes of problem behavior. The global measures of child behavior problems commonly found in large nationally representative data tend to rely more heavily on items that assess externalizing problems, such as aggression and oppositional behavior, than internalizing problems, including depression and anxiety.

Future research would benefit from more careful attention to unique associations between income/poverty and particular dimensions of children's behavioral functioning

as well as greater attention to internalizing problems. When it comes to socioeconomic variability in important adult behaviors, such as arrests, nonmarital childbearing, and educational attainment, the timing of income seems to be important, with income in adolescence more strongly related to adult behavior than is income in earlier life stages. Importantly, very few studies have assessed these linkages, so additional research is necessary to confirm these findings.

### *Physical Health*

Growing up in poverty is associated with a variety of worse health outcomes. Compared with children in nonpoor households, poor mothers report that their children have worse overall health. Currie and Lin (2007) found that only 70% of poor children were reported to be in excellent or very good health, compared with 87% of nonpoor children (Currie & Lin, 2007). In Western industrialized nations, some evidence suggests that economic disparities in general health tend to grow from early childhood through adolescence (Case et al., 2002; Case, Lee, & Paxson, 2008; Currie & Stabile, 2003; Murasko, 2008). The gap between poor and nonpoor children in excellent or very good health grows from 15.5% for 2- to 3-year-olds to 19.2% for 13- to 17-year-olds (Currie & Lin, 2007). This may be because income protects children's health at the onset of early chronic conditions (Case et al., 2002). The steepening of the income gradient as children age, however, is not consistently replicated in the literature (Chen, Martin, & Mathews, 2006; Currie & Lin, 2007; Khanam, Nghiem, & Connelly, 2009; Propper, Rigg, & Burgess, 2007; Reinhold & Jurges, 2012).

In the United States, children from poor households also have higher rates of chronic conditions such as asthma and diabetes, as well as hearing, vision, and speech problems. About 32% of poor children compared with 27% of nonpoor children are reported to have at least one such condition. Asthma is the most common chronic condition among poor children, followed by mental health conditions, with attention deficit hyperactivity disorder being the largest diagnosis within this category (Currie & Lin, 2007). Finally, poor children suffer from higher rates of health-related activity limitations and acute illness (Currie & Lin, 2007).

Associations between childhood poverty and health extend into adulthood. Economic disadvantage in childhood has been linked to worse overall health status and higher rates of mortality in adulthood (Case, Fertig, & Paxson, 2005; van den Berg, Lindeboom, & Portrait, 2005).

Johnson and Schoeni (2007) find that childhood poverty is linked to heightened risk for several chronic diseases in adulthood. By age 50, individuals who have experienced poverty in childhood are 46% more likely to have asthma, 75% more likely to be diagnosed with hypertension, 83% more likely to have been diagnosed with diabetes, 2.25 times more likely to have experienced a stroke or heart attack, and 40% more likely to have been diagnosed with heart disease, in comparison to individuals whose incomes are 200% of the poverty line or greater. Adult disparities in chronic health problems by poverty status tend to become more pronounced with age.

Unadjusted differences in physical health by childhood poverty status likely overstate the true causal effect of childhood poverty on physical health. Efforts to strengthen causal claims about the links between family income and child health have involved controlling for a richer set of potentially confounding variables (Khanam et al., 2009; Propper et al., 2007; Ziol-Guest, Duncan, & Kalil, 2009). For example, using data from the Longitudinal Study of Australian Children, Khanam et al. (2009) find that the income gradient in child health disappears with the addition of extensive controls. In this study, measures of maternal physical and mental health seem especially important in explaining the income gradient in child health; however, serious questions exist about whether some of these controls, such as maternal depression, may be pathways through which family income affects child health. Other studies have capitalized on more exogenous variability in family income (Duflo, 2000; van den Berg et al., 2005). Van den Berg and colleagues used business cycle conditions as a source of exogenous variation in family income during early childhood and found a robust effect of economic conditions in early life on individual mortality rates at all ages. Being born during a recession was associated with an 8% increase in the mortality rate after the first year of life.

A final group of studies has employed econometric techniques, such as fixed-effects models, to identify less biased estimates of income's links with child health (Burgess, Propper, & Rigg, 2004; Conley & Bennett, 2000; Doyle, Harmon, & Walker, 2007; Johnson & Schoeni, 2007, 2011). Johnson and Schoeni (2007, 2011) uncovered large and statistically significant links between childhood poverty and a variety of health outcomes in adulthood. However, comparing siblings who experienced different economic conditions (i.e., sibling fixed-effect models) greatly reduced these associations. The associations between childhood poverty and adult health status were

robust in sibling models, but associations with a variety of diseases in adulthood (e.g., asthma, hypertension, and stroke or heart attack) were not. This raises questions about the extent to which basic correlations between childhood poverty status and adult health are causal.

Turning to the conditional cash transfer (CCT) programs that pay families for using preventive health care services, the evidence on health impacts is mixed. Although poor households in the programs typically make more use of health and education services, the evidence on improvements in health outcomes is inconclusive (Fiszbein et al., 2009). Some CCT programs improved such health outcomes as stunting and improved nutrition, whereas others have not.

Evidence suggests that it may be important to consider age-specific effects when examining links between family income and adult health outcomes, because income in the earliest year of childhood may play a particularly important role for low-income families. For example, Ziol-Guest et al. (2009) examined associations between mean family income in early, middle, and later childhood and adult body mass index (BMI). They find that prenatal and birth year income is negatively associated with adult BMI among low-income participants of the study, whereas subsequent income is not. More specifically, \$10,000 increases in annual income over these 2 years was linked with a .43 SD reduction in BMI.

Ziol-Guest et al. (2012) investigated whether immune-mediated chronic diseases play a role in associations between poverty very early in life and adult productivity. Drawing data from the PSID, concentrating on families with incomes below \$25,000, they find significant associations with earnings and work hours between Ages 30 and 41 only for income between the prenatal year and Age 2. Turning to health outcomes, they find that increases in family income measured in the prenatal and second year of life are related to reductions in limitations on activities of daily living, hypertension, and arthritis in adulthood. Income between Ages 3 and 5 years and between Ages 6 and 15 years was not similarly protective for adult health. Moreover, they find that associations between early family income and these three health outcomes partially explain links between early childhood poverty and labor force productivity (i.e., work hours and earnings).

Despite recent growth in research addressing links between income and child health, it is difficult to draw causal connections because these outcomes have received much less attention than achievement and behavioral development. Synthesizing across the current research base that

has used more rigorous approaches to identifying associations, the literature suggests that there may be small links between income and some aspects of children's physical health.

Given the conflicting empirical results, the current literature raises more questions than it answers, pointing to the need for more research. Specifically, future work should consider differences in income's effect by developmental stage and the domain of health outcomes. Finally, methodological considerations, such as differences in measurement, may also be important. Indeed, prior studies suggest that income gradients tend to be more pronounced for more subjective measures of child health, such as parent-report measures, and are less evident in more objective measures, such as biomarkers or physician diagnosis (Currie & Lin, 2007; Reinhold & Jurges, 2012).

### Parental Schooling

Parental academic achievement and educational attainment are correlated with child developmental outcomes. Research on the effects of parental education are motivated both by the idea that parental education and skills might be a better measure of family's SES and permanent income than other SES indicators and because it is potentially less prone to measurement error than other SES indicators.

In the United States and other similar countries, rigorous research has largely focused on achievement and education outcomes, because of the seeming importance of intergenerational transfer of skills within domains. Nevertheless, the accumulating evidence seems to suggest that higher levels of parents' education are causally linked to children's better achievement and education, but these associations are selective. Whether it also has beneficial effects on children's health and behavior is still not clear.

### *Academic Achievement and Human Capital Attainment*

Children with more highly educated parents are consistently found to have more advanced cognitive skills and academic achievement than children of parents with lower levels of education (Haveman & Wolfe, 1995). Analyzing data from a recent nationally representative birth cohort, Isaacs and Magnuson (2011) find that children whose mothers have no higher than a high school degree perform about .7 standard deviations lower on math and .6 standard deviations lower on reading assessments compared with children of mothers whose highest level of education is a bachelor's degree or higher. Comparisons among children by similar categories of paternal education yielded

differences that were similar, but slightly smaller. Differences are apparent not only at school entry, but also in attainment in later years of schooling. In 1999, 82% of children whose parents had at least a bachelor's degree enrolled in college immediately after completing high school, this was the case for only 54% of children whose parents had only completed high school (U.S. Department of Education, 2001).

Most studies estimate linear effects, with little attention to how these effects may differ across the educational distribution or by family or individual characteristics, including developmental stage. If parental education is causally related to child development, it is possible that the effects are nonlinear, as higher levels of skills may represent the acquisition of specialized skills and have fewer economic and social returns, although most studies estimate linear effects. Haveman and Wolfe (1995) find that maternal educational attainment is more closely related to children's academic performance than paternal educational attainment. Their review provides evidence of a nonlinear link between parental education and achievement, such that additional years of school are more beneficial for parents' who have completed high school or only a year or two of postsecondary education, and smaller for parents with years of postsecondary education beyond that level. Given that parental education is often considered fixed, there has not been much attention to the timing of improvements in parental education. One exception is Magnuson (2007), which linked additional years of school for disadvantaged mothers to improvements in achievement during middle childhood, and found that associations were strongest for children who were younger (Ages 6–8).

In response to the challenge of identifying causal associations, social scientists have used two differing strategies. First, they have tried to exploit differing levels of relatedness within families either by using samples of twins or adoptees. Twin studies have compared the offspring of identical sisters who achieve differing levels of education. For example, Behrman and Rosenzweig (2002) used samples of 424 twin mothers and 244 fathers born between 1936 and 1955 with at least one child 18 years of age or older. This approach allowed them to rule out genetic confounds between parents' education and their children's achievement. They found that maternal schooling does not have a beneficial effect on children's educational attainment. However, their findings may be context dependent because the mothers in their sample who attained more education were more likely to work out of the home, and this may have had an offsetting

negative effect on children. In contrast, they did find that paternal schooling has a positive effect on their children's schooling. An additional year of paternal schooling raised their child's educational attainment by slightly more than a third of a year (see also Antonovics & Goldberger, 2005).

A similarly designed analysis of both Danish twins and Norwegian twins suggests substantial effects of paternal education and near zero effects of maternal education. However, in one of these studies Bingley, Christensen, and Jensen (2009) use Norwegian data and find that there has been a historical shift, such that for earlier cohorts, fathers' education mattered more than mothers' but that for more recent cohorts, mothers' education appeared to be more influential than fathers'.

Another within family approach to disentangling these influences has been to use samples of adopted and biological children. In this study design, if the adoption process mimics random assignment then there is not an association between the characteristics of the placed infant and the adopting family. However, in many adoption samples, the process is not well described and thus the "random" nature of the assignment is highly questionable. Three studies have been conducted with U.S. samples, and all provide some indication that parental education is linked with children's educational attainment. Using a sample of adopted adolescents and matched biological children in two-parent families, Neiss and Rowe (2000) estimate the proportion of the association between parental education and children's verbal IQ that is attributable to genetics and to education *per se*. They found that parental education was significantly but modestly associated with adolescents' verbal IQ. The correlation between maternal education and child's verbal IQ was .16, and the correlation between paternal education and child's IQ was .18. Analysis of the Wisconsin Longitudinal Study by Plug (2004) and of Korean adoptees by Sacerdote (2007) find that associations between biological children and parents' education are larger than those for adoptees, but the estimates for adoptees are still positive and significant.

A second strategy has been the use of quasi-experiments and instrumental variables. One study of the impacts of mothers' schooling on children's development involves experimental manipulation of mothers' schooling. Genetian et al. (2008) exploit the fact that the National Evaluation of Welfare to Work Strategies Child Outcome Study randomly assigned welfare recipients with young children to either an education- or work-focused program group or to a control group that received no additional assistance. Their work takes advantage of the experimental

design by using an instrumental variable approach to estimate the effect of maternal schooling on 5- to 7-year-old children's academic school readiness. They estimate that an additional 9 months of schooling causes a quarter of a standard deviation increase on a test of young children's academic school readiness and a similar sized reduction in academic problems such as grade retention.

More recently, differences in educational attainment due to changes in school-leaving policies have been examined. Using U.S. data, Oreopoulos, Page, and Stevens (2006) and Page (2006) find that increased parental education due to changes in compulsory school leaving laws and the GI Bill, respectively, are associated with significant reductions in a child experiencing grade retention. Similar patterns for grade retention are found in French data (Maurin & McNally, 2008) and for educational attainment in Britain (Chevalier, 2004). In contrast, using administrative data from Norway and leveraging changes in compulsory schooling policy changes, Black, Devereux, and Salvanes (2005) finds little consistent effect of parental education on completed schooling among the general population, although the estimates are positive and significant for maternal education among those at the lower end of the educational distribution. Using college costs as an instrument for maternal years of school, Carneiro, Meghir, and Parey (2013), find that an additional year of mothers' schooling predicts better reading and math skills during middle childhood.

A final strategy is to use within-family variation. Two studies have taken advantage of the fact that young mothers often acquire more formal schooling between the births of first and subsequent children to estimate whether achievement and behavior differences between earlier- and later-born siblings are related to increases in mother's formal schooling. These studies also provide contradictory evidence. Kaestner and Corman (1995) used this approach in an analysis of scores on the Peabody Individual Achievement Tests (PIATs) and found no consistent effect of increased maternal education on children's achievement scores. In contrast, Rosenzweig and Wolpin (1994) found that an additional year of maternal schooling did have a modestly positive and marginally significant effect on children's PIAT scores. Interestingly, they found that mothers' enrollment during a child's first 3 years had a significant and large positive effect on children's scores on the Peabody Picture Vocabulary Test (PPVT), a measure of receptive vocabulary.

Based on the work by Holmlund, Lindahl, and Plug (2011) and Pronzato (2012), Black and Devereux (2011)

argue that discrepancies across studies are more likely to be caused by differences in methods than by differences in the country of origin or data. Holmlund and colleagues' study applied all three approaches to Swedish data and found, as expected, that OLS methods yielded the largest associations. Using adoption samples, they found that fathers' education appeared to matter more than mothers' education, whereas using instrumental variable methods, mothers' education seemed to have larger associations with their children's schooling outcomes than fathers' education. The authors suggest that these differences might be due to the relative amounts of parent education that providing the identification of the parent education effects. Adoptees tend to come from the higher end of the education distribution whereas the identifying variables used in the instrumental variables studies tend show most variation among families at the lower end of the education distribution.

Pronzato (2012) used a sample of Norwegian twins and confirms this pattern of nonlinear associations in the data. At the low end of the parental education distribution, mothers' education has a stronger association with children's outcomes than fathers' education—the opposite is true at the higher end of the distribution, where fathers' education appears to be more influential.

In summary, understanding the causal associations between parents' education and their children's achievement and schooling is complicated by the seemingly large number of possible omitted variables that might bias such estimates. Efforts to reduce bias through using quasi-experiments and within-family variation have found noteworthy, but modest and selective, associations between parental schooling and children's achievement or attainment. It appears that mothers' education may exert a stronger influence at the lower end of the education distribution and fathers' at the higher end of the distribution. However, many studies supporting such a conclusion have been conducted in other countries, and the extent to which these findings would generalize to the United States is uncertain.

### ***Child Behavior and Health***

Parental education is also linked with children's behavior and mental health, although the associations are not as strong for these outcomes as they are with achievement and education. The difference between children of high school graduates and children of mothers who completed at least a bachelor's degree for teacher reports of externalizing behavior problems in kindergarten amounts to just under a third of a standard deviation (Isaacs & Magnuson, 2011).

A slightly smaller difference was found comparing children in the same categories of fathers' educational attainment. Differences were also apparent in whether children and youth experience psychological disorders, including mood, anxiety, conduct, and substance use disorders by parental education, with the largest differences found between children whose parents have college degrees and those who do not (McLaughlin, Costello, Leblanc, Sampson, & Kessler, 2012). Although these differences suggest the possibility of important gradients in children's behavior by parental education, there are few studies that use rigorous methods to test whether such associations are causal. This is likely because the large administrative datasets that provide evidence for children's school outcomes often do not include good measures of children's behavior.

A study that has used stronger methods than others is Attewell and Lavin's (2007) look at how expanded enrollment in postsecondary education has influenced family processes and children's development. Using nationally representative survey data on mothers' reports of children's behavior problems during middle childhood, they compare children whose mothers have completed college to those who completed high school. The mean difference—over half a standard deviation—is larger than that found by Isaacs and Magnuson (2011). But, when they used matching techniques to reduce confounding differences between the groups, the advantage of having a college educated mother fell to less than .2 of a standard deviation. Finally, Carneiro et al. (2013) use differences in the cost of postsecondary education as exogenous variation in maternal education, and find that an additional year of school is associated with small reductions in mothers' reports of their children's problem behavior problems. This suggests, holding constant many important confounds, that college completion still has a meaningful association with reports of children's behavior, but much of the observed association may be attributed to other factors.

Parental education also has strong associations with children's health—this is especially true in developing countries where more educated mothers are likely to have better birth outcomes, including lower rates of infant mortality (Basu & Stephenson, 2005; Fuchs, Pamuk, & Lutz, 2010). U.S. data show strong maternal education gradients for low birth weight and small-for-gestational-age outcomes, although such gradients are not apparent among Black or Hispanic families (Nepomnyaschy, 2009). Descriptive data indicate that among older children, parental education is also linked with better physical health measured in terms of height and weight (Currie, 2009).

In addition, children with less-educated parents are more likely to be rated as having poor or fair health and also more likely to have health problems that limit their physical or school activities (Chen et al., 2006). Again, however, such gradients differ by race with the most pronounced differences found for Whites and Blacks, and smaller differences among Asians and Hispanics (Chen et al., 2006).

There are only a few rigorous studies that try to identify the unique effects of parental education for children's health. All use instrumental variable methods, but they come to divergent conclusions. Currie and Moretti (2003) exploited variation in education due to college openings and found that higher levels of mothers' education improved birth outcomes. In contrast, focusing on discontinuities in school leaving policies in Texas and California as a source of exogenous variation in maternal high school completion rates, McCrary and Royer (2011) found no effect of increased maternal education on children's health outcomes. Finally, in the United Kingdom, an instrumental variable study of compulsory school leaving policy changes that affected the lower end of the education distribution found little association between parental education and a range of children's health outcomes such as low birth weight and chronic health conditions (Lindeboom, Llena-Nozal, & van der Klaauw, 2009).

In summary, although the correlations between parental education and children's health and behavior are strong, there is much more to learn. Important questions should start with whether such differences are due to education *per se*, rather than the range of other disadvantages that are strongly correlated with low education. In this work, it is also important to consider the functional form of education, for example, is postsecondary education especially important or do improvements at any point in the education distribution make a difference? Finally, health and education are diverse domains, and it is likely that there are differences in associations and causal connections across these outcomes. These will be important topics for future research.

### Parental Occupation

A growing literature has considered relations between parental occupational characteristics and child and adolescent development. Nearly all of the work is correlational and, when compared with the literatures addressing family income and parental education, far fewer studies rely on quasi-experimental designs or rigorous analysis of longitudinal data. Thus, it is challenging to rule out threats to validity posed by omitted variables and simultaneity

bias. Some address these concerns by including extensive sets of baseline characteristics of children and families in their analytic models (e.g., Parcel & Menaghan, 1994), or by modeling reciprocal effects of job characteristics on parental values, cognitive skills, or personality traits (Kohn & Schooler, 1982).

The evidence on causal links between parental occupational characteristics and children's development is quite tenuous. For example, it is difficult to know based on the literature whether more prestigious jobs that tend to be more cognitively demanding lead parents to value self-direction in their children, or rather if parents with higher academic aptitude may just be more likely to both obtain prestigious jobs and to value self-direction in children. When it comes to concerns of reverse causality, in most studies it is impossible to determine whether low-prestige jobs give rise to more behavior problems in children or if parents' labor force participation is compromised by their child's behavioral functioning (Coley, Ribar, & Votruba-Drzal, 2011). Also, much of this literature has fallen short of explicitly identifying family-level processes linking occupational characteristics and children's development. Instead there is a tendency in the literature to focus either on family processes or on child functioning, with the prior never making linkages to child functioning and the latter not delving into family-level pathways.

Three occupational characteristics consistently correlated with child development are nonstandard work hours, job stress, and occupational complexity. Nonstandard work schedules, typically defined as work schedules that occur outside the typical daytime hours (6 a.m. and 6 p.m.), have been related to moderately worse child functioning across several dimensions. When compared with children whose parents work standard schedules, children whose parents work nonstandard schedules exhibit lower reading and math scores, less participation in extracurricular activities, and tend to be less engaged in school (Han, 2006; Han & Fox, 2011; Hsueh & Yoshikawa, 2007). Children whose mothers work nonstandard hours also look worse when it comes to emotional and behavioral functioning, with higher rates of internalizing and externalizing problems, delinquency, school suspension, and lower levels of positive behaviors (Dunifon, Kalil, & Bajracharya, 2005; Han, Miller, & Waldfogel, 2010; Heymann, 2000; Hsueh & Yoshikawa, 2007; Joshi & Bogen, 2007; Strazdins, Clements, Korda, Broom, & D'Souza, 2006). Nonstandard work has been linked to increases in body mass index (BMI) (Miller & Han, 2008), though not consistently when using methods that more rigorously control for

omitted variable bias (Morrissey, Dunifon, & Kalil, 2011). Despite extant literature linking nonstandard work schedules to child well-being, endogeneity and simultaneity bias are major concerns when attempting to draw causal conclusions from this literature.

The existing literature has uncovered associations between job stress, which encompasses feelings of work overload, pressure, as well as negative social interactions in the workplace, and family functioning. (For a review, see Repetti, 2005.) A growing literature, relying on naturalistic methods linking day-to-day variability in workplace stress to family interactions, helps to reduce concerns of endogeneity and allows researchers to establish clearer temporal precedence when it comes to addressing concerns of simultaneity bias (Repetti, 1994; Repetti & Wood, 1997, Story & Repetti, 2006). For example, in the Daycare Reunion Study (Repetti & Wood, 1997), low- and middle-income mothers evidenced greater emotional and behavioral withdrawal during videotaped parent-child reunions on days when they reported heightened workloads and greater interpersonal stress at work, than on days when workloads were lower and interpersonal stress was lessened. Despite a large literature linking multiple dimensions of job stress to aspects of family functioning, few studies link these family processes to child well-being and those that do tend to uncover small or insignificant associations (Repetti, 2005). This may not be surprising, because much of this work focuses on short-term responses in family processes to possibly temporary work stressors, but when these stressors become chronic and associated with repeated activation of the stress response system, there may be more meaningful implications for child and adolescent health and well-being (Repetti, 2005).

Occupational complexity reflects the level self-direction, autonomy, and intellectual flexibility that are required in the workplace (Kohn & Schooler, 1973, 1982) and it is thought to influence children's development through differences in parental socialization and psychological distress. When it comes to parental socialization, it has been argued that occupational complexity shapes child rearing values, beliefs, and behaviors, with parents tending to socialize their children in a way that emphasizes the values and behaviors that are effective in their own workplace (Kohn, 1976; Parcel & Menaghan, 1994). For example, Lareau (2003) has shown that middle-class parents in higher complexity jobs are more likely to stress self-direction, autonomy, flexibility, and reasoning in their child rearing practice. In contrast, parents in low-complexity occupations tend to emphasize conformity to rules, constraint, discipline, and control (Luster et al.,

1989). These differences in values give rise to differences in parenting practices, which may have implications for children's development. Occupational complexity also may influence children's development through parental psychological distress as well. Low-complexity jobs, characterized by little autonomy, high levels of supervision, and routinized tasks, are associated with higher levels of psychological distress and lower levels of self-esteem, which in turn has negative implications for parent child interactions (Menaghan & Parcel, 1991).

Consistent associations have been established between occupational complexity and cognitive, verbal, and academic development, particularly in young children (Enchautegui-de-Jesus, Yoshikawa, & McLoyd, 2006; Menaghan & Parcel, 1995; Parcel & Menaghan, 1994; Yetis-Bayraktar, Budig, & Tomaskovic-Devey, 2013). Yet, there are several notable limitations to the literature, including very little attention to children's behavioral and emotional functioning, and a reliance on methodological approaches that are not effective in seriously addressing concerns of omitted variable bias. Much of this literature has controlled for a set of potentially confounding sociodemographic characteristic of parents and families, but few studies have moved beyond this approach and incorporated more rigorous econometric methods. An exception is a recent study by Yetis-Bayraktar et al. (2013) that used data from the PSID and Heckman two-stage corrections, which model differential selection into employment, and found enduring links between occupational complexity and children's academic achievement.

## POLICY IMPLICATIONS

The accumulated theory and evidence about the importance of SES for shaping family life and children's development suggest some important policy implications. Although no policy changes manipulate family SES directly, a variety of policies and programs target components of SES. As our review of the empirical literature has highlighted, some of the best evidence about the effect of SES components on children comes from quasi-experimental changes in real policies or programs. These studies suggest that on average, increasing the incomes of poor families will improve their children's achievement and attainment, especially if such improvements occur in early childhood. In the past 20 years, the largest cash transfers to low-income families have taken the form of refundable state and federal tax credits, specifically the earned income and the child tax credits; continuing to expand these programs is one policy

option. Another step might be to ensure that sanctions and other regulations embedded within welfare policies do not deny benefits to families with very young children. Not only might young children be the most vulnerable to the consequences of deep poverty, but also mothers with very young children are least able to support themselves through employment in the labor market.

Increased income support can also take the form of such near-cash benefits as food stamps or housing vouchers. Interesting quasi-experimental data on food stamps uses geographic variation in the timing of the rollout of the Food Stamp program in the 1960s and 1970s to link program benefits around the time of birth to adult outcomes (Hoynes, Whitmore Schanzenbach, & Almond, 2012). They find that access to food stamps in childhood leads to a significant reduction in the incidence of metabolic syndrome (obesity, high blood pressure, and diabetes) and, for women, an increase in economic self-sufficiency.

With respect to parental schooling, it is critical to identify policies to improve parents' educational attainment. The historical record shows large improvements in the completed schooling of young adults. In addition, studies of low-income populations routinely report that even without any programmatic intervention, close to 50% of disadvantaged mothers return to school after having children (Furstenberg, Brooks-Gunn, & Morgan, 1987; Rich & Kim, 1999). Yet even with high rates of continued schooling, educational attainment among economically disadvantaged parents remains much lower than among advantaged families and there is little agreement on which policies and programs might promote future increases in schooling (see Crosnoe & Benner, Chapter 7, this *Handbook*, this volume). One promising approach is to reduce the costs of education, particularly higher education, and increase access to adult educational opportunities (Attewell & Lavin, 2007). Indeed, public spending on higher education, including more generous financial aid and the expansion of community colleges, has been consistently linked to increases in college attainment and enrollment (Dynarski, 2002; Seftor & Turner, 2002; Turner & Bound, 2003; but see also Heckman, Krueger, & Friedman, 2005).

Policies related to improving parents' occupational standing are harder to identify. Most employment-related programs emphasize increasing labor market attachment and earnings among the unemployed or underemployed rather than building skills among those who are employed. Generally, the major employment initiatives that have been evaluated extensively have been characterized as providing disappointing results (Heckman et al., 2005), although recent analysis suggests that this conclusion overlooks

some important exceptions (Holzer, 2009). Nevertheless, most evidence suggests that interventions to boost workers' occupations are likely to occur indirectly, by improving their job skills through education and work-based training programs. That said, we note that some policy and programmatic interventions could be created to reduce some aspects of work-related stress. This might include, for example, changing work-based policies around scheduling and work hours as well as other benefits that may reduce work-family conflict for low-skill workers (Bianchi, 2011; Henly, Shaefer, & Waxman, 2006).

In emphasizing the potential importance of policies to boost income in early childhood, we do not mean to imply that focusing on this area is the only policy path worth pursuing. Obviously investments later in life and those that provide direct services to children and families may also be well advised. Economic logic requires a comparison of the costs and benefits of the various programs that seek to promote the development of disadvantaged children throughout the life course. In this context, expenditures on income-transfer and service-delivery programs should be placed side by side and judged by their benefits and society's willingness to pay for the outcomes they produce, relative to their costs.

## CONCLUSION

The study of SES and children's development has provided important insight both into how children's development is affected by social contexts and how social and economic structures affect the life chances of children. The stubborn and pervasive intergenerational transmission of SES advantage is striking, and yet the strength and historical persistence of these associations obviate neither the permanence nor causal nature of the associations. Social science and, increasingly, biological science, are important tools in understanding the extent to which parents' socioeconomic fortunes portend their children's life chances as well as explaining the social and individual developmental processes that link parents' and children's lives.

Continuing progress in the field requires advances in both theory and empirical work. Three mid-level theoretical frameworks, each aligned with a different disciplinary perspective, have guided empirical work to date. Each of these frameworks would benefit from greater specificity of key concepts and underlying mechanism so that the theories can be formalized in a way that lays the ground for more ambitious—and refutable—hypotheses. To date these theories are most commonly used to interpret

expected associations, rather than being pushed to generate concrete, disconfirmable predictions. To move theory forward, scholars must more carefully articulate the processes of influence and critically evaluate them in light of rigorous empirical work.

Second, additional theory building must articulate how processes of influence may differ across contexts and result from individual differences. Though each perspective incorporates these ideas to some extent, none of these theoretical frameworks has clearly specified how context and individual differences, including developmental age, affect these processes. Finally, meta-theoretical work that bridges and integrates these perspectives must be advanced to consider how the identified processes relate to each other so that the field has a more complete understanding of SES's influence on children and families (see for example, Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1).

Empirical research also has a role to play in moving the field forward. First, greater attention should be given to links between SES and several domains of development, specifically children's behavior and health. Theory supports these causal links, yet there are few studies that have good measures of these types of domains. Second, research should pay greater attention both to the functional form of associations and the developmental timing of the experiences, as both may moderate the effects of improvements in these components of SES. Third, there is a need for greater methodological rigor in empirical studies of the causal impacts of components of SES on child outcomes. There are many more correlational studies that were conducted well before stronger methods for causal analysis and the software to implement them became widely available. Sorely needed are a new generation of studies that employ strong methods to revisit some of the key causal connections, as well as journals that prioritize replication and extension studies as much as studies of novel topics. Finally, we expect that continued attention to neurocognitive and physiological pathways will yield important insights, but also caution that these approaches will be most fruitful when combined with methodologies that improve causal inference (Duncan & Magnuson, 2012).

## INTRODUCTION

This chapter presents information about the changing nature of children's health and approaches to the health care of children in various medical settings. Special emphasis is placed on the impact of medical advances made in the latter half of the 20th and beginning of the 21st centuries. These advances have heavily contributed to a significant change in the epidemiology of children's disease,

primarily a decrease in death and an increase in chronic disease.

Reduction in mortality and infectious diseases provided the opportunity to focus on new morbidity problems such as attention-deficit/hyperactivity disorder (ADHD), learning disabilities, autism, child maltreatment, and common behavior problems. The clinical challenges related to these problems center around prevention, early identification and effective management. Children with chronic disease face unique challenges differentiating them from healthy children in terms of coping with illness and hospitalization, education, pain management, adaptation to disease, impact on family and siblings, and preparation for death. These

---

We would like to thank Marilyn Augustyn, Melissa Brennan, and Julio Ma Shum, whose efforts have helped make this chapter possible.

children therefore have special health care needs that require collaboration across disciplines.

Advances made in the understanding of disease processes are the driver of change in how health care is delivered. Developmental science, neurobiology, and now the emerging field of epigenetics, the study of the influences of the environment on gene expression, continue to lead to a better understanding of the health, developmental, and life-course trajectories of children and what strategies and interventions can promote optimal outcomes. Additionally, disparities in health care in addition to socioeconomic conditions have significantly influenced the health outcomes of children today. Better understanding of the barriers to care faced by low-income children and families including the unequal access to efficacious treatment have led to programs and policies to better attempt to improve the outcomes for children and reduce this gap. Such interventions will be noted throughout this chapter.

To begin this chapter, we review historical events and innovations that have shaped the current setting of health care for children followed by the impact changing technology and epidemiology have made on how health care is delivered. Here we have conceptualized three major eras of health care to lay groundwork for the changing forces and dynamics of children's health care. Contributions of emerging frameworks will then be reviewed before describing the medical environment for healthy children. The specialized care and environments for children with chronic diseases will then be discussed followed by implications and changes for the future of the health care of children. Throughout the chapter, examples of diseases and conditions related to the section will be additionally presented.

## **HISTORICAL PERSPECTIVE OF MEDICAL CARE FOR CHILDREN**

Historical events and innovations since the beginning of the 20th century have shaped the current setting of health care for children. This section covers them in three major eras. The third era has not yet started but its scientific base is evolving and will likely lead to significant change.

### **The First Era of Medical Care for Children**

During the first era of medical care for children through the mid-20th century, infectious diseases (especially those causing gastrointestinal or respiratory disease) and unsafe

living conditions caused the majority of medical problems and death in children.

Physician expertise at the time was seen in their clinical descriptions and identification of diseases; however, their treatment options were rudimentary, consisting of bloodletting, laxatives, and mercury, especially for adult diseases (Jones, Podolsky, & Green, 2012). The lack of effective treatments for most diseases limited medical care for children. Doctors had little to offer except hand holding to help children survive acute illnesses. A common treatment was fresh air and sunshine; exemplified by "floating hospitals" in New York and Boston or related fresh-air facilities. Floating hospitals for children were actual boats tied to docks and floating in the harbor during the day so children would be exposed to fresh air. In addition many hospital rooms for both children and adults had porches connected to the rooms to provide access to sunshine and fresh air. Only poor children would be hospitalized because unlike their home, hospitals at least provided a clean bed with adequate and hopefully nutritious food. Children from more affluent families were cared for in their home, an environment that was cleaner and safer than the hospital. This was the era of doctors making house calls.

Most health gains during this era were the result of public health improvements, primarily clean water sources, improved sanitation, and pasteurization. Pasteurization that eliminates many bacteria was originally developed in 1864 to prevent wine and beer from souring (Carlisle, 2004) and milk was not pasteurized in the United States until 1892 (Selitzer, 1976).

### **The Second Era of Medical Care for Children**

The second era of health care began mid-20th century featuring significant biomedical innovation led by the introduction of vaccines to prevent many important infectious diseases and antibiotics to treat other infections. It is marked as the era of the emergence of children with chronic illness and special health care needs in response to this reduction in mortality.

Development of vaccines has saved lives and in some cases eliminated the disease they targeted. For example, smallpox caused by *Variola major* and *Variola minor* had mortality rates ranging from 9% to 62% depending on the virus subtype. In 1967, the World Health Organization (WHO) estimated 15 million people contracted smallpox with 2 million related deaths (Hopkins, 1989). The last case of smallpox in the United States was in 1949 (Centers for Disease Control and Prevention [CDC], 2007), the last

known natural case in Somalia in 1977 and was officially declared eradicated in 1979 (WHO, 2013b).

The history of polio not only illustrates disease eradication but also highlights key aspects of the second era of health care that involves the confluence of scientific advancements, political actions, public awareness campaigns, and public health measures in response to a disease epidemic. Similarly, rehabilitative medicine, medical philanthropy, the early beginnings of the social and civil rights movement for the disabled also have their roots in polio related efforts (Oshinsky, 2005).

The poliomyelitis virus mainly affects children under 5 years of age, has no cure, and has a 5% to 10% mortality rate due to paralysis of the diaphragm (WHO, 2013a). While there were sporadic outbreaks prior to 1916, from that year on the United States experienced a polio epidemic each summer in at least one part of the country. The United States would see its most serious epidemics in the 1940s and 1950s (Trevelyan, Smallman-Raynor, & Cliff, 2005). Polio reached a peak in the United States in 1952, with more than 21,000 paralytic cases (Atkinson & Hamborsky, 2012). Polio resulted in long quarantine periods separating children from their parents (Sass, Gottfried, & Sorem, 1996).

The first of two polio vaccines, the inactivated poliovirus vaccine, was developed by Jonas Salk in 1952 and made available for use in 1955. In 1957, Albert Sabin developed the oral polio vaccine, which became available for use in 1962. The last naturally occurring cases of paralytic polio in the United States, in 1979, developed with an outbreak among the Amish in several Midwestern states (Atkinson & Hamborsky, 2012). The Global Polio Eradication Program has contributed to the reduction of polio throughout the world with only three countries (Afghanistan, Nigeria, and Pakistan) remaining with endemic polio in 2013 (WHO, 2013a).

President Franklin D. Roosevelt, who became paralyzed from the waist down in 1921, helped while in office in 1938 to found the National Foundation for Infantile Paralysis, now known as the March of Dimes. This philanthropic organization was invaluable in providing care for affected children and families and investing in the research that led to the development, field trials, and later free distribution of the polio vaccines themselves (Smithsonian National Museum of American History, n.d.). Similarly, the first of the Shriners Hospitals for Children opened its doors in the 1920s with the primary goal of caring for children who contracted polio. This laid the groundwork for the role

that the nonprofit sector would begin to play in children's health care.

Vaccine development continues, and has led to the control of other communicable diseases such as measles, rubella, tetanus, diphtheria, *Haemophilus influenzae* Type b, invasive pneumococcal disease, and most recently rotavirus, as well as other infectious diseases in the United States and other parts of the world. At the same time effective medications to treat cancer and other conditions, such as asthma, have been developed, as well as new health care technology, including diagnostic tools like the PET scanner, equipment for intensive care units, microscopic surgery, insulin pumps for diabetes, and bone marrow transplants for cancer.

These and other biomedical innovations led to important changes in the epidemiology of children's disease by substantially reducing the mortality of various health conditions and eliminating many fatal infectious diseases while incidentally creating a dramatic increase in the number of children with chronic diseases (Perrin, Bloom, & Gortmaker, 2007). For example, care for premature newborns is more efficacious in preventing death but has allowed for increased numbers of children with neurodevelopment disability, blindness, cerebral palsy, intellectual disability, chronic lung disease, and nutritional-related growth problems (Wise, 2012). In addition, advances in the treatment of children with cystic fibrosis, sickle cell disease, and cancer, for example, prevent children with these conditions from dying during childhood, but these children then require ongoing medical and psychological challenges during their significantly increased life span.

There is a stark difference between children with and without chronic illness, not only regarding their symptoms and management of their condition, but also the impact the condition has on their family, educational system, health care system, and financial consequences. For example, the number of hospitalizations over the past 50 years has been concentrated among children with chronic disease; 20% of children contribute to 80% of health care expenditures for children. Between 1962 and 2000 hospitalization rates for all children declined 45% but the rate for children with chronic illness almost tripled from 25% to 70%. The percentage of hospital bed days for children with two or more admissions grew from 4% to 25%. Twenty percent of U.S. households with children have one or more children with special health care needs (National Survey of Children with Special Health Care Needs [NS-CSHCN], 2013).

### Groundwork for the Future Transition to the Third Era of Medical Care for Children

The future of children's health care will focus on wellness and will be based on the growing evidence of how early adverse childhood experiences become embedded in biology and which have short term consequences, but also appear to influence health years later (Halfon & Hochstein, 2002). As our understanding of the basic etiologies of adult illness (e.g., hypertension, diabetes, obesity, and cardiovascular disease) has deepened, there has been a growing appreciation of the role of early social and biologic processes in influencing the onset and severity of these adult diseases. Interventions to promote childhood wellness therefore also have the potential to be beneficial years later by changing the trajectory of biologic changes and delaying onset of disease and/or attenuating symptoms. This is especially important since interventions starting in adulthood have not been effective. This understanding of health trajectories from childhood to adulthood is called life course health (Halfon & Hochstein, 2002).

A key factor underlying most mechanisms of risk conveyance is stress in early childhood, especially as it relates to poverty (Conroy, Sandel, & Zuckerman, 2010). Poverty exerts direct and indirect transmission through parents, especially mothers, and through related environmental exposures that become biologically embedded and can lead to health problems after a long latency.

### SELECTIVE IMPACTS OF CHANGING EPIDEMIOLOGY OF CHILDHOOD DISEASE

The epidemiology of childhood disease has evolved. There are innumerable factors and dynamics that have shaped this process (see Table 15.1) and provided the stimulus and opportunity to shift the focus of medical efforts from child survival to child well-being. This shift includes attention to *how* the health care systems affect child development, including negative psychological impact of hospitalization and the emergence of attention to common problems known as the "new morbidity." Finally, despite an upward trend of improvement in health of children as a whole, disparity in the health trajectories due to socioeconomic status, race, and/or unequal access to efficacious medical treatments also garnered attention. This section highlights these three changes.

Weitzman (Eds.), *About Children* (pp. 204–215), Elk Grove Village, IL: American Academy of Pediatrics.

### The Changing Hospital Environment

Advances in medical care and lessening disease mortality shifted attention from preventing death among hospitalized children to buffering the stress of treating their illness in the hospital. Concurrent to understanding normal child development, clinical efforts focused on efforts to understand and address the needs of hospitalized children. The negative impact of hospitalization on children grew out of studies on the negative impact of institutionalization of children.

Starting in the 1950s, mental health professionals provided perspective and strategies in pediatric settings to better prevent emotional difficulties generated by hospitalizations. Changes in the care of hospitalized children were in part catalyzed by the 1952 film *A Two-Year-Old Goes to the Hospital* by James Robertson, a psychiatric social worker and psychoanalyst. This film depicted the impact of separating young children from their parents during hospitalization and drew public attention at a time when visiting by parents was severely restricted in hospitals. Adults, both parents and clinicians, had not fully appreciated the significant impact of separation from parents in the hospital. For older children and adults alike, the most significant concern in hospitalization is fear of bodily harm in the face of medical procedures, especially painful ones. This fear has been labeled *mutilation anxiety*. It was at this time that an application of attachment theory to medical care led to the understanding that children under 4 years of age consider their parents as part of them, and it the loss of a parent, not loss of a limb, that is most stressful.

John Bowlby along with James Robertson subsequently conceptualized the reactions of children to hospitalization as three stages: protest, withdrawal, and detachment (Nagera, 1978). *Protest* involves children's initial response to being left by parents and includes crying and calling out for their parents, which in the past has been a successful signal sent to parents, not strangers, to ask for comfort. During this stage, young children reject attempts by staff to distract or comfort them. After a day or two of protest, children experience *withdrawal*, which refers to indifference and apathy in their interactions with the staff. Children are described as quietly sitting and staring into space with little motor activity, vocalizations, or affect. This stage lasts days to weeks. The last stage is *detachment* and involves what appears to be a recovery when children actively engage with staff and parents, but their interactions are superficial and nonpersonal. Children in this stage do not discriminate between family and strangers. Any unfamiliar person, nurse, or doctor can pick them up and comfort them. The stress of the child's hospitalization on

the parents, and in turn on the responses of parents, can create a negative feedback system in the parent-child dyad resulting in feeding, sleeping, and other problems months after discharge.

These negative emotional and developmental effects of separation associated with hospitalization have been reduced as hospitals evolved away from pediatric wards with multiple beds toward more private double or single patient rooms allowing parents to visit and even stay overnight with their hospitalized child. Child Life programs emerged providing access to trained professionals who work in medical settings to promote effective coping through play, preparation, education, and self-expression activities for children. They help with preparation visits to the hospital, allowing children to take known and comforting objects, like blankets and teddy bears, which allow children to demystify the hospital setting. They also play an important role in educating clinicians, caregivers, administrators, and the general public about the needs of children under stress.

The problem of separation of children from parents has also secondarily resolved with the movement of medical care from an inpatient to an outpatient setting. Fortunately, Child Life programs have also moved to outpatient clinics, emergency departments, and outpatient surgery to help children and parents cope with stress in these settings.

### New Morbidity

Child accidents/injury and chronic illness overtook infectious disease as the leading causes of childhood mortality, and problems rooted in learning, emotional development, behavior, and in socioeconomic and environmental factors contributed to the majority of childhood morbidity. Understanding of disease etiology moved from that of a single "root" cause such as a specific virus or bacteria, to a consideration of multiple factors (Palfrey & Richmond, 2005). Examples of the changing problems encountered by children and addressed in the health care system can be seen in Table 15.2.

These new problems were labeled the "new morbidity" by Haggerty in the late 1970s (Haggerty, Roghmann, & Pless, 1975) and have resulted in significant changes in training of pediatricians to address learning disabilities, attention-deficit/hyperactivity disorder (ADHD), autism, developmental delays, enuresis, encopresis, sleep problems, aggressive behavior, and so forth. New specialties in Adolescent Medicine, Developmental-Behavioral Pediatrics, and Child Abuse Pediatrics obtained official status and requirements by the American Board of Pediatrics. In addition to providing specialty care, these specialists

**TABLE 15.2 Trends in pediatric morbidity****The First Era of Children's Health Care***The 1950s and Before*

- Infectious diseases
  - Epidemics (e.g., influenza, polio)
  - Diseases of overcrowding (e.g., acute respiratory infections, meningitis, typhus, cholera, scabies)
- High infant mortality rates
- Malnutrition
- Few cures for chronic disease

**The Second Era of Children's Health Care***The 1960s to 1980s*

- Specific learning disabilities (e.g., dyslexia, dyscalcula, and dysgraphia)
- Emotional/behavioral disorders (e.g., minimal brain dysfunction, an early understanding of ADHD)
- Family dysfunction
- Functional distress
- Sleep problems
- Toileting and related problems
  - Enuresis
  - Encopresis

*The 1990s to 2000s*

- Disease prevention
  - Sudden Infant Death Syndrome (SIDS)
  - Second-hand smoke exposure
- Injury prevention
- Asthma
- New epidemics (e.g., HIV/AIDS, substance abuse, homelessness)
- Increased survivorship of chronic conditions
- Technology-dependent children
- Lead poisoning
- Social disarray
- Community violence (e.g., intimate partner violence, child abuse, gang violence, sexual assault)

*The 2000s to the Present*

- Injury prevention
- Sports-related injuries including concussion
- Vaccination refusal
- Food allergies
- Overweight and obesity
  - Access and affordability of food
  - Eating behaviors
  - Exercise and activity
  - Childhood diabetes
  - Obstructive sleep apnea
- Autism and other developmental delays
- ADHD and other behavior problems
- Increasing mental health concerns
  - Adolescent depression
  - Childhood anxiety
- Health and social problems related to immigration
- Socioeconomic influences on health
  - Poverty
  - Homelessness
  - Health disparities
- Media use and influences of technology on health
  - Substance use/abuse
  - Media and body image
  - Sexual behaviors
  - Videogames and aggression
  - Internet safety
- School violence
  - Bullying
  - Cyberbullying

E), pp. 1327–1329; “Introduction: Addressing the Millennial Morbidity—The Context of Community Pediatrics,” by J. S. Palfrey, T. F. Tonniges, M. Green, and J. Richmond, 2005, *Pediatrics*, 115(4 Suppl.), pp. 1121–1123.

trained medical students and residents to address problems of new morbidity and generate new knowledge through research. This impact on health care includes increased emphasis on prevention and the identification of clinical problems through the use of screening tools and clinical assessment.

The federal government through fellowship training, research, and numerous expert reports supported this new focus. The Maternal and Child Health Bureau funded the development of the Bright Futures initiative that contains health care promotion and disease prevention guidelines with a developmentally based approach in the context of family and community (Maternal and Child Health Bureau, 2009). In 2000 the Institute of Medicine (IOM) influential report, *From Neurons to Neighborhoods: The Science of Early Childhood Development* (Shonkoff & Phillips, 2000) reviewed, compiled and summarized the emergent scientific knowledge and called for a fundamental reexamination of the best way to meet the needs of young children and families. This and selected work, including the Institute of Medicine (IOM) wellness report (National Research Council & IOM, 2004), is paving the way for the future of child health.

### Disparities in Health Care and Health

During this time of clinical innovation and reducing mortality, population data also showed some children benefited more than others; differences in access to health care due to family economic status emerged contributing to disparities in health. In the first era of health care, unequal access to medical care was less important because of lack of efficacious treatments. Unequal *access* to newer clinical innovations due to these societal divisions has been a special cause of increasing health disparities including infant death, asthma, and obesity.

The term *health care disparity* refers to the difference between groups in health coverage and access to quality care; minority children with chronic illness are less likely to have a usual source of care or receive care within the medical home (Mulvihill et al., 2007; Newacheck, Hung, & Wright, 2002; Raphael, Guadagnolo, Beal, & Giardino, 2009). Health disparity (or what some call “health inequities”) refers to a higher burden of illness, injury, disability, or death experienced by one group relative to another; in 2005 the rate of asthma was 12% in Black children, 19.2% in Hispanic children, and 8% in White children. Black children are 5 times more likely to die than White children (Akinbami, Moorman, Garbe, & Sondik, 2009). Other examples of White children with better health and health care includes differential morbidity in

cerebral palsy, human immunodeficiency virus (HIV) infection, spina bifida, diabetes, ADHD, Down syndrome, leukemia, and selected congenital heart defects (Berry, Bloom, Foley, & Palfrey, 2010). Finally, among Hispanic children, those from Spanish-speaking households compared to English-speaking households had poorer health functioning and health care suggesting language over and above race impairs access and use of medical care (Blumberg, Read, Avila, & Bethell, 2010). Much of racial disparity in health and health care is confounded by economic status, which is now considered the key driver of disparities (Docteur & Berenson, 2009, 2014).

The efficacy of medical interventions involves mediating the relation between risk of disease and access to care. Basic medical research that improves efficacious treatments contributes to disparities unless all people benefit from such advances; therefore, scientific advances need to be coupled with access to quality health care for all people regardless of ethnicity, income, gender, and other prejudice. For example, when new vaccines, such as the human papilloma virus (HPV) vaccine, which protects against common strains known to cause genital warts associated with cervical cancer, are unevenly provided to children due to ethnicity, insurance status, education, or cultural beliefs, disparities in that disease and the population it occurs in are likely to occur. In terms of therapeutic services, effective treatments for diseases such as autism, which requires intensive levels of coordinated behavioral and rehabilitative therapies, can be limited by insurance coverage or school district. Even a nonbiomedical advance like the Back to Sleep campaign to prevent sudden infant death syndrome (SIDS) maintains a disparity in the face of overall population improvement because more educated families are more likely to hear about and adopt this practice compared to less educated and culturally marginalized families. In response to ongoing disparities, special public health efforts have been implemented to reach groups marginalized by language or culture with the Back to Sleep message (Colson, et al., 2009).

### **EMERGING INFORMATION TO INFORM THE THIRD ERA OF HEALTH CARE: LIFE COURSE HEALTH DEVELOPMENT**

A growing body of evidence has called attention to the early childhood antecedents of adult disease. Childhood experiences including stress, the material environment, health behaviors, and nurturing and stimulation becomes embedded in biology, especially in the brain, cardiovascular,

neuroendocrine and immune systems, and shapes health over the life span. Mothers and their health become important mediators or buffers to many of these childhood experiences.

### **Prenatal Environment**

Initial observation of the association of low birth weight and low weight at 1 year of age and subsequent coronary heart disease was made in England among men then in their 60s and 70s who were born in the early part of the 20th century (Barker, Winter, Osmond, Margetts, & Simmonds, 1989; Barker et al., 1993). This finding was replicated and expanded in multiple studies indicating low birth weight, not weight at 1 year, being the strongest and most consistent predictor to cardiovascular disease among adults even after confounding variables such as smoking, employment, alcohol consumption, exercise, and social class were controlled. Though the replication from different samples and different countries of the correlation of low birth weight and poor in utero nutrition to cardiovascular disease and Type 2 diabetes has been remarkable, there remain methodological concerns with these studies, including failure to control for the life persistence of socioeconomic circumstances and the potential modifying role of health and nutrition during childhood.

Studies of the impact of low birth weight or in utero under nutrition on specific developing organs support these epidemiologic findings and suggest potential mechanisms linking low birth weight and coronary artery disease. For example, fetal under nutrition and/or lower birth weight leads to fewer beta cells within the pancreas at birth and higher concentrations of insulin and glucose concentrations (Hales & Barker, 1992; Kaijser et al., 2009). Low birth weight is also associated with increased blood pressure as adults (Gennser, Rymark, & Isberg, 1988). Reduced birth weight or even protein restriction in animal models is associated with reduced number of nephrons in the kidneys (Mañalich, Reyes, Herrera, Melendi, & Fundora, 2000). Individuals with few nephrons compensate with a higher glomerular filtration rate potentially leading to glomerular injury and hypertension. Whether low birth weight in combination with genes or other factors explain the development of all or some essential hypertension remains to be seen.

Low birth weight itself is a consequence of gene–environment interaction that is just becoming better understood. For example, cigarette smoking's impact on low birth weight is well known but the magnitude of impact among women who smoke the same amount varies based

on mother's biology. Newborn birth weight is 1 pound less when women smoke one pack per day but who possess polymorphisms for two genes that express enzymes that metabolize cigarette smoke compared to mothers who smoke the same amount but are homogenous for these same genes (Wang et al., 2002). Toxic chemicals in cigarette smoke are metabolized much quicker reducing the duration of exposure to harmful chemicals that contribute to lower birth weight. However, this genetic vulnerability has no independent effect on birth weight and is only expressed when women smoke in pregnancy.

Gene–environment interactions (epigenetics), many of which occur in utero, also alter the development of molecular structures that determine the risk for specific diseases later in life including mental health problems, obesity, lipid and glucose metabolism, and adult-onset cardiovascular disease problems (Guttmacher & Collins, 2002). Early experiences and exposures can turn genes on or off leading to changes in function, through DNA methylation and histone modification primarily, and contributes to the pathogenesis of common complex disease. Tissue specific methylation patterns are established before and after birth. For example, studies in humans have shown that factors such as maternal age, race, smoking, and gestational age can be identified by methylation patterns among genes in cord blood or placental cells (Adkins, Krushkal, Tylavsky, & Thomas, 2011; Adkins, Thomas, Tylavsky, & Krushkal, 2011; Schroeder et al., 2011) and demonstrate association of fetal and infant experiences and risks for diseases later in life. When the epigenetic mechanisms for these associations are better identified, potential opportunities to interrupt this conveyance of risk across the lifespan may be possible.

### **Poverty: Material Environment and Stress**

Poverty is a significant determinant of health and occurs along a gradient of poorer health, the lower the social class (Marmot et al., 1991). Poverty is defined by more than low income; it involves deprivation, including measures of the material environment, which are more commonly used in Europe than the United States. Different measures have been developed and debated for both poverty level, income and material hardship (USDHHS/ASPE, 2004). Children in poverty suffer disproportionately, for example, from poor nutrition/anemia, lead exposure, unsafe housing conditions, poor air quality, poor schools, asthma, violence, and developmental and behavioral problems in brain and cognitive development (Call, Smith, Morris, Chapman, & Platts-Mills, 1992; Dowswell, Townner, Simpson, & Jarvis,

1996; Gergen et al., 1999; Mani, Mullainathan, Shafir, & Zhao, 2013; Raizada & Kishiyama, 2010; Sandel, Phelan, Wright, Hynes, & Lanphear, 2004). For children the material environment and stress, especially chronic stress (Baum, Garofalo, & Yali, 1999), provide an important analytic framework to understand the different and synergistic pathways from poverty to child health and development and subsequently adult health (Evans & Kim, 2007; Felitti et al., 1998; Geronimus, Hicken, Keene, & Bound, 2006). Children respond differently to poverty and its components depending on the intensity and duration of exposures to many factors—the number of exposures, the type of protective factors (including temperament and supportive relationships), timing, and biologic and genetic differences (Boyce & Ellis, 2005).

### **Material Environment**

The individual's physical environment mediates exposure to toxins, infectious disease, and inadequate nutrition. For example, among low-income families, poor housing conditions may increase exposure to toxins (e.g., lead) and allergens (e.g., mites), leading to lower IQ (Needleman & Gatsonis, 1990) or lost-school days due to increased asthma (Call et al., 1992). The surrounding social environment brings varying degrees of lessened stimulation, both in terms of amount contingent to child's verbal efforts resulting in less exposure to words and reduced verbal acquisition and readiness for school (Hart & Risley, 1995; Walberg & Marjorikbanks, 1976).

Community and social structure influence the quality of and access to health care and education that leads to poor health, poor education, and inadequate social capital. Social marginalization is also a breeding ground for community violence, a risk factor for serious injuries, posttraumatic stress disorder (Glaser, 2000) and other sequelae of mental illness. However, the significance of material aspects of childhood poverty is likely to be underestimated if health outcomes are measured only during childhood because poverty during childhood also appears to be an important predictor of adult health even with improved social class as an adult (Conroy, Sandel, & Zuckerman, 2010).

### **Stress**

Stress or early life adversity shapes the function of the biologic systems (including the brain) that increase vulnerability to health problems directly and indirectly (Farah et al., 2006). Directly it affects the hypothalamic-pituitary-adrenal axis leading to release and ultimate dysregulation of cortisol and multiple downstream negative effects (Gunnar & Quevedo, 2007). A less well known but emerging

role of hypothalamic-pituitary-adrenal axis (HPA axis) functions is its impact on the brain through cytokines released from the immune system. In addition to neutralizing an immune threat, cytokines act directly on the brain (Dantzer, O'Connor, Freund, Johnson, & Kelley, 2008) and may contribute to depression, behavior dysfunction, and post-traumatic stress symptoms (Keller, El-Sheikh, Vaughn, & Granger, 2010; Pervanidou et al., 2007).

Early infancy is exquisitely sensitive to interactions with caregiving adults. Infants and children experiencing chronic stress or social deprivation demonstrate specific patterns of neurotransmitter release, leading to structural alterations in the brain development. These alterations affect memory (Brunson, Grigoriadis, Lorang, & Baram, 2002), educational attainment, and ability to cope with subsequent stressors (McEwen, 2007). An important study of Romanian children who spent 2 years in an orphanage had a lower IQ and attenuated brain activity compared with foster children and those never institutionalized (Nelson, Fox, & Zeanah, 2013; Rutter, 2002; Rutter, Kreppner, O'Connor, and the ERA Study Team, 2001). Multiple social and family risk factors combine to increase the risk for poor child outcomes (Evans & Kim, 2007; Parker, Greer, & Zuckerman, 1988; Sameroff, Seifer, Baldwin, & Baldwin, 1993).

The impact of multiple stressors on allostatic load results in a process of reestablishing equilibrium after a stressor. (McEwen, 2007) Each time the body goes through allostasis it pays a small price to reestablish equilibrium leading to cumulative impact on the child. For example, low-SES children recover as well from early single health insults as higher-SES children; however since they suffer more health insults their health is poorer in adolescence and adulthood (Keating & Hertzman, 1999). Stressful events appear to form "a pathway or chain of risk" leading to poor health (Ben-Shlomo & Kuh, 2002; Power & Hertzman, 1997).

Specific physiological alterations caused by stress can be highlighted by examining how a selective factor from the social environment becomes biologically subsumed. Rat pups not groomed frequently by their mothers in infancy elicit epigenetic programming; methylation of the gene encoding for expression of the glucocorticoid receptor, which ultimately participates in feedback inhibition of the stress response (Meaney, 2001; Weaver et al., 2004). Those groomed show less methylation, express more glucocorticoid receptor, and then have greater feedback inhibition of the stress response and subsequent lower hypothalamic-pituitary-adrenal axis responses to stresses in adulthood (Hyman et al., 2009). Notably, methylation of

genes is found to be a stable response and is not altered in adulthood (Weaver et al., 2004).

The same epigenetic control of the stress response is also described in humans: Those abused in early childhood have been shown to have methylation at a key promoter site encoding the gene for the glucocorticoid receptor (McGowan et al., 2009). Fewer glucocorticoid receptors in the hippocampus reduce feedback inhibition as adults, leading to greater hypothalamic-pituitary-adrenal responses to stresses than their nonabused peers, resulting in increased cortisol. However, while being abused as a child enhances risk to become an abuser, not all or most abused children become perpetrators. This is likely due to genetic vulnerability of some children. Homozygosity for genes encoding certain enzymes that metabolize common neurotransmitters reduces the likelihood of abused children developing a conduct disorder that involves victimizing others later in life. On the other hand, children who are abused and polymorphic for this gene are more likely to victimize others (Caspi et al., 2002) compared to abused children who are homozygous for these genes. Whether prevention of these and other complex diseases related to gene-environment interaction is best served by identifying biologically vulnerable individuals or universal strategies are unknown and an important challenge for the future.

Stress-related conditions arising from severe childhood physical and sexual abuse (Bremner et al., 1995) also show actual structural changes in the brain by magnetic resonance imaging; atrophy of the hippocampus. This is consistent with the above mechanism and data that shows prolonged stress induced cortisol release leads to damage to neurons in the hippocampus (Gunnar & Vazquez, 2006; Weaver et al., 2004) which can lead to learning and memory problems (Brunson et al., 2002; Gunnar & Quevedo, 2007). Even exposure to family violence leads to structural changes in the brain that can be seen by fMRI as heightened neural responsiveness in the face of "perceived threat" (McCrory et al., 2011).

Exposure to stress associated with low socioeconomic status (SES) among children also has consequences, outside of the central nervous system, mediated by cardiovascular and immunologic systems consistent with allostatic load (McEwen, 2007). For example, low-SES children have increased inflammatory markers, particularly C-reactive protein, fibrinogen, and white blood cells (Danese et al., 2008; Pollitt et al., 2007; Taylor, Lehman, Kiefe, & Seeman, 2006) that may be part of the causal pathway between low childhood SES and adult cardiovascular disease (Pollitt et al., 2007; Taylor et al., 2006).

## Health Behaviors

There is strong evidence that health-related behaviors have their roots in childhood and are associated with social class and many may, in fact, be difficult to change once adulthood has been reached (Conroy et al., 2010). Attitudes and habits regarding eating and exercise patterns, self-care, and the health care system play an important role in determining the emergence and impact of adult-onset disease. Behaviors beginning in childhood including overeating, physical inactivity, and cigarette smoking lead to health problems among adults, resulting in approximately 50% of all adult mortality in the United States (McGinnis & Foege, 1993). Diet and physical activity in childhood contribute to childhood obesity, which is strongly associated with obesity in adulthood (Deckelbaum & Williams, 2001). Eating behaviors early in life are strongly influenced by parental behavior; the choice a parent makes regarding a child's diet starting with whether or not to breastfeed, strongly shapes a child's experience with food and tendency toward obesity. While not definitive, data continue to accumulate that children who are breastfed are less likely to be obese (CDC, 2007).

Children who experience adverse experiences in the early social environment also display other high-risk health behaviors, such as cigarette smoking, alcohol abuse, and multiple sexual partners (Anda et al., 1999; Anda et al., 2002) leading to alcoholism, sexually transmitted disease, unintended pregnancy, and suicide (Dietz et al., 1999; Dube, Anda, Felitti, Edwards, & Croft, 2001; Hillis, Anda, Felitti, Nordenberg, & Marchbanks, 2000). This relationship was found to be graded: Those who had experienced more adverse experiences or household dysfunction displayed more high-risk behaviors as adults.

## Maternal Health

The impact of women's health on the health of their children is not limited to birth outcomes; maternal health conditions and behaviors, especially maternal mental health, cigarette smoking and drug abuse, violence, and traumatic stress, continue to mediate the link between social environment and child outcomes well after delivery. The vulnerability of child behavioral and developmental outcomes to maternal depression is well recognized. Maternal depression shows a strong social gradient, correlating with educational attainment, housing, marital relationship, work role, and stressful life events (Weissman & Olfson, 1995; Zuckerman & Beardslee, 1987). Depressive

symptoms in a mother appear to lead to diminished maternal-infant attachment, less spontaneous interaction with the child (Zuckerman & Beardslee, 1987), and increases in children's cortisol responses to adverse family environment (Ashman, Dawson, Panagiotides, Yamada, & Wilkins, 2002), cognitive outcomes (Cooper & Murray, 1998), and reading skills (Richman, Stevenson, & Graham, 1982). These children also exhibit significantly reduced activity in a region of the brain specialized for expression of positive emotions (Dawson, Frey, Panagiotides, Osterling, & Hessel, 1997). Effective treatment of a mother's depression has been shown to have a beneficial effect on their children (Weissman & Olfson, 2005) suggesting a causal link and opportunity "twofer" by treating the mother.

Child abuse and neglect is a focus of considerable public attention, but only recently recognized is the significant impact of children witnessing violence, especially when the victim is their mother as it is in most cases of intimate partner violence (IPV) (Zuckerman, Augustyn, Groves, & Parker, 1995; Bair-Merritt, Zuckerman, Augustyn, & Cronholm, 2013). Over 15 million children who live in the United States live in families with IPV. Approximately 7 million of these children witness the assault. Childhood exposure to IPV is another example of biologic embedding of stress (McDonald, Jouriles, Ramisetty-Miller, Caetano, & Green, 2006). A child responds with a "flight or fight" reaction to witnessing violence. Although adaptive in the short term, repeated activation of the autonomic nervous system and HPA axis results in pathologic changes in multiple biologic systems. Such activation of the HPA axis stimulates cortisol release leading to an excess of T helper 2 cells leading to airway inflammation and hyperactivity, which along with down regulating cortisol receptors, increases the risk of incidence and severity of asthma (Miller & Chen, 2006). In addition, increased cortisol induced hippocampal neuron loss and damage leading to learning and memory problems (Bremner et al., 1995). Social-emotional health is similarly adversely affected by childhood IPV exposure; 63% of child witnesses to IPV showed worse emotional health compared to the average child (Keeshin, Cronholm, & Strawn, 2012). The co-occurrence of a mother's depression and exposure to violence has an adverse impact on children's learning and behavior in school that is not additive but rather synergistic (Silverstein, Augustyn, Young, & Zuckerman, 2009). The co-occurrence of these two problems may explain lack of effectiveness of some maternal depression intervention studies if exposure to violence is not identified and addressed.

## HEALTHY CHILDREN: NEWBORN NURSERY AND PRIMARY CARE

Medical care is provided to healthy children in the Newborn Nursery and Primary Care offices. In these settings, care is focused on prevention and early identification of problems.

### Newborn Nursery

The vast majority of newborns have uncomplicated deliveries and routine medical care in the nursery focused on respiration and maintaining body temperature immediately after delivery. The use of the Brazelton Neonatal Behavioral Assessment to train doctors and nurses has resulted in more individualized care of healthy newborns and guidance to parents (Brazelton, 1973). Routine screening for potential problems includes conducting a physical and behavioral exam, assessment of intrauterine growth and gestational age, universal newborn blood screening (to identify metabolic problems), and universal hearing screening. Common but important routine medical care involves erythromycin ophthalmic ointment to baby's eyes to prevent gonococcal disease, injection of vitamin K to prevent bleeding, and special care of the umbilical cord to prevent infection. Approximately 10% of infants require some assistance at birth such as mild tactile stimulation to initiate breathing. Approximately 1% require extensive assistance to ensure that they are breathing and obtaining adequate oxygen, sometimes needing suctioning of mucous from the mouth and trachea or possibly endotracheal intubation (passage of a breathing tube down the windpipe to aerate the lungs).

Once newborns are stable after birth, placing them with their mother through skin to skin care is the health care team's next priority (Kennell & Greenough, 2003). Having babies share their mothers' rooms facilitates the mother beginning to read the cues and the signals her baby uses to communicate, allowing her to get to know her child through breastfeeding, consoling, and bringing the infant to alertness. Promoting breastfeeding prior to and following delivery is important since breastfeeding promotes children's health, especially preventing gastroenteritis, ear infections (Ip et al., 2007) and improving receptive language at Age 3 and higher verbal and nonverbal IQ at Age 7; the longer and more exclusive breastfeeding, the higher the scores (Belfort et al., 2013). Given the importance of breastfeeding to child health, WHO and UNICEF launched the Baby Friendly Hospital Initiative, which is a designation a hospital can receive by demonstrating compliance

with 10 steps associated with successful breastfeeding. As of 2010 there were approximately 20,000 Baby Friendly sites world wide with 84 in the United States.

### *In Utero Drug-Exposed Infants: An Example of Problems Encountered in the Nursery*

Drug-exposed babies and drug-using parents are a special problem in newborn care; in 2005 more than 10% of American births included prenatal exposure to alcohol or illicit drugs (SAMHSA Office of Applied Studies, 2003). Categorization of drugs by legal status is not related to their impact on newborns. The effects of marijuana on pregnancy remain debated. Cigarettes and tobacco have a significant impact on fetal growth, later learning, and behavior. In addition to the well-known adverse effects of excessive alcohol use during pregnancy, alcohol also has an important impact on parenting. Illicit drugs, including narcotics (heroin, methadone, codeine, etc.), barbiturates, tranquilizers, and stimulants (cocaine, methamphetamine), are associated with poor prenatal growth and withdrawal when drugs concentrations are high enough. Prescribed drugs like antidepressants for mental health problems also have adverse effects on newborns. Many mothers may use more than one substance during pregnancy, exposing newborns to cumulative and/or potential interactive effects of these substances.

Infants exposed to these drugs in utero, specifically opiates such as heroin or methadone, develop a tolerance to the drug. Following birth, as the concentration of the drug begins to wane these infants develop signs of withdrawal, called neonatal abstinence syndrome (NAS), which include excessive crying, jitteriness, diarrhea, and poor state regulation.

The Finnegan scoring system is used to monitor and guide treatment for NAS (Finnegan, 1986). Scoring takes place at 2-hour intervals evaluating 21 different symptoms grouped into three categories: neurologic, respiratory, and gastrointestinal (Minear & Zuckerman, 2013). Three consecutive scores greater than or equal to 8, or two consecutive scores greater than or equal to 12, indicate severe withdrawal requiring need to initiate pharmacological treatment with either morphine, deodorized tincture of opium, Phenobarbital, and/or more recently clonidine. To date, there are insufficient randomized trials evaluating the benefits of one pharmacological approach over another, and no treatment has been found to be optimal for all of these substance exposures (Minear & Zuckerman, 2013). Hospitalization for NAS ranges from 1 to 4 weeks, weaning newborns from narcotic exposure before they can be

sent home. Parenting is a special challenge; more than 50% of women with substance abuse histories have comorbid psychiatric illnesses (depression, anxiety, bipolar disorder) and most women with addiction have a past history of physical or sexual abuse (National Institute of Drug Abuse, 1994).

### Primary Care and Prevention

Health care for children consists of primary preventive care to promote health, prevent disease, and reduce unhealthy behaviors; intermittent care to diagnose and treat acute problems; and ongoing care to manage chronic illness, many times in collaboration with a specialist. (See Table 15.3.)

Most children are healthy and are expected to receive well child care, or preventive health care, as part of primary care. As of 2011, the CDC reports that 82.2% of school-aged children (5–11 years of age) are in excellent or very good health (CDC, 2011a).

The establishment of an effective clinician-parent/child relationship is the cornerstone to providing effective medical care and is formed when the physician provides continuity of care; the same physician sees the patient at all well-child visits and when available at sick visits. Alternatively, when different physicians see families at different visits, problems can easily fall between the gaps due to either the expectation that someone else will or is taking care of the problem, or limitations in communication (Alpert, Zuckerman, & Zuckerman, 2004).

### Preventive Care

The cornerstone of preventive care in pediatrics is the ever growing number of immunizations that prevent significant infectious diseases. Prevention also involves providing education and advice listed in Bright Futures to promote health and prevent disease. These topics include but are not limited to breastfeeding, sleep positions for infants, discipline, injury prevention, nutrition and sexual health, and alcohol and tobacco use for adolescents. Although

important, studies have not been conducted to determine the effectiveness of most advice in the office setting on actually improving health let alone changing health behaviors.

Other evidence based prevention practices includes promoting literacy through giving books to low-income children and advice to parents to read aloud (Zuckerman, 2009) and selected injury prevention topics. Reach Out and Read (ROR) is a pediatric, evidence-based strategy to prevent problems of early childhood development and learning. ROR also has become a model for a different way of thinking about parent education during primary care encounters, based less on telling and more on creating real-time learning experiences, including modeling developmentally appropriate “reading” strategies (e.g., pointing, naming, and asking questions), and then giving parents a book to take home to implement the recommendation (Zuckerman, 2009). Studies evaluating ROR reported that parents who participated in ROR, compared with parents who did not, were more likely to report (a) reading aloud as a favorite activity, (b) increased centered literacy orientation, (c) frequent reading aloud, and, most importantly, (d) increased language development (Golova, Alario, Vivier, Rodriguez, & High, 1999; High, LaGasse, Becker, Ahlgren, & Gardner, 2000; Needlman, Toker, Dreyer, & Mendelsohn, 2005). In one study, with controlling for confounding variables, children in the ROR group scored 8.6 points higher in receptive language and 4.3 points higher in expressive language, compared with non-ROR groups (Mendelsohn et al., 2001). The homes of children who participated in ROR demonstrated higher scores for directly observed child home literacy and Home Observation for Measurement of the Environment assessments (Weitzman, Roy, Walls, & Tomlin, 2004).

Children with chronic illness present special challenges to the primary health care system as they require tracking and coordinating data from multiple specialists. Surveys show that the medical home model of primary care reaches only about 50% of children with special health care needs leaving many children with chronic diseases, such as asthma, cystic fibrosis, or sickle cell disease, receiving

deficiencies in the quality and coordination of their care (Berry et al., 2010).

### **Screening**

Another key element of preventive care is screening for early identification of physical, developmental, and social issues that affect children's health and well-being. Universal screening is a strategy used to detect a disease in children without signs or symptoms of the disease in question. Selected screening is used for children who have risk factors for a disease and is based on clinical utility. The first consideration is a high cost of not detecting the disease if the disease is untreated; suffering by the child and financial cost on the public health scale. A second equally important consideration is that early treatment is more effective than later treatment. Finally, screening necessitates that diagnostic criteria are identified, treatment is available, and an appropriate screening instrument is available. Screening tests should be easy to perform and interpret, be a direct measure related to the disease in question, and have low risk, low cost, high sensitivity, and high specificity (Fletcher & Fletcher, 2005; Minkovitz & Wissow, 2006).

Laboratory screening tools including metabolic screening of all newborns is now mandated by state laws to detect possible conditions that are treatable, but not clinically evident in the newborn period. Specific disorders screened for vary from state to state but commonly include phenylketonuria (PKU, a metabolic condition that can cause irreversible mental retardation unless detected early), congenital hypothyroidism (CH), congenital adrenal hyperplasia (CAH), sickle cell disease, and cystic fibrosis (CF) and many disorders that are rare. The gravity of late detection and efficacy of early intervention has led to near universal newborn hearing screening to identify and treat infants with hearing loss (Helfand et al., 2001). In primary care, medical screening includes vision screening in children from birth to Age 5, anemia (CDC, 1998), lead (Risshitelli, Nygren, Bougatsos, Freeman, & Helfand, 2006), tuberculosis (Ozuah, Ozuah, Stein, Burton, & Mulvihill, 2001), and sexually transmitted infections. Recent recommendations to conduct universal lipid screening to identify children at risk for future cardiovascular problems, EKG screening to prevent sudden cardiac death among athletes, and newborn pulse oximetry screening to detect critical congenital heart disease in infants raises important questions when the targeted disease is rare, has a prolonged latency, or lack of data to document the effectiveness of screening to reduce morbidity and mortality. Positive

screening can also cause harm including anxiety and invasive evaluations or treatment of pseudodisease (Kaltman, Burns, & Pearson, 2013).

Pediatrics has expanded its reach beyond traditional medicine, which typically focuses on the individual patient to identify psychosocial risk factors for improving health (American Academy of Pediatrics, 2001). Studies of screening efficacy primarily focus on a single psychosocial problem including maternal depression (Olson, Dietrich, Prazar, & Hurley, 2006), parental smoking (Winickoff, Buckley, Palfrey, Perrin, & Rigotti, 2003) or intimate partner violence (IPV) (Siegel, Hill, Henderson, Ernst, & Boat, 1999). One study screened multiple problems including alcohol and drug use, homelessness risk, food insecurity, employment status, and child care needs in addition to the above three risks (Garg et al., 2007).

Developmental surveillance and developmental screening attempt to identify the 17% of children (birth to 18 years) with a developmental delay (CDC, 2011a) to institute diagnostic evaluation and timely intervention. Formal developmental screening is recommended for all children at the 9-, 18-, and 24- and/or 30-month well-child visits and developmental surveillance at every office visit through the age of 5 years (Council on Children With Disabilities, 2006).

Developmental surveillance is a general process involving five key activities that should be performed at every well-child visit: (1) eliciting and addressing the concerns of parents; (2) monitoring developmental milestones; (3) observing the child and family in clinic; (4) maintaining record of the child and families' medical history; and (5) monitoring and identifying both protective and psychosocial risk factors (Council on Children With Disabilities, 2006; Glascoe, 2006; Glascoe & Dworkin, 1995). Developmental screening on the other hand refers to the use of specific, brief, and validated measures that can sort children with a high likelihood of having developmental problems from those who probably do not (Glascoe, 2006).

Three developmental screening tools are commonly used in primary care: (1) the Parents' Evaluation of Developmental Status (PEDS); (2) the Ages and Stages Questionnaire (ASQ); and (3) the Modified Checklist for Autism in Toddlers (M-CHAT). The PEDS is a brief 10-item open response instrument asking parents about developmental concerns for children age birth to 9 years. It has a sensitivity of 74%–79% and specificity of 70%–80% across age levels (Schonwald, Huntington, Chan, Risko, & Bridgemohan, 2009), it is also available in multiple languages. The ASQ is a system of 19 different age-specific

questions inquiring about child specific skills for children 4 months to 5 years. Although it has a sensitivity of 72% and specificity of 86% (Schonwald et al., 2009) and is written at a fifth-grade level, it can take as long as 20 minutes to complete. Although these two screens rank among the best available, discordance between the results of the PEDS and ASQ developmental screens has been noted (Sices, Stancin, Kirchner, Bauchner, 2009). These findings suggest that reliance on a single generalized, validated screening tool may not be sufficient to detect delay.

In general, autism is difficult to detect in very young children. Although average age at which parents first report concerns associated with possible autism spectrum disorder (ASD) is generally reported to be around 17–18 months (Kleinman, Robins, & Fein, 2008) the average age of diagnosis is around 4 years (CDC, 2012). Children of low socioeconomic status are at additional risk of delay in detection of autism (Gray, Tonge, & Brereton, 2006). Autism specific screening is recommended at both the 18- and 24-month pediatric visits (Johnson & Myers, 2007).

The M-CHAT is a 23-item, parent-report autism screening questionnaire that takes about five minutes to complete and also includes a follow-up parent interview. The M-CHAT has a high false positive rate, which is significantly reduced by using the follow-up interview (Chlebowski, Robins, Barton, & Fein, 2013). M-CHAT has low specificity in children born before 28 weeks' gestation who have associated motor, cognitive, visual, and hearing impairments; therefore results should be interpreted with caution for these children (Kuban et al., 2009; Moore, Johnson, Hennessey, & Marlow, 2012).

Children who fail a developmental screening test (either general or specific) should be promptly referred for additional assessment and evaluation. The assessment process should enhance parents understanding of their child, the fit between parents while providing care, and child's behavior and modeling of constructive ways to interact with the child (Parker & Zuckerman, 1990). Additional medical evaluation to determine the primary etiology of the disability may be warranted. For all children with developmental delays, evaluation for iron deficiency anemia and lead poisoning, in addition to hearing and vision screening, should be performed if not yet routinely done (Council on Children With Disabilities, 2006). Genetic, metabolic testing, and/or neuroimaging should also be considered in children with significant problems or those with selective history and physical findings. While most American pediatricians (82%) routinely look to identify general developmental delays (dosReis, Weiner, Johnson, & Newschaffer, 2006),

a national survey of pediatricians and family physicians found 53% reported not using a validated instrument to screen children for developmental delays (dosReis et al., 2006; Sices, Feudtner, McLaughlin, Drotar, & Williams, 2003). Only 8% report screening for autism (dosReis et al., 2006). Efforts to improve these rates are ongoing.

## ADDITIONAL HEALTH CARE ENVIRONMENTS

The majority of healthy children receive health care only through primary care; however acute problems may require the Neonatal Intensive Care Unit following birth and emergency care for significant acute illness or injury.

### The Neonatal Intensive Care Unit (NICU)

The NICU is an evolving health care environment filled with an array of medical devices and lifesaving equipment for children who prior to their development often did not survive the first few hours of life. In this section the unique history of the development of the NICU is discussed followed by the population of infants served and the challenges they face.

#### *History of the NICU*

The care of the premature or sick newborn is linked to the first infant incubator put into use in 1880 at the Paris Maternity Hospital (Baker, 2000). Modeled after incubators for chickens, it was then exhibited in 1896 at the World Exposition in Berlin, which had six incubators and six infants and was called the Kinderburtanstalt, the "child hatchery." The incubators and wet nurses who supplied milk for the neonates constituted the first special care setting for sick newborns. The first early incarnation of a neonatal care in the United States was at the Weiss Hospital in Chicago in 1914.

Sick term and premature newborns and other young infants were previously cared for on the pediatric floors in open wards, whereas well premature infants were given care in premature infant nurseries. The division of sick and well premature infants was related to fear of the spread of infectious disease, especially *Staphylococcus aureus*. This fear persisted despite studies demonstrating that hand washing between handling babies prevented the spread of infections. It was not until 1960 that the first NICU opened at Yale New Haven Hospital and cared for full term and premature born babies with problems, including babies that were infected. Technology was adapted from adult medical care including ventilators to help infants breathe

and EKG machines to monitor the heart. A large open ward layout was used to optimize monitoring of infant vital signs (Gluck, 1992).

From the 1970s onward, clinical and animal research provided important understanding of the underlying physiologic changes associated with birth: asphyxia, respiratory distress, necrotizing enterocolitis, infection, and other disorders. Clinical innovations, such as positive pressure ventilators for respiratory problems, phototherapy for high levels of bilirubin (seen as jaundice), intravenous fluid, electrolytes, and nutrition for nonfeeding infants, were developed and improved over time.

From 1975 to mid-2000 infant mortality decreased from 16 to 7 per 1000 births but the disparity between European American and African American infants remained the same (Wise, 2003). The decline in infant mortality since 1970 is primarily attributable to neonatal intensive care, not the prevention of low birth weight. The *limit of viability*, the gestational age at which an infant has a 50% chance of survival, has been significantly reduced and is currently thought to be around 24 weeks of gestation. The majority of deaths of infants younger than 1 year occur during the first 28 days of life; most of these during the first 7 days. Most survivors younger than 32 weeks gestation, especially extremely-low-gestational-age infants and extremely-low-birth-weight infants, experience an increased risk of serious medical and developmental problems.

### ***Infants Requiring NICU Care and Related Challenges***

Approximately 1.5% of all newborns born in the United States each year have very low birth weight (less than 1,500 grams), and chronic lung disease or bronchopulmonary dysplasia (BPD) develops in about 20% (Baraldi & Filippone, 2007). The development of artificially produced pulmonary surfactant, a biochemical lubricant that facilitates the opening and closing of the lungs, almost single handedly reduced the limit of viability to before 28–32 weeks of gestation.

The brain is the organ system that has proved to be the most vulnerable to premature birth, which leads to later neurodevelopmental problems (Arpino et al., 2010; Vaucher et al., 2012). The risk of neurodevelopmental impairment increases as gestational age decreases. Infectious, gastrointestinal, and respiratory conditions lead to diminished delivery of oxygen and nutrients to the brain and cause hypoxic-ischemic events (HIE); occurring in approximately 2.5 per thousand births (Bonifacio et al., 2011). HIE lead to a sequence of biochemical events

triggering inflammation and nerve cell death resulting in neurologic impairment, seizures, and death. Although early use of surfactant and continuous positive airway pressure (CPAP) decreased mortality and rates/severity of BPD, they have not been shown to reduce further reductions in mortality or neurodevelopmental disability (Vaucher et al., 2012).

A longitudinal study of surviving school age children who had been born at 25 or fewer weeks gestation in 1995 followed until early school age found cognitive impairment in 21% of the children born extremely preterm (compared to 1% in standardized data). When compared to the scores of their classmates, this value rose to 41%. Cerebral palsy was present in 12% of the children (Marlow, Wolke, Bracewell, & Samara, 2005). Even appearing well functioning, children within the normal range of cognitive functioning experience learning difficulties and are less likely to complete higher education than their term peers (Griffiths et al., 2013; Moster, Lie, & Markstead, 2008). Newer more sensitive technology documents previous unknown selective deficits among extremely preterm (EPT) infants. For example, blood oxygen level dependent activation during functional magnetic resonance imaging show reduced working memory and selective attention among 11-year-old EPT children compared with term-born controls (Griffiths et al., 2013). Very preterm children are also at increased risk of problems in social and academic functioning (Schothorst & van Engeland, 1996). Long-term follow-up studies show former preterm infants who did not have medical disabilities as adults have lower educational attainment, lower income, are more likely to receive Social Security benefits, and were less likely to establish a family (Moster et al., 2008).

An important new innovation for term infants with perinatal asphyxiation (deprivation of oxygen at birth) is use of hypothermia (cooling of the brain by 2–4°C) to prevent the progression of neuron cell death and inflammation. Randomized control studies show that cooling of the head as well as the whole body can reduce death and disability as well as decrease lesions seen on MRI in infants with moderate to severe HIE (Edwards, Brocklehurst, & Gunn, 2010).

During the same era of clinical advances, regional perinatal care centers came into being as a mechanism to combine expensive high-tech resources and medical expertise in one place to meet the needs of sick newborns for an entire geographic region. To further concentrate expertise, obstetric care was linked to these specialized centers to combine the care of high-risk mothers and high-risk infants. By the late 1970s, guidelines for the new perinatal centers and the care of individual premature infants were developed and

implemented. The combined impact of clinical innovation and development of these centers had a significant impact on reducing newborn mortality.

Advances in the developmental care of premature newborns in the NICU have paralleled advances in medical care. The developmental aspects of premature babies were initially studied and filmed by Arnold Gesell in the premature incubators in the New York World's Fair in the 1930s. These and other studies led to the contemporary work of Barnard, who first looked at the early extra uterine environment of the premature infant, and Als, who further identified environmental stressors to premature infants and developed interventions to protect them from significant and important negative external stimuli (Als et al., 2011).

The Newborn Individualized Developmental Care and Assessment Program (NIDCAP; <http://www.nidcap.org/>), developed in 2001, encourages individualized care of premature infants to support their physiologic stability and behavior. Direct observation of the infants is an important component of this program. Using a self-named detailed observational tool, the NIDCAP observation, an infant's behaviors can be interpreted as steady and relaxed or as representing stress or discomfort. Once observed, behaviors are interpreted and developmental care plans are developed to support the infant and foster self regulation. These plans involve the structuring individualized care of the infant and family with appropriate physical environments and timing/organization of medical and nursing interventions. Multiple professionals work together to coordinate a developmental framework to support and nurture the parents-infant bond while bolstering parent confidence in caring for their infant's development. NIDCAP is an example of interprofessional collaboration, including providers such as respiratory therapists, occupational and physical therapists, social workers, nutritionists, early intervention professionals, public health nurses, and others (Als, 2013).

### Acute Illness and Urgent/Emergency Care

All children experience episodes of illness that may require a visit to their physician's office, the emergency room, or occasional hospitalization. One of the important developmental tasks for parents is to help their child cope with an acute transient illness. A special role for clinicians is to aid and teach parents to help their child cope. This is particularly true for parents facing a first illness in their child or a more serious illness at any age that requires emergency or hospital care.

Children under 2 years of age, especially those going to childcare settings, experience up to 12 episodes of upper respiratory infections (the common cold) a year. Children over 2 years experience 2.4 episodes of illness (defined here as activity restriction or medical visit) a year. Approximately 1 in 8 children in a given year has at least one emergency room visit with about 1 in 30 children hospitalized at least once in his or her lifetime. For children described by their parents as being only fair or poor in health over the course of 1 year, 80% have at least one office visit, 5% have at least one emergency room visit, and 15% are hospitalized at least once (Owens et al., 2008). About 70% of children in elementary school miss some school each year because of illness, but 15% miss more than 1 week (Bloom, Cohen, & Freeman, 2010).

As the need to respond in a timely fashion to childhood emergencies gained importance, a system with designated roles and handoffs called the Emergency Medical System (EMS) was developed. *Prehospital care* refers to emergency assistance before a child reaches a medical facility. A 911 call triggers a response by EMS providers whose training ranges from emergency medical technicians (EMTs) who have 120–150 hours of training, or paramedics who have 1,200–1,800 hours of training with a 2-year degree. The skill set of EMTs and paramedics includes basic life support, intubation, placing IVs, and cardioversion. Although only about 10% of EMS cases involve children, special federal Maternal and Child Health funding has promoted and improved EMS care for children. Other potential first responders, such as police, firefighters, or volunteers, usually have about 40 hours of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained individuals.

EMS response times vary from a few minutes to more than an hour depending on the location of the incident and the availability of EMS. A pediatric trauma score is used to assess the severity of injury and determines if the child should be treated in an emergency department (ED) that is designated as a pediatric trauma center. Guidelines of care of children in the ED include supporting parents to be with their child during invasive procedures and even at bedside resuscitation as desired.

### *Injury and Traumatic Stress: An Example of a New Morbidity Related to Health Care*

Injuries are the single largest cause of morbidity and mortality among children in the United States (CDC, 2011b), which has led to a shift to recognize the common

psychological effects of injury in addition to the physical (De Vries et al., 1999; Stoddard & Saxe, 2001). Almost 25% of children who were injured in traffic accidents and 15% of their parents had a diagnosis of posttraumatic stress disorder (PTSD). This disorder is associated with older age at the time of traumatic exposure and the presence of parent PTSD. A third of road traffic accident child victims had PTSD compared with 3% of children with sports injuries (Stallard, Velleman, & Baldwin, 1998). Female gender, previous experience of trauma, and subjective appraisal to life threat are associated with presence of PTSD. Almost 90% of children who were admitted to the hospital after a traffic injury and 83% of their parents had at least one symptom of acute stress disorder. Almost 30% of hospitalized injured children had clinically significant symptoms of a stress disorder (Daviss et al., 2000), and 12.5% of these children had PTSD 1 month after injury. Burn injury, which involves painful dressing changes and permanent changes in his or her body's appearance, likely explain the high rate of over 50% of burn-injured children with posttraumatic symptoms (Stoddard, Norman, & Murphy, 1989). Psychological interventions and therapy are complex but beneficial to children exposed to nonrelational traumatic events (Forman-Hoffman et al., 2013).

## CHILDREN WITH CHRONIC ILLNESS

Many children with conditions that once were universally fatal now survive into adolescence, early adulthood, and beyond. *Children with special health care needs* (CSHCN) is defined as children "who have or are at increased risk for a chronic physical, developmental, behavioral, or emotional condition that will also require health and related services of the type or amount beyond that required by children generally" (McPherson et al., 1998). They include children with ADHD, asthma, autism, cancer, cerebral palsy, cystic fibrosis, sickle cell anemia, depression, and diabetes, for example. Approximately 15% of all children have a chronic condition with about a third of these conditions considered to be moderate or severe. Most chronic problems are life-long, but others like food allergy or asthma can remit; only about 25% of children with asthma had wheezing that persisted from childhood to age 26 (McPherson et al., 1998). CSHCN need ongoing care in addition to standard well-child care including frequent monitoring of signs and symptoms of their disease, specific interventions to prevent or manage complications of their illness, and often acute care in an emergency department

or hospital for severe episodes of the illness leading to 3 times the average number of physician contacts (Wise, 2012). In this section we will review issues related to the care for children with chronic conditions.

## Health Care Framework for Children With Chronic Conditions

The traditional approach to children with chronic conditions or CSHCN has been categorical; classification is based by the affected organ system or diagnosis and is best understood through the use of the term *chronic disease*. This approach uses etiology, pathophysiology, signs, symptoms, and treatment as guiding principles. Chronic disease is: long in duration; has a protracted clinical course; can be of multifactorial etiology; may or may not have a definite cure; has gradual changes over time; has a common pattern of evolution (Bentzen, 2003). Chronic disease can be congenital or acquired and either communicable (i.e., HIV/AIDS) or noncommunicable (most all diseases previously mentioned). Dimensions that differentiate chronic disease are listed in Table 15.4. Related terminology includes the World Health Organization (WHO) definition of *impairment* as an abnormality in physical structure or function of the body, while a *disability* is an impairment that restricts activity. A *handicap* is a disability that causes an individual to be limited by society.

Alternatively, even though specific challenges vary by disease, a noncategorical approach of a chronic illness emphasizes the common challenges faced by children with chronic illness, including stress and coping with disease, identity formation in terms of illness, financial stressors, adherence, self-care, and self-esteem. (Pinquart & Shen, 2011b).

## Attention-Deficit/Hyperactivity Disorder: An Example of Identification and Management in Primary Care

Learning and behavioral problems are the most common chronic problems of children. Attention-deficit/hyperactivity disorder (ADHD) is a chronic condition and the most common neurobehavioral disorder of childhood affecting 7%–10% of school-age children in the United States (Froehlich et al., 2007; Merikangas, He, Brody, et al., 2010). It is characterized by significant difficulties with inattention or hyperactivity and impulsiveness, or more commonly, a combination of the two. Symptoms, which may include an inability to sit still, restlessness, interrupting others, making careless errors, difficulty sustaining attention, failing to finish tasks, difficulty organizing,

**TABLE 15.4** Dimensions for describing a child with a chronic health condition

Duration of condition	Brief -----Lengthy
Age of onset	At birth-----Acquired
Limitation of age-appropriate activities	None-----Unable to Perform
Visibility of condition	Not Visible-----Highly Visible
Level of support needed	Minimal-----Substantial
Life expectancy	Typical-----Shortened
Course of illness	Stable-----Variable-----Progressive
Developmental Skills:	
Motor skills	Not Impaired-----Extremely Impaired
Language and communication	Not Impaired-----Extremely Impaired
Sensory modulation	Not Impaired-----Extremely Impaired
Social/emotional skills	Not Impaired-----Extremely Impaired
Cognition	Not Impaired-----Extremely Impaired
Adaptive skills	Not Impaired-----Extremely Impaired

forgetfulness and fidgetiness (*DSM-5*; American Psychiatric Association [APA], 2013b), must be identified as present in two or more settings/environments.

In 2006, there were an estimated 7 million ambulatory care visits for ADHD (Schappert & Rechsteiner, 2008). Boys (13.2%) are more than twice as likely as girls (5.6%) to be diagnosed with ADHD (CDC, 2012), but the highest rates of parent-reported ADHD diagnosis are noted among children covered by Medicaid. ADHD is associated with almost 3 times as many peer problems, 6 times as many emotional and conduct problems, and the child with ADHD is 9 times more likely to have interference with home life, friendships, classroom learning, and leisure activities (Strine et al., 2006). Children with ADHD are also at increased risk of physical injury, with a 10% higher probability of accidental injury and a 7% higher probability of injury resulting in inpatient hospitalization (Leibson, Katusic, Barbaresi, Ransom, & O'Brien, 2001). Children and adolescents with ADHD often have other comorbid psychiatric disorders, including, depression, anxiety, and learning disabilities (Larson, Russ, Kahn, & Halfon, 2011).

ADHD is a highly inheritable disorder involving catecholamine metabolism in the cerebral cortex (Biederman & Faraone, 2005) with additional impact from environmental factors. Factors associated with the development of ADHD include prematurity and low birth weight, prenatal exposure to alcohol and tobacco, and head trauma (Braun, Kahn, Froehlich, Auinger, & Lanphear, 2006; Keenan, Hall, & Marshall, 2008; Knopik et al., 2006; Lindström, Lindblad, & Hjern, 2011).

A primary care clinician should initiate an evaluation for ADHD for any child 4 to 18 years who presents with academic or behavioral problems and symptoms of inattention, hyperactivity, or impulsivity (Subcommittee on

ADHD, 2011). The core symptoms must be confirmed and comorbid problems must also be assessed and ruled in or out. Evaluation using *DSM* criteria can be made using readily available behavior rating scales. The Vanderbilt ADHD Diagnostic Parent Rating Scale is an example of such a measure commonly used and has a sensitivity of .80, specificity of .75, positive predictive value of .19, and negative predictive value of .98 (Bard, Wolraich, Neas, Doffing, & Beck, 2013).

Treatment of noncomplicated ADHD takes place in the primary care setting consistent with the chronic care model and medical home (Subcommittee on ADHD, 2011) and consists of a combination of pharmacotherapy, referring for behavioral modification and parent training, and advocating for families to work with schools to develop appropriate educational accommodations for their child. The NIMH-funded Multimodal Treatment of Attention Deficit Hyperactivity Disorder (MTA Cooperative Group, 1999a) study was a multisite study designed to evaluate the leading treatments for ADHD, including behavior therapy, treatment with stimulant medications, and the combination of the two. It found that combination treatment and medication management alone were both significantly superior to intensive behavioral treatment alone and to routine community care in reducing ADHD symptoms with benefits lasting for as long as 14 months (MTA Cooperative Group, 1999a). Regarding other functional areas, (e.g., anxiety symptoms, academic performance, parent-child relations, and social skills), combination treatment was consistently superior to routine community care, whereas medication alone or behavioral treatment alone were not (MTA Cooperative Group, 1999a, 1999b). Frequent visits and monitoring are required to titrate an effective dose of medication to maximize the reduction in ADHD symptoms

while monitoring and minimizing potential medication side effects. Additional investigation in the development of self-regulation is gaining prominence in applications for behavioral training and management, but is not covered here. For further information on early social interaction and the emergence of self-regulation, see Thompson, Chapter 6, this *Handbook*, Volume 3.

*Cystic fibrosis* (CF) is a serious genetic disorder that involves persistent pulmonary infections, pancreatic insufficiency, elevated sweat chloride levels, male infertility, and a reduced life expectancy. In the 1980s life expectancy of people with cystic fibrosis was 14 years. Through better diagnostic measures (newborn screening now accounting for as much as 30% of diagnosis with 80% of patients diagnosed by the age of 3) and better biomedical treatment (vaccinations, antibiotic therapies, pancreatic enzyme and nutritional supplementation, and emerging studies on gene therapy), life expectancy for people in the United States affected by CF has greatly increased with the median predicted age of survival of about 35 years in 2009 (Cohen-Cymberknoh, Shoseyov, & Kerem, 2011; Costa et al., 2011).

As the life expectancy for people with CF increased, further aspects of CF as a chronic illness have emerged including the implications the disease has on development and human behavior. Children with CF, like many other children with chronic diseases, have experiences that differ from their biomedically typically developing peers. They have numerous clinic visits in both primary and subspecialty care with the addition of ancillary services such as clinical nutrition. They suffer from symptoms of their CF (e.g., cough, fatigue, poor growth, lung and sinus infections) and from side effects of some of their medications (e.g. swelling from steroids). They can have frequent hospital admissions for pulmonary exacerbations and significant infections and may need to have surgical placement of gastric tubes for supplemental overnight nutrition; both affect children's presence (or absence) at school and their range of daily activities.

### Technology-Dependent Children

A small subset of children with CSHCN are "technology dependent" because they rely on life-sustaining medical technology and typically require complex, hospital-level, nursing care. The reliance on machinery varies. Children require feedings through a mechanical pump connected to a gastrostomy tube (G-tube). Some children on mechanical ventilators face respiratory failure if their equipment fails, leaving the daily care for these children and their families

complicated. They often reside in acute or subacute facilities such as pediatric intensive care units or hospitals for special care, although some live at home.

The prevalence of technology dependent children is increasing. Twenty percent of children discharged from a large children's hospital in 2000 were found to depend on a medical device in some manner. One percent of these children were dependent on a tracheotomy, a surgically created hole through the front the neck and into the windpipe (Feudtner et al., 2005). A study of home-ventilated children in the state of Utah found a prevalence of 6.3 in 100,000 children dependent on home mechanical ventilation in 2004 (Gowans, Keenan, and Bratton, 2007).

When care for these children takes place at home, family members have many responsibilities not usual among most families. They must be trained in how to troubleshoot the machinery as well as in more-than-basic CPR if the machinery stops working. They must have plans in place for potential power outages, evacuations, and other emergencies. They must coordinate between medical aides in the home and be prepared for transportation to clinic visits and urgent care for both routine and unplanned emergencies. Often the care of these children is so complex that many parents spend the majority of their day (and devote their identity to) caring for their child.

### Impact of Chronic Illness on Children

Children with chronic illness face disease-related challenges in addition to the daily developmental challenges of childhood. Children have to learn to cope with the impact of the diagnosis and symptoms of their chronic disease and they have to adapt to daily hassles such as frequent medical appointments, learn how to take daily medication, and live with restrictions in diet or activity. For example, an oncology patient who is immunocompromised cannot go outdoors or eat any uncooked foods due to risk of infection. Both the symptoms and daily hassle have an impact on academic, psychological, and social functioning.

### Development and Identity Formation

A child's response to a diagnosis of a chronic illness depends on several factors including temperament, personality, developmental stage, cognitive abilities, the specific disease at hand, and family environment. Infants and toddlers have little understanding of their illness, but developmentally are beginning to develop trust and an overall sense of security. As part of their care they may experience pain, restriction of motion, and separation from parents, all of which pose challenges to their development.

Parental presence and engagement in their care can buffer most adverse effects.

Preschool children face the challenge of developing independence and autonomy, which can be affected by being in the hospital, adjusting to medication schedules, or missing school and other social environments with their peers. For example, children with spina bifida overall show considerable developmental resiliency, but they appear to be at greater risk for exhibiting delays in autonomy development (Friedman, Holbeck, DeLucia, Jandasek, & Zebracki, 2009). Children may also try to counter lack of control by challenging limits set by parents.

Early-school-aged children are developing a sense of mastery over their environment. They may cognitively understand what it means to get or be sick, but magical thinking may cause them to misinterpret the cause of illness. For example, some children may feel that they are being punished for doing something wrong or not doing something they should have, and therefore have become ill (Schonfeld, 1993). Certain attributions may lead to long-term beliefs and behaviors that create difficulty for children as they get older (Sossin & Cohen, 2011).

Older school-aged children and young adolescents are more capable of understanding their illness and its treatment, but they face increasing developmental challenges in terms of independence, mastery, and identity formation. Restrictions may prevent them from attending school and other social activities. Children with chronic diseases are perceived by their parents to display more submissive behavior than their healthy peers. Certain disease characteristics, physical restrictions, and pain are associated with restricted social activities, but not with other measures of social peer interaction. Children with chronic illness are more vulnerable to problems with social development (Meijer, Sinnema, Bijstra, Mellenbergh, & Wolters, 2000). Data regarding self-concept in children with chronic diseases remains inconclusive. In two studies, compared to controls, children with asthma reported similar self-concepts (Hamlett, Pellegrini, & Katz, 1992; Hazzard & Angert, 1986). Other studies show the self-concept of children with physical disorders lower than that of healthy children; however, these differences were no longer significant when compared to another normative group following careful matching (Boekaerts & Röder, 1999).

Along with emerging independence, an important developmental task for older adolescents and emerging adults is identity formation. The study of identity development in adolescence with chronic diseases remains a fairly neglected area of research. These adolescents face continued struggles with control and emerging

independence. They may neglect to take medications, follow special diets, or check blood sugars (see the section "Medical Adherence"). When chronic illness begins in adolescents they may struggle with disruptions to educational and vocational plans and emerging intimacy and serious relationships. More so, as typically developing peers are increasingly independent, parents who have been very involved in a chronically ill adolescent's care for many years may find it difficult to let go of their role as primary caregiver (see the section "Adolescence and Health Care Transition").

Identity differences between adolescent and young adults with Type 1 diabetes and their nondiabetic peers found that youth with diabetes scored lower on proactive identity exploration (Luyckx et al., 2008). Different combinations of exploration and commitment to values are referred to as identity statuses. The same identity types and status emerged in young adults with diabetes as did with their nondiabetic peers, but identity statuses of the diabetic youth were related to diabetes-related problems, depressive symptoms, and illness coping. A strong sense of identity to diabetes-related problems and depressive symptoms is modulated by adaptive and maladaptive coping.

Peer relationships are important for identity formation. A study of children and adolescents with congenital heart disease (CHD) found these adolescents to be as competent as children without CHD in addressing the tasks of identity formation due to supportive peer relationships (Rassart et al., 2012).

### *Academic and Neurodevelopmental Functioning*

Diseases such as sickle cell disease, spina bifida, and epilepsy may have central nervous system abnormalities that have direct impact on cognition, attention, and other functions, thus impairing academic performance (Fowler, Johnson, & Atkinson, 1985; Fowler, Davenport, & Garg, 1992). Some treatments for diseases such as cardiac surgery or radiation to the brain, especially in the case of CNS cancer, can also cause neuropsychological deficits that impair learning (Albers, Bichell, & McLaughlin, 2010; V. A. Anderson, Godber, Smibert, Weiskop, & Ekert, 2000). Children treated with chemotherapy for non-CNS cancers can also show neurocognitive problems (F. S. Anderson & Kunin-Batson, 2009; Hill, Ciesielski, Sethre-Hofstad, Duncan, & Lorenzi, 1997). In one of the few prospective studies starting in early infancy, more, but different neurodevelopmental deficits were seen in select mental and verbal functions compared to a matched control group of children without chronic illness (Bornstein et al., 2012). It remains to be determined whether

these deficits will impair functioning over time beyond potential contributions of social/emotional factors associated with cancer. Chronically ill children also experience a higher than average rate of school absenteeism; however, research on school performance in these children is inconclusive.

### ***Emotional Functioning and PTSD***

Children with a chronic disease had more behavior problems compared to children without, normative groups, and controls with acute illness (Turkel & Maryland, 2007). There is a higher level of internalizing problems among these children (Pinquart & Shen, 2011b). Signs of depression, somatic complaints, social withdrawal, and increased levels of anxiety have also been found (Worchel, Rae, Olson, & Crowley, 1992). One specific and important psychological impact of chronic illness is the potential development of posttraumatic stress disorder (PTSD) which can occur in response to any life threatening, painful, or perceived to be life threatening or painful experience including medical treatments, cancer, intensive care, organ transplants, or other painful medical procedures.

Through an effort to identify the important psychological response to medical treatment, the term pediatric medical traumatic stress has been coined (Kazak et al., 2006) to better elucidate the psychological and physiological responses of children and their families to pain, injury, serious illness, medical procedures, and invasive and frightening treatment experiences. These responses are often related to the child's subjective experience rather than the objective severity of the medical event and involve symptoms of "arousal, re-experience, and avoidance" similar to a posttraumatic stress disorder. Beyond the type of medical trauma, other factors including sudden or gradual onset of intensity and length of exposure or likelihood of recurrence, affect a child's experience and the development of these symptoms. Responses vary in intensity and can be adaptive or disruptive to functioning. Most patients are resilient to such consequences, but it is important to identify those children who do experience such symptoms. Children might report feeling like the traumatic event is happening again, and get upset when something reminds them of it or the event pops in their mind before they go to sleep or in their dreams. Statements suggesting arousal symptoms include "I can't concentrate or sleep. I'm always afraid something bad will happen." Avoidance includes statements such as, "I block it out and try not to think about it or I try to stay away from things that remind me of it," and finally dissociation, which might include, "I can't even

remember parts of it. It felt unreal like I was dreaming" (Cohen & Scheeringa, 2009).

Posttraumatic symptoms have been documented in children from a variety of life-threatening medical illnesses especially transplants and cancer (Stuber, Shemesh, & Saxe, 2003). Transplant recipients have many sources of traumatic stress: prior life-threatening illness, the transplant procedure itself, and medical problems associated with recovery. Posttraumatic symptoms are significantly greater in a liver transplantation compared to chronic medical illnesses or routine surgical procedures (Walker, Harris, Baker, Kelly, & Houghton, 1999). High rates of PTSD symptoms in children who experienced liver transplantation are associated with nonadherence to treatment regimen due to avoidance (Shemesh et al., 2000), demonstrating a perpetuating threat to life in some children.

Studies of children with severe medical illnesses (non-cancer or transplant) yield inconsistent findings; some studies have reported relatively high rates of posttraumatic symptoms, whereas others have reported similar rates to comparison groups of children. The child's perception of life threat and the intensity of medical/surgical treatment appear to be emerging as important risk factors. The studies that have reported low rates of posttraumatic symptoms assessed children many years after the trauma, when the perceived life threat is likely to be significantly diminished (Pynoos et al., 1987).

Advances in medical sciences are blurring the distinction between an acute life-threatening illness and a chronic disease. Many forms of cancer and HIV/AIDS are now considered chronic diseases. It is not known, with the exception of transplantation and cancer treatment, which medical or surgical procedures constitute "a threat to the physical integrity of self." Can relatively common procedures, such as lumbar puncture or even venipuncture, ever reasonably be considered a traumatic stressor? Most importantly, what are the behavioral and pharmacologic strategies that reduce risk if a child developing traumatic symptoms in response to a disease and/or treatment?

### ***Social Functioning, Bullying, and Vulnerable Children Syndrome***

Children with chronic disease face social repercussions related to their condition. They have to learn how to navigate social systems to advocate for themselves in terms of their condition. This can pose a set of challenges for children, especially for adolescents where social capital is of utmost importance. A high school student with a severe peanut allergy has to choose to sit at a potentially

stigmatized “nut-free” table in the cafeteria and has to carry a cumbersome pair of EpiPens (a self-injecting device that administers epinephrine into the thigh muscle when used) when going out with friends. A child with asthma might have to ask an adult, perhaps a complete stranger, to stop smoking a cigarette while in his or her presence.

In general, children with chronic illness are at increased risk of being socially isolated. Peers might have misconceptions about their disease, whereas the child might experience misperceptions of isolation or increased anxiety leading to social isolation. The responses of peers to chronic illness range from avoidance to fascination leading to isolation or potentially negative attention such as bullying. Chronically ill children may also self-isolate, because they feel different from peers and therefore modulate and limit their social behaviors.

Social isolation varies among children with chronic illness, but difficulties are seen in peer relationships for some diseases and may be related to physical appearance and to restrictions in activities (Spirito, DeLawyer, & Stark, 1991). The presence of a medical device, a child who has visible seizures, or a child with alopecia (hair loss) from cancer treatment all feature traits and behaviors that separate ill from healthy children in the social milieu of school settings.

There are a growing number of studies on the prevalence of bullying among children with special health care needs. Adolescents with disability or chronic illness are more likely to be victimized than their peers even when confounding variables are controlled (Sentenac et al., 2011). Furthermore, having a behavioral, emotional, or developmental problem is associated with both bullying others and being a bully victim.

A special aspect of “social” impact is the *vulnerable child syndrome*, which was coined to describe children whose parents perceive them as uniquely susceptible to medical problems because of a prior life-threatening illness. The criteria for vulnerable child syndrome include (a) a real or imagined event in the child’s life that the parent considered to be life-threatening, (b) the parent’s continuing unrealistic or disproportionate belief that the child is especially susceptible to illness or death, and (c) the presence of symptoms in the child that appear disproportionate to the apparent level of illness or impairment (Weitzman, 2010). The initial description registered the impact on parents and children following significant illness during the newborn period that many parents were told that their child would die. Although the children recovered from their initial illness, parents subsequently viewed them as uniquely susceptible to later illness or even

death. Parents within the first year were hypervigilant and anxious manifesting as overprotective behaviors. Often they would not leave their child with anyone but the other parent to ensure the child’s health and safety. In many cases, mothers never left their infant. In the second year parents had problems related to limit setting and would not say “no” to their children because they were grateful their children were alive. Without necessary limits these children developed a tendency to behave out of control, sometimes even hitting their parents, which the parents silently permitted. In the third and fourth year, parents worried about their children’s health and complained of a variety of psychosomatic symptoms in their children, such as poor appetite, headache, and tiredness. Finally, during the early school years, many children had episodes of school refusal because they were unable to separate from their parents (Green & Solnit, 1964).

It is now recognized that vulnerable child syndrome can occur even in the absence of life-threatening events. In the perinatal period, false positives on one of many prenatal screening tests, transient acute newborn medical problems, or spending time even for observation in the NICU are associated with vulnerable child syndrome (Forsyth & Canny, 1991). It is also likely that parents’ perception of the child’s vulnerability may be related to parents’ own previous experiences including difficulty conceiving, recurrent miscarriages or a stillbirth, and any other event that raises concern for fetal loss during the pregnancy. Low socioeconomic status, parent mental health problems, and specific trauma history are also risk factors to parental perception of vulnerability (Thomasgard & Metz, 1995). Vulnerable child syndrome represents special perturbation to the ongoing adaption and relationship between parent and child and presents with symptoms related to parent-child relationships. For example, parents may complain of a child’s refusal to sleep through the night, but further investigation might reveal the parents are waking the child multiple times each night to check on him or her and ensure the child’s safety. Overall, vulnerable child syndrome results in negative outcomes for the parent, child, and the dyad. Any minor complaint may result in a visit to the doctor’s office or emergency room leading to high and unnecessary health care utilization. In that setting, the doctor’s assurance as to the minor nature of the illness is not helpful to these parents because their specific worry is not the present illness but their perception of their child’s unique susceptibility to illness, and that this episode could quickly lead to something more serious. Unfortunately, parents do not always express this “second agenda” and

leave dissatisfied with care, leading to repeated potentially negative encounters with health care professionals as second opinions are sought. To prevent or attenuate vulnerable child syndrome, clinicians need to be aware that real or imagined life threatening events, especially in the perinatal period, can have such consequences on parents. They need to assure parents that specific events during pregnancy or newborn illness are self-limited and explicitly state that they do not carry any future risk for illness. Clinicians who perceive parents as unusually anxious about a child's minor illness should ask parents whether their concern is related to a previous event or illness. This allows the clinician an opportunity to address parents' "second agenda." Eliciting parents' concerns along with a complete history and a meticulous physical exam with explicit feedback about normal findings can be reassuring to parents.

### Medication Adherence

The effectiveness of efficacious medication is limited if not taken as prescribed. Similar to adults, approximately 50% of children and their families do not follow medication plans as prescribed, which increases risk for relapse, increased morbidity and mortality, and the development of drug resistance depending on the treatment. Common reasons given by parents for lack of adherence (sometimes referred to as noncompliance) include forgetting to administer the medication, resolution of symptoms, misunderstanding instructions, refusal by the child, medication side effects, busy schedules, and cost of the medication (Rapoff, 2010). Simply put, adherence issues are not black and white.

Many of the nonfinancial barriers to adherence can be captured under the heading of *health literacy*, the set of skills people need to obtain, process, and use information to function effectively in the health care environment. Severity of an illness does not guarantee medication adherence. Even children with life threatening conditions such as cancer, bone marrow, and renal transplants are at risk of treatment failure because of suboptimal adherence with drug therapy. The more complex and demanding the drug treatment regimen is, the more likely there will be decreased compliance. The duration, frequency, and intermittent nature of medication are important contributors to lack of adherence. This is especially true when medication schedules are inconvenient or out of synch with the normal family routine (Modi et al., 2012).

A number of strategies address a lack of medication adherence. The most important is to help children

beginning at young ages, 4 years and older, to be responsible for their own medication (Modi et al., 2012). This is a common practice for children with diabetes on an insulin regimen, but is often neglected for children with most other diseases. Electronic monitors have been developed to assess adherence and remind patients when to take their medication (Rapoff, Belmont, Lindsley, & Olson, 2005). The most common type of such monitoring is a microelectronic circuit that records the date, time, and frequency of opening medication containers or using inhalers. Output from such devices can reveal important medication taking behaviors, leading to more individualized and specific behavioral interventions. These systems continue to be developed using smart phone technology, improving the processing and recording of information. However, as with all electronic monitors, these systems are subject to problems including malfunction, misuse, and a lack of specificity (uncertainty as to whether opening the container actually results in the use of the medication, or recording the correct dose).

Other strategies to improve adherence include development and use of longer acting medications, either in pill, skin patches or injectable form to ensure the child receives required medication. As an example, long-acting insulin lasts 24 hours. Newly developed forms of insulin will last up to 7 days. Similarly, challenges of adherence have shaped the form and delivery methods for birth control medications. Although beneficial, these longer acting medications and devices pose their own set of behavioral challenges. Children with diabetes still need to learn to count carbohydrates and administer short-acting insulin as needed, and adolescents equally need to be reminded about the importance for barrier protection to prevent sexually transmitted infections. Global strategies, such as *directly observed therapy*, have effectively reduced drug resistance for tuberculosis by promoting adherence through administration and documentation of medication by trained personnel (Moonan et al., 2011). A number of simple behavioral strategies are effective at improving adherence, including self-monitoring, contracting, reward-based privilege programs, and the use of cues or reminder techniques, such as putting an inhaler next to a tooth brush so child patients will use medications at the same time that they are brushing their teeth.

### Chronic Illness and Pain

In the not too distant past, barriers to pain management in children included myths, such as those purporting that

children, especially infants, do not feel pain as adults do because of an “immature nervous system.” Further contributors to poor pain management included a lack of standardized pain assessment and treatment protocols and a fear of potential adverse effects of analgesic medications including respiratory depression and addiction.

Acute pain resulting from injury, illness, and/or medical procedures is the most common type of pain experienced by children followed by chronic and recurring pain associated with underlying medical conditions. Important advances have been made in understanding the neurobiology of pain. Pain, or nociception, results from tissue injury leading to autonomic, hormonal, and metabolic changes transmitted from a peripheral nerve to the central nervous system. These pain signals occur as early as 26 weeks of gestation and are followed by later developing inhibitory pathways (Berde & Sethna, 2002). The concepts of pain and suffering, however, transcend a simple sensory experience with its biologic underpinnings. Pain management uses medications to affect the biological pathway while its primary aim is to eliminate suffering.

### ***Pain Assessment***

Assessment of pain is an important first step to determine the type and dose of medication for both initial and ongoing pain management. The current standard for pain assessment is a simple self-report numeric pain scale equating pain from 0 to 10. This scale was developed for adults, but it is accurate for older children with moderate to severe pain. Other approaches include a visual analog pain scale, the Wong-Baker FACES scale, which uses “smiley faces” appearing with a range of expressions from happy to distressed. Pain in newborns can be evaluated using various neonatal pain scales consisting of facial expressions, level of crying, breathing patterns, movement of the extremities, and state of arousal.

### ***Pain Management in Medical Settings***

Pain management practices are influenced by environmental, developmental, cultural, and contextual factors and involve consideration of longer-term impact and goals. Inadequate sedation and pain control that may worsen a child’s reaction to later medical procedures. Even minor painful procedures such as circumcision or blood draws in the newborn nursery show increased pain and distress months later during minor painful procedures such as immunization (MacLaren & Cohen, 2007); children as young as 2 years have been shown to be able to recall urethral catheterization 6 months after the procedure (Kleiber

& McCarthy, 1999). The understanding of the emotional and contextual aspects of pain and suffering has resulted in important environmental and psychological approaches to reduce pain and anxiety. Use of videos, music, light wands, image projectors, and other distracting devices reduces stress anxiety and promotes comfort.

The availability of a child life specialist in outpatient and emergency department settings during painful procedures began over the past ten years with great success. Besides comforting children through play and distractibility, Child life specialists spend time with children and teach them what to expect during a procedure, showing them specific medical tools that will be used, and offering them choices appropriate in creating a comfortable stress reducing environment, demystifying unfamiliar medical procedures, and offering a feeling of control, all which ameliorate anxiety and anticipated pain and are now considered as necessary as a pharmacological approach to treating pain. Behavioral strategies as simple as blowing bubbles or a pinwheel to strategies as sophisticated as self-regulatory activities including deep breathing or even hypnotic approaches are very successful in reducing the perception of pain (Srouji, Ratnapalan, & Schneeweiss, 2010).

Optimal pain medication and control make children more comfortable and compliant in the evaluation and treatment of a pain producing medical problem. Pharmacological treatment involves matching the need of a patient with appropriate medications and dose. In the case of pain with an obvious fracture or with a patient with sickle cell disease, oral analgesics are not sufficiently quick acting. However, placing an IV can take additional time. Intranasal Fentanyl is being used increasingly because it is delivered as a mist, immediately absorbed, and provides pain relief within minutes. When added to IV Propofol and topical anesthetics for lumbar puncture or bone marrow aspiration, Fentanyl has been shown to reduce movement of the patient during the procedure, the dose of Propofol required, and recovery time. Protocols provide the dose for weight of appropriate medications ranging from acetaminophen and ibuprofen for mild to moderate pain to oral opiates for more significant pain. In some select cases, especially children suffering from multisystem trauma, suboptimal doses of opiates are used so as not to obscure important neurologic findings from the clinical examination.

The development of patient-controlled analgesia (PCA) was an important advance in acute pain management among older hospitalized children and adolescents. With a ceiling set to prevent overdose, patients push a button to give themselves a predetermined dose of pain medication

into their IV. Advantages of PCA over traditional muscular injections or oral medication include the following: (a) there is virtually no delay between the perception of pain and delivery of analgesia; (b) patients can fine-tune their doses to avoid excessive sedations as an overly sedated patient will be too drowsy to activate their PCA device; (c) patients do not have to “prove” their degree of discomfort; and (d) PCAs support autonomy allowing adolescents to have some control over their body.

Topical anesthetics such as lidocaine when mixed with other compounds further reduce pain. Some need to be placed about 60 minutes prior to use while others such as vapocoolants are applied immediately before the placement of IVs, immunizations, and other minor procedures. Pain control and anxiolysis (control of anxiety) also decreases movement leading to better accuracy during suturing lacerations or conducting MRIs and CT scans.

Studies suggest that sugar water (12% sucrose) effectively diminishes a newborn’s response to painful stimuli during blood draws, circumcision, and injections. This effect appears to be strongest among newborns and decreases gradually over the first 6 months of life (Stevens, Yamada, & Ohlsson, 2010). Skin-to-skin contact between a mother and an infant (including breastfeeding), as well as swaddling during a procedure, also decrease behaviors associated with pain (Harrison, Beggs, & Stevens, 2012).

### ***Chronic and Intermittent Pain***

The most common pain syndromes in children are recurrent abdominal pain and headaches. Some patients respond to reassurance and treatment with simple medical approaches, but a significant proportion goes on to develop varying degrees of chronicity that are difficult to treat. Other than pain syndromes, children can experience pain due to underlying chronic diseases, such as cancer, juvenile rheumatoid arthritis, and sickle cell disease.

Pain management teams and services involve interprofessional collaboration from pediatrics, anesthesiology, psychiatry, psychology, and child life specialists. Novel approaches to pain management include use of smart-phones to monitor in real-time to better understand pain patterns as they relate to everyday activities. Additional approaches include massage, acupuncture, biofeedback, and medical hypnosis.

### **Siblings of Children With Chronic Disease/Illness**

Chronic diseases of childhood have implications for the psychosocial well-being of siblings. Some siblings suffer

the consequences more than others; some do not experience any negative outcomes. The variables that have an impact on siblings include, among others, age, gender, temperament, and family system. At the most basic level, disease management of the affected child can interfere with many aspects of daily life for siblings. They may have to take on a care giving role for their affected sibling or may have to care for other children in the household as their parents are preoccupied with the ill child. A child may have to avoid social outings or be restricted in their attendance of social activities.

Early studies concluded that siblings were “a population at risk to experience psychological difficulties” but suggested that there could be positive benefits to growing up with an ill sibling, such as developing greater compassion (Faux, 1993; Hannah & Midlarsky, 1985; McKeever, 1983; Packman, 1999). While earlier studies continued to suggest siblings are found to be more caring, mature, supportive, responsible, and independent (Houtzager, Grootenhuys, & Last, 1999), more recent information shows that siblings face internalizing or externalizing problems and less positive self-attributes than healthy comparisons (Vermaes, van Susante, & van Bakel, 2012). Regardless of the specific chronic disease experienced by the affected child, parents report more negative symptoms for siblings than do the siblings themselves (Sharpe & Rossiter, 2002; Vermaes et al., 2012). For example, parent ratings of siblings can be confounded by other factors such as their mental health (Wood, Rijdsdijk, Saudino, Asherson, & Kuntsi, 2008).

Disease severity (mortality) itself does not seem to exert a direct effect on psychosocial functioning of siblings. Illnesses, however, that affect the day-to-day functioning of the ill child such as bowel disease or cancer are associated with more negative effects on siblings compared to illnesses that do not affect daily functioning (Sharpe & Rossiter, 2002).

A consistent finding has been the relation between age of the sibling and their quality of life and self-attributes (Vermaes et al., 2012). The older the sibling, the lower their observed quality of life has been reported across multiple domains. Adolescent and school aged siblings of children diagnosed with cancer report a lower quality of life at 1 month post-diagnosis with adolescent girls reporting more emotional problems compared with peers. At 6 months, the quality of life of adolescent-aged siblings remained relatively impaired (Houtzager, Grootenhuys, Hoekstra-Weebers, & Last, 2005).

This moderation effect of age suggests that younger siblings are less vulnerable than older siblings in regard to

their self-attributes, but not to internalizing or externalizing problems. It is plausible that younger siblings' naïve concepts of the affected sibling's disease shelter them from the effect of negative self-attributes, whereas older children who can cognitively appreciate the reality of disease and may be expected to be more self-sufficient, assume a care giving role and/or take on more domestic responsibilities (Houtzager et al., 2005; Labay & Walco, 2004). This effect could also be a reporter artifact. In most studies, parents are the likely reporters for young children's functioning, whereas older siblings provide a higher degree of self-report data (Vermaes et al., 2012).

### Parents of Children With Chronic Disease/Illness

Parents of children with chronic disease can experience numerous stressors related to caring for their affected child. Each specific chronic disease features its own profile (see Table 15.1) of demands on time, finances, and stress on family relationships related to unpredictability and uncertainty of the disease at hand. There is decreased self-esteem and efficacy as parents' senses of themselves as providers and protectors are severely challenged by their child's illness. As family routines are disrupted, marital and other family relationships become severely strained.

The time of diagnosis involves feelings similar to those experienced by individuals grieving the death of a loved one, described as loss for their "hoped for child" (Barnett, Clements, Kaplan-Estrin, & Fialka, 2003) and parents experience grief, shock, denial, and disbelief followed by anger directed toward the medical staff and professionals involved with their child. Parents may wonder whether it would be better if the child dies and consequently experience feelings of guilt. After diagnosis, many parents question how they themselves had acted during the prediagnosis period. They wonder whether they could have done more to expedite their child's diagnosis. Some express regret and guilt about their perceived failings in the role of guardian of their child's well-being and begin to doubt their adequacy as parents (Riedesser & Wolff, 1985).

Caregiving strain and self-perception are important determinants of the health related quality of life, adjustment, and coping skills of parents of children with cancer (Klassen, 2010). It is not fully understood why some parents cope well with the stress of caring for their child and others do not. Traditional approaches investigating the psychosocial aspects of chronic childhood illnesses such as cancer have tended to characterize parents' experience of their child's illness in terms of "maladjustment"

and "coping," rather than the ongoing process of adaption through which parents learn to sensitively read and respond to their child's signals and needs (Young, Dixon-Woods, Findlay, & Heney, 2002). Learning to care and advocate for their children becomes a significant part of the lives of these parents (Jerrett, 1994). Over time, parents proceed in sharing and ultimately championing the management of their child's disease in addition to becoming an advocate (Swallow, 2008). Parents' levels of adaptation to their child's diagnosis have been found to predict both family well-being and their child's attachment security (Barnett et al., 2003).

PTSD has been described as well in parents after their child has experienced an acute trauma or life threatening illness, chronic disease, and in parents who have a premature infant in the NICU. The reported incidence of PTSD in these situations ranges from 21% to 25% when a child has been in the NICU or PICU to 30% for parents of children with leukemia (Kazak & Barakat, 1997). It appears to occur more often in mothers than fathers. When parents suffer from PTSD it not only affects their health but their relationship with their children, interactions with the health care team, and may also interfere with helping a child manage his or her own illness. Parents of leukemia survivors also experience significantly higher levels of post-traumatic symptoms than do the parents of comparison children (Barakat et al., 2003). Fully, 83% of children with cancer and PTSD had mothers with PTSD.

The needs of parents of children with chronic illnesses can be conceptualized within three major themes: (1) the need for normality and certainty; (2) the need for information; and (3) the need for partnership (Fisher, 2001). Hospital care in the United States has responded by implementing family-centered rounds (FCR) described as "interdisciplinary work rounds at the bedside in which patient and family share information and the management for that day" (Sisterhen, Blaszk, Woods, & Smith, 2007). This new approach improves communication between families and physicians, allowing for shared decision-making, family satisfaction, and more efficient use of health care resources (Kuo et al., 2012).

### Adolescence and Health Care Transition

The transition from pediatric to adult care involves more than a new doctor and clinical setting. It involves the inherent attitudes and expectations of the respective health care teams. As generalizations go, pediatric health care teams tend to be supportive because their patients start out as dependent. Adult health care providers expect

independence and self-management and they perceive their role is to provide information and recommendations and not “hand holding.” The basic challenge for patients goes from being nurtured and relatively dependent in the pediatric care system to needing to be able to function independently as an adult in the adult care system. This transition occurs ideally in an uninterrupted manner and is needed for approximately 90% of youth with chronic health conditions who survive to adulthood (Blum, 1995).

Implementing systems that can bridge care between the pediatric and adult worlds is a relatively slow process, with most patients drifting away from pediatric care rather than having an explicitly mapped and effectively transitioned plan. A study in Texas showed a spike in death rate of youth with sickle cell disease from Ages 18 to 24, which overlapped with the time spent in the gap between leaving pediatrics and establishing adult medical care (Bryant, Young, Cesario, & Binder, 2011). Recognition of the need for transitions need is relatively new, due in part to the increased longevity of those living with chronic illness.

There are multiple reasons for gaps in transition in the contemporary U.S. medical system (Cooley & Sagerman, 2011). Pediatric care providers and their staffs have limited training in implementing the transition process; there is little evidence-based research on strategies or programs that are effective at coordinating the handover of care and transferring information from the pediatric site to the adult care site. Adult providers are often inadequately prepared to care for young adults with complex chronic conditions due in part to their training. For example, children with a surgically corrected congenital heart malformations tend to be cared for by pediatric cardiologists until ages 30 or more because most adult cardiologists are not trained or do not have experience in the care of these children as adults. Similarly, developmental disorders including autism and cerebral palsy are beyond the training and comfort of most adult clinicians.

Transitions are potentially emotionally charged events for parents and patients because of strong relationships with their pediatric clinicians. While most pediatric leaders support transition efforts, some are stating that pediatric specialists should expand significantly the age of children under their care until the medical problems exceed their expertise.

Youth with special health care needs and their parents need to be involved in discussions regarding the process of transition to adulthood as early as 12 years of age depending on the individual patient. Child patients need to be introduced to developmentally appropriate self-care and work

on activities of daily living beginning before 12 years of age. The timing of these discussions should be individualized. Expectations for independent living, education, continuing education, vocation, reproduction, expectancy, and other life concerns should be discussed with parents and other appropriate caregivers well before it is time for any of these new activities and functions. The health care transition should also be part of a broader mastery planning that includes such issues as educational attainment, career choices, and independent living needs. A child’s interests, personal strengths, level of skills, ability, and desires should be at the core of the transition process. Overall, this process involves transitioning medical care for all *three* categories of health care: primary care, emergency room care, and ongoing specialty care (Cooley & Sagerman, 2011).

### Specialized Care for Children With Chronic Illness

Children with chronic illness may have need to access two unique types of health care delivery: home care and palliative, or end-of-life, care.

#### Home Care

Advances in medical technology have allowed a growing number of children with chronic conditions to be cared for in the community. The “Medicaid Model Home and Community Based Waiver” in 1982 allowed children to receive funding from home care if the costs were less than or equal to hospital costs. This act began the trend towards earlier hospital discharges, and ill patients began to enter the community more quickly.

Skilled nursing services and home health aides are the most commonly used home care service for children. Nurses can administer medications and change devices in the home while home health aides can assist with basic personal care needs such as bathing and feeding. Rehabilitation services such as occupational, physical, and/or speech and language therapies can be offered in the home. Personal care attendants are unlicensed care givers who provide care for children at the training and direction of the family with services ranging from assistance with activities of daily living (e.g., meal preparation, shopping, dressing) to more complicated nursing care skills. Each of these services requires a lengthy approval process and the number of hours of service each day vary according the disease, availability of resources and state laws.

*Palliative care* is treatment that serves patients with life threatening or life limiting diseases to enhance the comfort and the quality of their life. Palliative care is not limited to

children near death and consists of providing active total care of the child's body, mind, and spirit, while giving support to the child's family. *Hospice care* is similar, but for patients with a prognosis of 6 months or less. The expected outcome in palliative care is relief from distressing symptoms, easing of pain, and enhancing the quality of life rather than necessarily affecting the underlying disease. Palliative care requires iterative assessment and evaluation of treatment options in the context of the child's symptoms and their family's desires and values (WHO, 2008). Palliative and hospice care can be provided in the home, nursing home, residential facility, or inpatient unit.

### THE FUTURE OF CHILDREN'S HEALTH CARE: USHERING IN THE THIRD ERA

The future of child health care will continue to evolve to treat children's health problems but expand efforts to promote wellness and functioning. Personalized medicine will mean that many chronic diseases will be treated based on molecular markers that will identify specific medications to reduce side effects and enhance efficacy. Information technology will become more important, including use of quality metrics for quality improvement to coordinate care, health systems will be better integrated and families will have more information available to them to become health conscious consumers. Technological tools and organizations (such as Collaborative Chronic Care Network's work with inflammatory bowel disease management) that are devoted to care of patients with complex health care needs, will enhance and increase patient, parent and family engagement to promote self-management, patient/family activation and empowerment, especially for children with chronic illness (C3N, 2013). Broad scale standardized data collection holds important ability to study outcomes, treatment responses and identification of best practices. Information technology systems in emergency departments will become early warning systems for new epidemics of infectious diseases.

Medical problems with increasing prevalence have emerged and evidence-based strategies will need to be developed for identification and treatment. Finally, better understanding of the impact of early experiences on lifelong health will lead to wellness efforts to prevent or attenuate both child and adult diseases.

#### Medical Problems With Increasing Prevalence

An epidemic is a widespread occurrence of an infectious disease in a community at a particular time. Throughout

history epidemics have traditionally consisted of infectious diseases with intermittent outbreaks occurring affecting thousands to millions. HIV (the human immunodeficiency virus) and the ever-changing influenza virus remain two influential epidemic infectious diseases in first world nations today.

The 21st-century "epidemics" are now primarily non-infectious in nature as, for example, with asthma. Thirty years ago, a rise in rates of childhood asthma was identified and thought to be triggered by immunological system alterations through exposure to asthma producing allergens, although viruses are still considered a potential contributor. Mass media is a relatively new factor that contributes to what parents worry about. A recent survey of 1,000 parents showed they were primarily worried about healthy nutrition, obesity, lack of exercise, healthy growth and development, safety and injury prevention, and mental health issues (Garbutt et al., 2012). These parents were also asked to rank what they believe are top health concerns for children and adolescents in their community; allergies, lack of exercise, asthma, ADHD, Internet safety, obesity, smoking, and bullying were identified as important problems by 57%–70% of parents.

This section will review a selection of problems, all with a behavioral/developmental or emotional component, with significant or rising prevalence in primary care in the United States. These problems reflect the continued need for health care providers to develop skills to address these problems and to advocate for new community resources and policy at local and national levels (Satcher, Kaczorowski, & Topa, 2005).

#### *Childhood Depression and Anxiety*

Approximately 13% to 20% of children living in the United States experience a mental disorder in a given year, with surveillance between 1994 and 2011 demonstrating the prevalence of these conditions to be increasing (Perou et al., 2013). Many of these children are reared in environments characterized by early life stress (Merikangas, He, Burstein, et al., 2010). For additional discussion of the development of mood and anxiety disorders, see Cummings & Valentino (Chapter 15, this *Handbook*, Volume 1).

Depression affects 12% to 25% of adolescents (Lewandowski et al., 2013). Information for younger children is less readily available. Data from National Survey of Children's Health 2007 (NSCH, 2007) demonstrated a parent report point prevalence of depression in children 3 to 5 years of 0.5% and for children 6 to 11 years of 1.4%.

Likewise, the lifetime prevalence of depression was found in children 3 to 5 years to be 0.6% and for children 6 to 11 years to be 2.3%. In adolescents, female-to-male ratio approaches 2:1. Data from the 2007 NS-CSHCN (NSCH, 2007) indicates for children 3 to 17 years of age, there is a point prevalence of 3% and lifetime prevalence of 4.7% for anxiety. Phobias are diagnosed in 2.6% of children 4 to 17 years old (Perou et al., 2013). These disorders are also associated with a higher risk of suicide, which was the second leading cause of death among children 12 to 17 years old in 2010 (CDC, 2011a).

Mood and anxiety disorders in childhood are both commonly found together (Angold, Costello, & Erkanli, 1999; NRC & IOM, 2009) and can recur over time (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Kessler et al., 2012). These disorders are also often comorbid with and affect adherence to treatment for other health problems including asthma, food allergy, and other chronic health problems (Delmas et al., 2011; Friedman & Morris, 2006; Pinquart & Shen, 2011a; Pinquart & Shen, 2011b; Roy-Byrne et al., 2008). Children with depression and anxiety also have an increased risk of substance use, abuse, criminal behavior, sexual risk taking behaviors, and lower educational attainment (Perou et al., 2013).

The U.S. Preventive Services Task Force (USPSTF) and the National Institute for Health and Clinical Excellence (NICE) both recommend universal screening of 12- to 18-year-olds for depression in primary care (USPSTF, 2009; NICE, 2005); although successful implementation of screening has previously been poor (Halpern-Felsher et al., 2000; Klein et al., 2001). Screening tools have been developed for primary care including the Patient Health Questionnaire (PHQ-2, PHQ-9), the PHQ for Adolescents (PHQA), and the Beck Depression Inventory–Primary Care Version. Their use has been successful with adolescents (Lewandowski et al., 2013). All adolescents who screen positive for depression should have an assessment of potential for harm to self and others (Birmaher et al., 2007).

Treatment for childhood and adolescent depression and anxiety is complex. Pediatric clinicians should always offer support, counseling, and problem solving for adolescents with very mild depression symptoms. However, for younger children and adolescents with more moderate or severe levels of symptoms, refer to appropriate behavioral health services. Evidence-based treatment for depression includes cognitive-behavioral therapy, interpersonal psychotherapy, or pharmacotherapy with selective serotonin reuptake inhibitors (SSRIs) (Lewandowski et al., 2013).

### *Autism Spectrum Disorder*

Autism spectrum disorder (ASD) is defined by significant delays and impairments in reciprocal-social communication and interaction associated with restricted and or repetitive behaviors and interests. These symptoms manifest in early childhood although they may not be recognized until later. Symptoms, which vary in intensity and impact, include abnormal social interactions to a lack of social initiation, failure of back and forth conversation, poor use of eye contact in social interaction, lack or delays in imaginative play, stereotyped speech including echolalia, adherence to routines, excessive resistance to change, highly restricted/fixated interests that are abnormal in intensity or focus, and hyper- or hyporeactivity to sensory input or unusual interest in sensory aspects of environment (APA, 2013b).

The criteria for ASD have evolved with the release of the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (*DSM-5*; APA, 2013b) in May 2013. *DSM-IV* criteria consisted of impairments in three major domains—socialization, communication, and behavior—and were consolidated into two primary domains for *DSM-5*: (1) deficits in social communication and social interaction, and (2) restricted, repetitive patterns of behavior and interests. *DSM-IV* featured criteria for three separate diagnoses of autism spectrum disorders: (1) autistic disorder, (2) Asperger syndrome, and (3) pervasive developmental disorder, not otherwise specified (PDD-NOS). With the release of *DSM-5* these three separate disorders have been consolidated into a single diagnosis of autism spectrum disorder. The new diagnostic criteria for autism were designed to encourage earlier diagnosis while also allowing for diagnosis of children whose symptoms might not be fully recognized until their social demands exceed their capacity (APA, 2013a).

As of 2008, the CDC's estimate of the prevalence of ASDs in the United States is 1 in 88, or 1.13% of children (Baio, 2012), which is increased from data in 2000 when the prevalence was estimated to be 1 in 150 children. ASD is almost 5 times more common among boys (1 in 54) than among girls (1 in 252) (Baio, 2012) and occurs in all racial, ethnic, and socioeconomic groups.

There is an ongoing trend for children in the United States to be diagnosed at earlier ages with as many as 18% of cases identified by Age 3, however most children are not diagnosed until after Age 4 (Baio, 2012). This trend likely represents the impact of developmental screening in pediatric primary care (see earlier this chapter) in addition

to heightened parent and media awareness. Primary care clinician's also coordinate with subspecialists to manage many of the common comorbid disorders including ADHD, anxiety, behavior problems, intellectual disability, seizures, feeding problems, toileting problems, sleep disorders, and genetic disorders (Simonoff et al., 2008; Zafeiriou, Ververi, & Vargiami, 2007).

### **Obesity**

Obesity is a growing epidemic faced by children in the United States today and is associated with an array of additional health problems. Body mass index (BMI) is the measure using a child's weight and height to determine whether a child meets criteria for being overweight or obese. Unlike for adults, when the BMI alone can be used to determine their status, for children age- and sex-specific percentiles for BMI are used because children's body composition varies as they grow (Barlow & the Expert Committee, 2007). Overweight status is defined as having a BMI between the 85th and 95th percentile for children of the same age and sex, while obesity is defined as having a BMI at or above the 95th percentile (Barlow & the Expert Committee, 2007).

Approximately 17% (12.5 million) of children and adolescents aged 2 to 19 years in the United States meet criteria for obesity; since 1980, obesity prevalence among children and adolescents has almost tripled (Ogden & Carroll, 2010; Ogden, Carroll, Curtin, Lamb, & Flegal, 2010). Latino American boys and African American girls are significantly more likely to be obese than their counterparts. Causes include factors that increase caloric intake like portion size, sugary sweet beverages, marketing, lack of affordable nutritious food, and decreased physical activity, including TV viewing (for further information please see Calvert, Chapter 10, this *Handbook*, this volume), more sedentary activities, especially computers, decreased school physical education, and unsafe neighborhoods, which all can result in parents limiting their children's outdoor activity (Lumeng, Appugliese, Cabral, Bradley, & Zuckerman, 2006). Obesity is a known risk factor for the development of diabetes during childhood and cardiovascular, endocrine, and other adult health problems. Obesity can have a significant impact on the mental health of children including eating disorders, body image issues, bullying, and depression.

A four-staged stepwise care approach for weight management in pediatric primary care is recommended (Spear, 2007). First is prevention through counseling and provision of anticipatory guidance about nutrition, eating behaviors,

and exercise. Second is structured weight management involving use of logs and nutrition guides and frequent follow-up in primary care. Third is the recruitment of a comprehensive multidisciplinary intervention involving clinical nutrition, exercise physiologists, and behavioral health resources. The fourth and final level is tertiary care intervention, which involves consideration of the addition of medication to assist with weight management or surgical intervention such as gastric bypass; this level is reserved for the select few children who do not respond to intensive interventions from the first three levels (Spear et al., 2007).

### **Concussion and Head Injury**

A concussion may be caused by a direct blow to the head, face, neck, or elsewhere on the body with an impulsive force transmitted to the head. It typically results in the rapid onset of short-lived neurologic symptoms with or without loss of consciousness that resolve in a sequential course spontaneously. The term *concussion* is often used in medical literature as a synonym for mild traumatic brain injury (TBI). Each year in the United States, approximately 1.7 million people are diagnosed with a TBI, about 75% of which are classified as mild TBIs/concussions. By the time children reach 10 years of age, 16% will have had at least one head injury requiring medical attention (NCIPC & CDC, 2006).

Although symptoms typically resolve in a matter of weeks, children may suffer from postconcussion syndrome that may last for months or longer (Yeates, 2010). Symptoms can include headache, dizziness, cognitive impairment, and a range of psychological symptoms that may include changes in mood, alertness, anxiety, and PTSD-related symptoms.

Sports-related concussions appear to be common among pediatric and adolescent athletes but the prevalence is unknown. Team and contact sports such as football and ice hockey have the highest incidences of concussion, followed by soccer, wrestling, basketball, field hockey, baseball, softball, and volleyball (Koh, Cassidy, & Watkinson, 2003), but concussion can also occur in individual sports such as gymnastics or diving. Concussions in the high school setting occur more frequently in games than in practice. In coed sports concussion rates are higher for female than male high school athletes. Very little is known about the epidemiology of concussions in middle school-aged athletes and younger children (Jinguji et al., 2012).

Common approaches to treatment include (a) removal from sports and physical activity restrictions, (b) cognitive

rest with restriction such as television viewing, reading, and telephone or computer use, and (c) graduated return to activity. Such limitations pose significant challenges to children, their parents, and their teachers.

To better identify children who suffer concussion without loss of consciousness, there is an increasing trend to obtain either brief or comprehensive individualized baseline neuropsychological/neurocognitive testing of athletes. The challenge presented here is the child's individual desire to return to play. Some children and adolescent athletes report "fudging" their scores so they may return to play sooner. The wisdom, let alone safety, of children participating in contact sports is being widely discussed by parents and professionals. Children athletes (and even their coaches) may often need reminders of the long-term benefits as opposed to short-term gratification when deciding when to return to play (Cantu & Hyman, 2013).

### **Food Allergy**

Allergic conditions (asthma, dermatitis, food or chemical allergy with or without anaphylaxis, and allergic rhinitis) are the most common medical conditions currently affecting children and adolescents in the United States (Stone, 2003). Estimates of the prevalence in the United States indicate that approximately 35% of children under the age of 18 are diagnosed with a form of allergy (Braunam & Lukacs, 2008). The true prevalence of food allergy is unknown. Up to 25% of the general population believes that they may be allergic to some food; however, the actual prevalence of food allergy diagnosed by a provider appears to be 1.5% to 2% of the adult population and approximately 6% to 8% of children (Perry & Pesek, 2013). Food allergy affects nearly 6 million children in the United States and has been shown to limit social interactions and impair children's quality of life due to the ubiquity of food where children live, learn, and play (Dyer & Gupta, 2013).

Children and adolescents with allergies seem to have more symptoms of anxiety (Friedman & Morris, 2006). Anaphylaxis is an acute allergic reaction resulting in immediate symptoms of diarrhea, bleeding, vomiting, and bronchospasm. The pressure on parents to be vigilant about such exposures is significant and they live with a fear of death for their child due to inadvertent exposure (Broome-Stone, 2012). For children with such a severe allergic reaction, a mild level of anxiety can be adaptive because such children are less likely to participate in risk behaviors potentially exposing them to a known antigen (Mandell, Curtis, Gold, & Hardie, 2005). However, there is an increasing prevalence of debilitating anxiety which

imposes unnecessary restrictions on an affected child's life, preventing them from engaging in important daily activities at home, at school, or socially and need to be addressed (Manassis, 2012).

### **The Future of Prevention and Wellness**

The third era of health care will move beyond treating disease, child mortality, and rates of disease and, to a much greater extent than in the past, will emphasize wellness. An Institute of Medicine Report defined children's health as the extent to which they are able to develop their potential, satisfy their needs, and develop capacities to engage their world. The challenge for the future will be to operationalize and measure these important functional outcomes based on these goals (NRC & IOM, 2004). To accomplish these goals the child health system will require a more robust primary care that have information technology systems able to integrate and coordinate care not only within the health care system but also with the community health and human development systems. This includes schools, childcare centers, home visiting programs, family support programs, and other social scaffolding programs that are necessary to optimize a child's health and development. Physicians will need more training in child development, motivational interviewing, communication, and other areas related to child well-being.

A key component, especially for low-income families, will include mechanisms that complement public and community health efforts to address their material environment and social determinants of health. While Bright Future pediatric guidelines emphasize the importance of viewing the child in the context of the family and community, future guidelines for a patient-centered medical home (PCMH), especially for low-income families, will require routine identification of basic unmet material needs (e.g., food, employment, benefits, education, and pediatric visits) and will depend on access to the knowledge and resources available through appropriate community services (Garg et al., 2007). Presently, colocation of services such as the Women and Infant and Children program (WIC) within PCMH facilitates access, but such efforts need to be expanded to include housing programs, child training centers, GED programs, and food pantries to enhance access. If not fully colocated, linkages to community resources ensure access and need to be developed and monitored over time.

Home visiting programs to promote child development and parenting skills as well as assist parents with specific

needs such as school enrollment, employment, and accessing social safety net programs, have expanded and should be linked and potentially colocated in clinics to facilitate synergy of action and communication between the health care team and the home visiting team. Healthy Steps is an example of colocated child development services in a pediatric practice that increased home visits, child development screenings and advice, and selective parenting practices (Zuckerman, Parker, Kaplan-Sanoff, Augustyn, & Barth, 2004). Healthy Steps is the only one of eight federally approved programs for funding home visiting that is based in pediatric practices and needs to be expanded.

Primary care efforts to ensure health are undermined when patients do not receive the benefits and protections of laws that address a host of influential social determinants. Studies reveal that low-income households have an average of one to three unmet legal needs related to income, housing problems, employment, and family issues such as guardianship or domestic violence. Medical-Legal Partnerships, an innovation in health care delivery, have lawyers on site in health care settings, which improves the system by being able to address social determinants of individual patients and develop practice and policy changes for all members of the community (Sandel et al., 2010). Medical-Legal Partnership practices screen patients to identify problems including: Income Supports, housing and utilities related disputes, education, employment, immigration status, and personal/family stability and safety. The potential for doctors and lawyers working together to go beyond individual patients to promote community health has been demonstrated (Klein et al., 2013). While MLPs are in over 200 practices nationally, further expansion will help more families address legal problems they face.

Unlike the single clinician of the past, the future PCMH will consist of a physician-led team that may include some or all of the following trained care coordinators: nurses, nurse practitioners, nutritionists, social workers, developmental specialists, and other ancillary providers. To be family-centered, PCMH will solicit input from families, whether by surveys or advisory boards, not only about care of their children but also how the practice can best meet their needs. Examples of PCMH team tasks for newer problems listed in the preceding section are as follows. For obesity: (a) track and facilitate regular follow-up, (b) engage families in the process of adopting healthier life styles, and (c) coordinate with nutrition, subspecialists, schools, and other community resources. For ADHD: (a) referral to community resource for psychosocial aspects

of management, (b) coordinate with schools, therapists, etc., (c) track medication use, and (d) track follow-up visits to monitor behavioral and academic progress, blood pressure, and growth.

### *Two-Generation Approach to Child Health Care*

A life course approach to promote childhood wellness in health care will need to involve a two-generational model of health care since both child outcomes and women's health are strongly linked to each other and to upstream social factors (Zuckerman & Kahn, 2000). Social factors associated with child outcomes have found sizeable effects for women's health (usually depression) as a potential mediator of social factors (Duncan, Brooks-Gunn, & Klebanov, 1994; Korenman, Miller, & Sjaastad, 1995). Male or fathers' health is also important but little data exists except for mental health problems, smoking and violence and its impact directly or indirectly on the mother and children. At the present time, women's health is approached as a series of distinct risk factors posing threats to specific child outcomes. Many intervention and policy opportunities are missed as a result of the failure to recognize that many child health disparities have their origins further upstream in the general health of women starting with the health of girls during their childhood.

Prenatal care affords only a limited period of time to initiate intervention to prevent poor birth outcomes, since many women's health conditions exist prior to conception, and their impact often begins well before any effective prenatal care intervention can be put in place or be effective. Effective treatments for such problems as domestic violence, depression, poor nutrition, cigarette smoking, drug and alcohol use, and infections require timely and prolonged therapies that are not well served by prenatal care that starts after conception and often ends with a single postpartum visit.

Even women who enter the health care system prior to conception face substantial fragmentation of their health services (Weissman & Olfson, 1995). Obstetrician-gynecologists tend to be more thorough in the provision of Pap smears, breast examinations, and mammography, while other adult care providers are more likely to offer cholesterol screening, smoking cessation aids, and screening and initial treatment for depression. The likelihood that a woman sees both a gynecologist and an internist increases with higher income and more years of education. Reproductive health care services, such as family planning and abortion, are also frequently splintered from mainstream medicine (Gottlieb, 1995).

The availability of effective clinical interventions for such problems as depression (Katon et al., 1995), smoking (Hurt et al., 1997), drug addiction, and emergency and nonemergency contraception (Glasier, 1997) increase the need to reevaluate existing systems of health care for women. Since many mothers may not seek help for their own needs, the pediatric or other child health clinician has a special opportunity to identify and engage women with depression, violence exposure, cigarette smoking, and other potentially endangering conditions. For example, two simple questions have been shown to identify depression in mothers with 83% sensitivity and 90% specificity (Kroenke, Spitzer, & Williams, 2003, p. 1287): "Over the past two weeks, how often have you been bothered by any of the following problems: (1) Loss of interest or pleasure in doing things and (2) Feeling down, depressed or hopeless?" Because depressed individuals are not well motivated to take care of themselves, the challenge to the health care team goes beyond identification to support a successful referral to a mental health specialist for evidenced based treatment (Zuckerman & Kahn, 2000).

A similar opportunity exists for identification of intimate partner violence (here, IPV) to obtain safety and intervention for both mother and child (Bair-Merritt et al., 2013). While child health clinicians may not be able to prevent initial exposure to IPV they can at least attenuate the health and emotional consequences. Since children over the age of 3 may be traumatized by direct IPV discussions in their presence or may later repeat the conversation with the perpetrator, providers are encouraged to screen the mother alone or use general questions about how parents work out arguments or how would they describe their relationship with their partner (i.e., a lot of tension, some tension, or no tension). When IPV is disclosed, community IPV programs are an important resource to protect women and children's safety. Children should be referred to trauma informed health providers for evidence based interventions, such as trauma focused cognitive behavioral therapy, that reduce children's trauma symptoms (Groves, 1999).

Preventing unplanned pregnancies is another example of a pediatric opportunity for the future. While the studies have limitations, unintended live births suffer a disproportionately high rate of maternal and infant health problems, interfere with young mothers completing their education, and reduce the financial and emotional resources available to support and nurture existing children (Brown & Eisenberg, 1995). Helping to prevent unintended pregnancies; 3.3 million per year, 43% of which end in abortion (Finer &

Zolna, 2011) is another opportunity for a two-generational model of pediatric primary care. Long-acting reversible contraceptive (LARC) methods, as well as intrauterine and other implantable devices, are over 99% effective, safe, and save money, making access to these methods an important goal for the health care system (Zuckerman, Nathan, & Mate, 2014). In the future, pediatricians in primary care should ask mothers about their child spacing plans since an unplanned pregnancy may dilute a family's emotional and financial resources to that child. Beyond providing information and referral, pediatricians could be trained to provide implantable devices because the procedure is relatively simple and quick. Placement of IUDs takes more time and training and will need a referral.

## CONCLUSION

The past century has seen significant changes in the epidemiology of children's disease and in the ecosystem of children's health care. The progressive understanding of the causes of child health problems as rooted in an interaction between social-environmental and biologic factors will inform the future. Children's social, emotional, and developmental functioning and well-being are even more important because they are most vulnerable to the confluences of factors and forces affecting their health. Supporting the health and wellness of children has the potential to alter the trajectory of disease throughout life span and improving the health and wellbeing of adults as well as children.

## INTRODUCTION

This chapter provides a broad overview of the legal regulation of children and the extant or potential use of developmental science to guide legal decision making. The term *legal regulation* includes two related considerations. The first concerns *protections* afforded to minors, and the degree to which these protections are subordinate to the rights of parents, or can otherwise be curtailed in service of state goals. Many such protections are independent

of developmental status (e.g., rights to privacy, due process, protection from harm), so legal policy in their regard has typically been grounded in nondevelopmental considerations, such as the need to balance protection of the child with the rights of parents to discipline their children, or the need to ensure that a child's rights do not interfere with a school's educational mandate. In some contexts, minors are afforded greater protection than adults, and developmental science can inform discussions of the degree to which such additional protections are justified.

In other contexts, minors receive less protection (primarily in situations involving autonomous decision making), and developmental science can again be brought to bear.

The second aspect of legal regulation focuses on the *responsibilities* of minors, including the extent to which minors should be granted autonomous decision-making authority and held accountable for their decisions. In certain respects, such considerations overlap with the protective ones, since limitations to minors' autonomy or accountability can be viewed as legal protections (i.e., protecting minors from the consequences of their own poor judgment). Regardless of how they are categorized, these questions are specifically concerned with the extent to which minors differ from adults in ways that warrant differential treatment under the law. Because questions about the presence or magnitude of differences between minors and adults are most likely to be raised when the minors are relatively older, and their abilities not so obviously different from those of adults, the focus of these debates is almost always on the regulation of adolescents. It is in this context that developmental science has been, and can be, most informative. For example, the science of adolescent development can inform judgments regarding whether minors of a certain age are able to provide informed consent for medical procedures, participate in their own defense during a trial, understand the terms of a legal contract, or know their legal rights in different contexts. The same developmental considerations also may influence judgment regarding whether minors are better candidates for rehabilitation than adults, or should be subject to adult-scale punishment for antisocial behavior.

Any discussion of legal policy must be placed within a broader social context. In this chapter, we focus our attention on legal policy regarding children and adolescents within the United States, and further narrow our discussion to issues sufficiently important (and controversial) to have reached the highest level of jurisprudential analysis, the United States Supreme Court. We acknowledge that an analysis of a different country's approach to the legal regulation of children might paint a very different portrait, but a full discussion of the legal treatment of children and adolescents internationally would be prohibitively lengthy and complex, because laws and social standards vary considerably from nation to nation. Indeed, even within the United States, many laws that concern minors vary from state to state (e.g., the age at which offenders can be tried as adults). Focusing on judicial decisions at the federal

level allows us to consider standards of legal treatment that apply broadly within a single legal framework, and permits us to examine the ways in which developmental science might inform legal decision making across a range of topics. Thus, the discussion that follows will consider existing U.S. Supreme Court decisions, examining the differences and commonalities in the treatment of children and adolescents across a variety of legal domains, specifically in light of current understanding of development.

Legal policy in the United States regarding children and adolescents has evolved gradually based on conventional wisdom, philosophical reasoning, and practical considerations codified into law and distilled into precedent via legal opinions. Developmental science sometimes informs such opinions, but frequently the relevant research, by necessity, must be designed to address presumptions behind existing legal precedent. Specific standards often vary depending on the issue, but legal presumptions about the inherent immaturity of children and adolescents are numerous. With rare exceptions, those below the age of legal majority (which is 18 in all but four states) are neither expected nor permitted to be responsible for their own welfare. Minors' rights in school and their access to offensive material are limited in many respects, as the court has taken the stance that states have a primary responsibility to properly socialize the nation's youth. In medical settings, adolescents are considered unable to provide informed consent for most health care procedures; the consent of a parent or legal guardian is typically required. Under contract law, minors receive special protection, because immature individuals are more easily taken advantage of; minors are allowed to enter contracts but may disavow them at any time. The contemporary juvenile justice system is based on the premise that many transgressions committed by minors are the result of poor or immature judgment, and that minors can be rehabilitated more easily than adults (i.e., that their character is less mature, or less fully formed).

Although younger children and older adolescents are often lumped together as "minors," adolescents are treated differently than younger children in some contexts. In recent years, the prevailing view of adolescents as inherently less mature than adults has been challenged on several fronts. Public outrage over juvenile violence has provoked debate about the longstanding practice of treating adolescents within a separate justice system, and instances of young defendants being tried as adults have become commonplace. In discussions of adolescent health

care, it has been argued increasingly that teenagers are sufficiently mature to provide informed consent in a variety of situations, and several states have enacted statutes that authorize minors to consent for health care or that allow adolescents to seek treatment without parental consent for health problems related to sexual activities, drug and alcohol use, or psychological distress.

Developmental science has led to significant improvements in our understanding of the underpinnings of mature decision making and is increasingly used to inform legal arguments that historically have relied less on empirical evidence than on conventional wisdom. Chief among the key developmental findings related to the evolution of maturity during adolescence is a nuanced understanding that maturity involves a combination of different factors, such as cognitive sophistication, the ability to resist peer pressure, the capacity to resist impulsive urges, and the forbearance to consider factors such as long-term consequences, the viewpoints of others, and the recommendations of experts. These various competencies and characteristics emerge and stabilize at different times during adolescent development and have differential effects on decision making, depending on the context. For example, impulsivity and peer pressure play a greater role in decisions related to delinquent behavior than they do in decisions regarding medical treatment. Therefore, to the extent that we wish to rely on developmental science to inform where we draw age boundaries between adolescence and adulthood for purposes of public policy, it is important to match the policy question with the relevant science.

In the sections that follow, we review the ways that the legal regulation of children and adolescents has evolved across a broad array of domains, including the family, school, the justice system, medical settings, and society more broadly. In the section on the treatment of children in family contexts, we note that the relevant legal decisions emphasize protections, leaving little room for developmental considerations. In the section on the treatment of children at school, we similarly conclude that legal decisions grapple primarily with the extents and limitations of students' rights from a paternalistic vantage point, without regard to developmental competencies. In contrast, in the section on the treatment of children in the justice system, we find that developmental science has been a key consideration and has shaped several important legal decisions. In medical decision-making contexts, developmental considerations also play a role, but are often considered secondary to questions concerning the relative rights of minors and their parents. Finally, in other social

contexts, such as those involving contracts, exposure to indecent material, sexual behavior, and the transmission of indecent material via electronic communications, the focus again returns to the protection of children and adolescents (from car salesmen, pornographers, sexual partners, and themselves), and to a debate about the extent to which privacy rights apply to minors' intimate behavior.

## LEGAL TREATMENT OF CHILDREN AND THE FAMILY

Before considering how children and adolescents are treated at school, at the police station, at the doctor's office, or at the bank, we start by considering how they are treated at home, in relation to their family. In the midst of a society of "helicopter parents" where childrearing is considered the primary priority of any parent, with all other duties considered secondary, and with "the best interest of the child" always at center stage, it is difficult to imagine that prior to the early 1800s, children were legally considered to be property or chattel (Hart, 1991), valuable to their parents for their economic contributions, but without any inherent legal rights of their own. (This is not to say they were not loved by their parents. But legally speaking, their status was essentially equivalent to that of livestock.) With unlimited power over their children, parents could ignore, abuse, or abandon them with impunity (Pappas, 1983). Early state law codified parental control to the point of expressly allowing for capital punishment of disobedient children (Horowitz, 1984).

Social norms began to evolve in the 18th century, with parents "almost beginning to consider their children as of the same flesh and blood as themselves" (Bayne-Powell, 1939, p. 1). But the state's role in protecting children did not begin to reflect this shift until the 19th century, with the first reported *parens patriae* court action (in which the state intervenes for the protection of a child against an abusive or neglectful parent) appearing in 1838, and eventually leading to the establishment of the explicitly paternalistic, authoritarian juvenile court system of the first half of the 20th century. More recently, "the best interests of the child" has been adopted as a fundamental principle of the UN Convention on the Rights of the Child (Article 3), referring to "such protection and care as is necessary for his or her well-being" (UN General Assembly, 1989, p. 7). The United States signed the convention in 1995, but has not ratified it.

The gradual recognition of children as having interests worth protecting was obviously a major step forward in

ensuring their welfare. But this recognition has led to conflict in determining who is responsible for defining a child's best interests. When children were livestock, it was simple: children were the property of their fathers, and remained so despite divorce or abuse. But as children's welfare became a priority, legal policy evolved to allow mothers to receive custody, and to allow the state to revoke parental rights to protect a child's safety. A foster care system grew. A juvenile justice system grew. Each was designed with the goal of acting in the child's interests. Yet, despite this focus on the child's interests, there still remain very few situations in which the child is granted direct legal status. They generally are barred from initiating legal proceedings themselves. They may be allowed to express a preference in custody hearings. In every domain related to family law, legal decisions have evolved to protect the interests of children and adolescents, but have stopped short of presuming them to be competent to determine those interests. The history of family-related legal decisions is therefore dominated by decisions made by adults *about* children, rather than decisions in which children are actively involved. Issues relating to "best interests" are distinct and separate from those relating to "self-determination," and courts continue to operate under the presumption that minors are not competent to act in their own interests.

The exception to this general rule prohibiting minors from having independent legal status is the granting of "emancipated minor" status to minors. The conditions under which such status may be explicitly granted by courts will be discussed later in this chapter, and revisited in the portions dealing with medical and social contexts. Youths with "emancipated minor" status are, legally, free from parental control, and thus no longer subject to disputes over custody, adoption, or parent-child immunity laws. As a rule, however, such status is not granted solely on the basis of a youth's demonstrated level of maturity, unless other situational requirements also apply.

In the following sections we review the evolution of the treatment of children in several domains of family law, including custody decisions, foster care and adoption proceedings, the ability of children to pursue legal action against their parents, and the pursuit of "emancipated minor" status. In all but the last, considerations relating to decision-making abilities and maturity play little, if any, role. Nevertheless, a review of these areas provides a useful backdrop for subsequent discussion of the treatment of children in other legal domains. For additional information on the historical perspective of childhood, see Stearns, Chapter 20, this *Handbook*, this volume.

## The Treatment of Children in Custody Decisions

Until the early 1800s, children were viewed as chattel, and fathers were automatically considered to be their owners. Fathers thus had legal claim to any economic output of his children. This provided motivation for fathers to provide support and protection. Mothers, in contrast, had no legal standing in any court action, including divorce. They did not have any presumptive rights regarding child custody or to have continued contact with children, who remained the property of the ex-husband. Parental fitness considerations began to take hold during the early 19th century, along with the emerging role of the court as a protector of the child's interests.

The first case precipitating this change was *Rex v. Greenhill* (1836). A husband had moved out of the marital home to live with his mistress, after which his wife took her young daughters to live with her family for financial support. The husband filed a habeas corpus action for the return of the children, in response to which the wife fled to Europe with her children. The incident prompted Talfourd's Law in 1839, giving courts discretion to grant mothers custody of children under the age of 7, and visitation rights for children of any age. This "tender years doctrine" established an explicit preference for mothers as more appropriate caregivers for young children (with some exceptions), and was further expanded in 1873 to allow mothers to be granted custody of children as old as 16.

The tender years doctrine dramatically shifted the basis of custody decisions in divorce proceedings. Instead of being the presumptive owner of his children, a father had to prove the mother an unfit caregiver if he wished to retain custody. Although the tender years doctrine was established with the best interests of the child in mind, it took almost a century before the doctrine's explicit preference for the mother as caregiver evolved, state-by-state, into a more gender-neutral "best interests of the child" standard. Currently, West Virginia is the only state in which either parent is presumed to have a superior right to child custody.

The Uniform Marriage and Divorce Act (1979) lists factors a judge may consider in reaching a custody decision. These include the mental and physical health of all individuals; the child's adjustment to home, school, and community; each parent's ability to provide food, clothing, medication, and other care; each parent's lifestyle; the child's needs; and the wishes of the parent and the child. The last factor (the wishes of the child) is indicative of a recent trend toward increasing the degree of self-determination afforded to minors. At least 20 states

permit children beyond a specified age to state which parent they prefer for custody. Jurisdictions vary widely, however, in the amount of weight placed on the child's stated preference.

Generally speaking, the evolution of custody law has moved from considering children as commodities to considering their interests, but while children are often allowed to express an opinion, the court ultimately decides what is best for the child.

### **Adoption, Foster Care, and the Termination of Parental Rights**

The above-noted shift in philosophy, establishing the interests of the child as a prime consideration in custody disputes, leads to a new, but related question: To what extent should the state intervene to protect the interests of children in families where there is no custody dispute? On one hand, the state has generally avoided interfering with parents' rights to raise and discipline their children as they see fit. On the other hand, when a child is being severely or chronically maltreated, the state's interest shifts to the protection of the child, and laws now mandate that children be removed from homes in which they cannot live a safe existence.

The appropriate balance between family preservation and child protection has varied over the past several decades. Prior to 1980, children removed from their families frequently spent extended periods in foster care. The federal Adoption Assistance and Child Welfare Act (AACWA), passed in 1980, attempted to prevent unnecessary foster care placements, reunify families when possible, and limit time spent in foster care by encouraging adoption when return to a birth parent is not possible. The law was generally considered unsuccessful, with critics arguing that it focused too much on family preservation (White, Albers, & Bitonti, 1996). In 1997, Congress passed the Adoption and Safe Families Act (ASFA), which requires a permanency hearing within 12 months of a child entering foster care, and requires that a petition to terminate the parent's rights be filed for any child who has spent 15 of the past 22 months in foster care (excepting cases where a relative is caring for the child or there is some other compelling reason that termination would not be in the child's best interests). While the ASFA was designed to prevent children from being repeatedly moved to foster homes and then back to their parents by streamlining the process through which parental rights are terminated,

the drawback of this approach is that parental rights are more often terminated before a subsequent adoption can be arranged, leaving larger numbers of children with no legally recognized parents (O'Laughlin, 1998).

The involuntary termination of parental rights requires a strict standard of proof, in which it must be ruled that parents are *unfit* as parents before their rights can be terminated (*Quilloin v. Walcott*, 1978). Standards vary from state to state, but generally, abuse, neglect, mental instability, drug or alcohol addiction, and incarceration are typical factors that would lead to finding a parent unfit. Because of the irreversible nature of the termination of parental rights, many judges are reluctant to grant terminations (Sommer, 1994).

In most cases, termination of parental rights begins with potential neglect or maltreatment coming to the attention of law enforcement or social service agencies, which then intervene on the child's behalf. As in custody decisions, children's wishes may sometimes be considered when placement decisions are made, but children are not granted formal legal standing. In 1992, after the department of social services decided to remove him from a foster home and return him to his birth parents, Gregory Kingsley (Age 11) petitioned to terminate his birth parents' rights. Gregory was initially successful in terminating his parents' rights, but the Florida appellate court overruled the trial court decision, stating that "unemancipated minors do not have the legal capacity to initiate legal proceedings in their own name" (*Kingsley v. Kingsley*, 1993, p. 782). Similarly, in divorce proceedings, children are prevented from formally intervening on their own behalf. In *Miller v. Miller* (1996), the children involved in a custody dispute employed their own attorney, but the court held that there was no common law basis for intervention of minor children in their parents' divorce action. Generally, although some states allow children direct access to the courts, most children can only gain such access through a guardian ad litem.

### **Children as Plaintiffs, and Parent-Child Immunity**

Protections against the abuse of children have evolved considerably since the 1800s, with courts intervening to remove children from unsafe environments and terminate the rights of unfit parents. However, children have, at the same time, been prohibited from suing their parents, based on a series of state Supreme Court decisions establishing as common law the so-called parent-child immunity rule. In *Hewellette v. George* (1891), Mississippi ruled that minors

could not sue parents for bad acts, holding that the integrity of the family and the best interests of society barred a child from suing for personal injuries sustained at the hands of a parent. In *McKelvey v. McKelvey* (1903), Tennessee denied a child damages from her father, who had criminally assaulted her. Similarly, in *Roller v. Roller* (1905), Washington rejected a suit brought by a child whose father had raped her. Some more recent cases, however, have begun to erode the precedent of the parent-child immunity rule. In *Hoffman v. Tracy* (1965) a Washington state court wrote, "A parent who takes a child in an automobile with him and drives it while he is intoxicated is temporarily abdicating his parental responsibilities and is not entitled to immunity" (p. 327). There is also now federal precedent that children who suffer intentional harm at the hands of their parents can pursue compensation in personal injury actions (*Wilson by Wilson v. Wilson*, 1984). As has been the case with custody and parental rights, it appears that there is a continuing trend, in which the legal system is increasingly willing to overrule the default assumption that parents know best in situations where the parents abuse or neglect their children, and to provide means for the protection of children's interests. By requiring children to be represented by a guardian ad litem, however, courts have generally avoided issues of competence and maturity of judgment that would otherwise come into play in family-related legal disputes.

### Emancipated Minors

The one area of family law where a child's maturity and decision-making abilities have a direct bearing is in the granting of "emancipated minor" status, whereby a minor can be granted legally autonomous status. Such status is generally applied only to minors who, for situational reasons, are understood to be legitimately beyond the reach of parental authority, that is, when a youth has de facto independence from his or her parents. Though the specific applications of this doctrine vary from state to state, emancipated minor status may be awarded based on financial independence, military service, or the adoption of a primary relational role other than "child," either by marrying or by becoming a parent. In the absence of statutes specifying otherwise, common law permits emancipated minors to be treated like adults for most purposes (Garber, 2009; Hill, 2012; Robertson, 2008). Emancipated minors can thus buy and sell property, borrow money, provide medical consent, sue or be sued, or be tried as adults.

### Summary of Legal Regulation of Children in Family Contexts

The gradual evolution of the legal treatment of children and adolescents in family-related matters has been driven largely by concern for their safety and well-being, recognizing a child's right to an existence free of abuse or neglect, but stopping short of recognizing any right to self-determination or independence. Accordingly, the decision-making competencies of minors are not a consideration in most family-related legal contexts. A mechanism does exist for minors to be granted "emancipated" status. In some cases, the maturity of the minor (as evaluated by the judge) is one of the factors considered in determining whether to grant such status. But it is never the only factor, and, in many situations, is not even a necessary factor if certain other conditions (e.g., parenthood) are met. So while developmental science has the potential to inform judges' evaluations of maturity, the factors driving emancipation decisions typically are driven more by practical and logistical considerations, rather than by a youth's cognitive or psychosocial characteristics.

In the sections that follow, similar themes will emerge. The rights of minors are stratified, with protections against harm or mistreatment generally being upheld, but with rights of self-determination, self-expression, or autonomy generally being denied or substantially restricted. It is primarily in the areas where these rights overlap (for example, where denying autonomy could cause harm) that courts have been willing to relax restrictions on self-determination. Absent such circumstances, autonomy-related rights are considered secondary to the rights of parents (to control their children's upbringing) or the priorities of schools (to limit disruptions to the education and development of the broader student population).

## CHILDREN'S RIGHTS AT SCHOOL

Compulsory school attendance laws have made schools a context to which virtually all American children and adolescents are exposed. Given that society relies on schools to educate and socialize its citizens, schools exhibit a pervasive influence on the lives of American youth. Through a series of contentious cases, the Supreme Court has demonstrated its deference to school by taking the stance that, although minors should indeed be afforded some constitutional protections, schools should have the authority to take necessary steps to ensure that they can uphold their primary

goals of educating, socializing, and protecting the welfare of their students.

Two interwoven themes are at issue in the court's discussions of children's rights at school. The first theme has as its focus on the unique mission of schools and the degree to which students' rights in public schools may be curtailed in service of state goals, such as avoiding disruption, protecting youth, and promoting proper socialization. The second theme concerns the degree to which schools may infringe on students' privacy in service of these goals. We focus on how these two themes are manifested in the decision-making process and rhetoric of the most influential school-related United States Supreme Court cases. Specifically, we explore the cases that have reinforced or set limits on public school students' rights in regard to free speech, due process, including search and seizure, and corporal punishment. In general, the Supreme Court has shown much deference to schools with respect to regulating and protecting students, however, the court will rule in favor of students when schools violate student rights to privacy or due process without some minimal threshold of reasonable justification. We also discuss schools' zero tolerance policies, as they relate to due process concerns, and the potential *school-to-prison pipeline* that may result from these and other "get tough" school policies. Developmental science has not made a substantial impact with respect to students' rights in school: the relevant Supreme Court decisions generally focus on the perceived vulnerabilities of schoolchildren, and the need for protection, rather than on issues relating to developmental competencies.

### **First Amendment Rights in Public Schools (Free Speech and Expression)**

U.S. Supreme Court justices have mixed opinions with respect to the First Amendment rights that should be extended to public school students. For example:

It can hardly be argued that either students or teachers shed their constitutional rights to freedom of speech or expression at the schoolhouse gate. (Justice Fortas's opinion in *Tinker v. Des Moines*, 1969)

And almost four decades later:

As originally understood, the Constitution does not afford students a right to free speech in public schools. (Justice Thomas's opinion in *Morse v. Frederick*, 2007)

Although adults enjoy the right to freely and openly express their ideas, students in the public school system

do not have the same rights, at least while involved in school-related activities. There are five Supreme Court cases that have demonstrated the court's position regarding the rights that should (or should not) be guaranteed to public school students. This section takes as its point of departure the landmark case of *Tinker v. Des Moines Independent Community School District* (1969), which was the first and most influential First Amendment case for students. After *Tinker*, in all but one case (*Board of Education of Westside Community Schools et al. v. Mergens*, 1990), the Supreme Court has continued to limit the free speech rights of schoolchildren.

### ***Tinker v. Des Moines Independent Community School District* (1969)**

In *Tinker*, three public school students, Ages 13, 15, and 16, were suspended from school for knowingly violating a school policy that prohibited the wearing of black armbands in protest of the United States' involvement in the Vietnam War. These three students, whose parents knew about their children's decision to wear the armbands, were not allowed to return to school until they removed the black bands. After appeals and hearings in lower courts, led by their fathers, the case eventually made it to the Supreme Court. The issue was twofold: whether the constitutional right of free speech and expression should be extended to children attending public schools, and whether the mission of public schools gives schools a special obligation to override the individual rights of school children. In the end, the court ruled in favor of the students and held that free speech rights of minors in the public school system should be protected except when school authorities have reason to suspect that doing so would interfere with the normative functioning of the work of the school or cause "substantial disruption." In this case, the disclaimer attached to the First Amendment rights for schoolchildren was not based on developmental science, but rather, was a matter of balancing children's rights with the mission of the school and the rights of other students. In support of schools' obligation to provide a safe and supportive environment for all children, the court chose to place restrictions on children's rights of freedom of expression.

The *Tinker* case recognizes that although minors indeed have the Constitutional right of free speech, those rights can be subject to limits not normally applicable to adults. Since *Tinker*, however, the Supreme Court has expanded the definition of "serious disruption," which has correspondingly scaled back students' speech rights.

***Bethel School District v. Fraser (1986)***

The first Supreme Court case to challenge the speech rights established in *Tinker* was the case of *Bethel School District v. Fraser* (1986). The case centered on a sexually suggestive speech delivered by Matthew Fraser, a 17-year-old public high school student, to 600 classmates:

I know a man who is firm—he's firm in his pants, he's firm in his shirt, his character is firm—but most of all, his belief in you, the students of Bethel, is firm. Jeff Kuhlman is a man who takes his point and pounds it in. If necessary, he'll take an issue and nail it to the wall. He doesn't attack things in spurts—he drives hard, pushing and pushing until finally—he succeeds. Jeff is a man who will go to the very end—even the climax, for each and every one of you. So please vote for Jeff for A.S.B. vice president—he'll never come between you and the best our school can be. (*Bethel School District v. Fraser*, 1986, p. 687)

School authorities determined that Fraser had been in violation of a Bethel High School rule: "Conduct which materially and substantially interferes with the educational process is prohibited, including the use of obscene, profane language, or gestures." In response to the speech, school officials suspended Fraser for 3 days and denied him the previously approved opportunity to speak at the graduation ceremony. With support from his mother, Fraser filed a civil rights action. Though lower courts initially ruled in favor of Fraser, citing a lack of proof that the speech violated *Tinker*'s "serious disruption" requirement, the Supreme Court reversed the ruling and held that Fraser's punishment was warranted. The court ruled that, although adults may use offensive speech, public school students are not permitted to use speech that is vulgar or features excessive sexual innuendo, even if the speech does not cause "serious disruption" at school. The court, focusing on the content of the speech and the youthful audience, stated that the *Tinker* criteria were intended to apply to political messages—not sexually suggestive (or morally motivated) messages. The Supreme Court ruled that student First Amendment rights "are not automatically coextensive with the rights of adults in other settings" and that school authorities did, in fact, have the right to shield students from offensive and insulting speech. Fraser's speech was deemed "offensively lewd and indecent" and the court found that his right to subject a captive audience of other children to such messages could be curtailed.

The idea that adults (i.e., public school officials) can—and should—shelter minors from vulgar or offensive speech was not new to the Fraser case. Cases such as

*Ginsberg v. New York* (1968) and *Federal Communications Commission v. Pacifica Foundation* (1978) had already affirmed the parental responsibilities of state officials in some contexts. The common law doctrine of *in loco parentis* provides a standard by which states should protect youth, as parents would, for example, by regulating children's exposure to material that is perceived to be offensive or inappropriate for young people—including obscene material that would be constitutionally protected for adults. This argument emphasizes the court's concern for protecting youth from offensive speech while also teaching young people the boundaries in which ideas and opinions can be expressed in socially acceptable ways. As such, the court has allowed schools to regulate student speech when such speech is either disruptive or viewed as implicitly harmful to other children who are exposed to it.

***Hazelwood School District et al. v. Kuhlmeier et al. (1988)***

The Supreme Court again emphasized its deference to school authorities in *Hazelwood School District et al. v. Kuhlmeier et al.* (1988). The issue in this case was whether public school authorities could censor articles in a student-authored school newspaper that was edited by the teacher of a journalism course and published using school resources for subsequent distribution to other students.

The case involved three high school students who believed the principal violated their First Amendment rights when, based on the content of the articles, he instructed the journalism teacher to delete two pages of text before printing the newspaper. One of the deleted articles described students' experiences with teenage pregnancy, which was a topic the principal believed was inappropriate for younger students. The principal was also concerned that the pregnant students quoted in the article could reasonably be identified, given the information in the story and low prevalence of student pregnancies at the school. The second deleted article concerned students' experiences with their parents' divorce, which the principal believed was unfair to parents referenced in the article (the principal did not realize that the journalism teacher had deleted the student's name from the final draft). The students believed that the articles had been unjustly censored, and that, per the *Tinker* "disruption" criteria, their speech and expression rights had been violated.

Lower courts disagreed about whether the principal violated the students' First Amendment rights, and the case was eventually heard in the Supreme Court. The court ruled that schools are allowed to censor student speech if

the decision to censor is genuinely related to the goals or mission of the school. As in the previous cases, freedom of expression is trumped by the duty of schools to protect students from harmful messages. It was this line of reasoning that allowed the Court to give less emphasis to the *Tinker* criterion of “serious disruption” and focus its decision on whether the school was *required* to promote and disseminate certain student opinions. This decision again underscored the court’s deference to school authorities and its desire to give schools fairly broad discretion when regulating student speech, as long as such regulation is not arbitrary.

### ***Morse v. Frederick (2007)***

Decades later, but in line with the decisions of the *Bethel* and *Hazelwood* cases, *Morse v. Frederick* (2007) resulted in further limitations on minors’ speech rights. At issue in *Morse* was whether students could be punished for off-campus speech perceived to promote illegal behavior. Just before the 2002 Winter Olympics in Alaska, Deborah Morse, the principal of Juneau-Douglas High School, allowed students to leave school grounds (chaperoned by teachers) in order to walk across the street and watch the Olympic Torch relay. While observing the relay, senior Joseph Frederick held up a 14-foot sign that read, “BONG HiTS 4 JESUS.” After Frederick refused to take down the banner, Morse confiscated the sign and gave Frederick 10 days of suspension for violating a school district policy that prohibited the promotion of illegal substance use. Frederick sued, and a round of trials and appeals in lower courts followed, which eventually landed the case in the Supreme Court. In the end, the Supreme Court held that Principal Morse was justified in suspending Frederick, as it was clear that the banner promoted illegal substance use and the school was right to punish students who openly encourage or celebrate unlawful behavior.

### ***Board of Education of the Westside Community Schools et al. v. Mergens (1990)***

Interestingly, though the Supreme Court curtailed minors’ First Amendment rights in the three previously described cases, students’ right to express religious beliefs has been upheld in at least one Supreme Court since *Tinker*. In *Board of Education of the Westside Community Schools et al. v. Mergens* (1990), a group of high school students wanted to add an after-school Bible study group to an existing list of available student clubs. The principal and superintendent denied the request to form the religious group and Bridget Mergens (unsuccessfully) appealed the case to the board

of education. The case eventually reached the Supreme Court, where the court recognized the existence of other “noncurriculum related student groups” (e.g., chess club, swimming club, skin and scuba diving), and concluded that the Equal Access Act therefore prevented the school from denying equal support to the proposed Bible study group. Because the school already allowed groups that were centered on topics that were not a part of the school curriculum, the Supreme Court ruled in favor of Mergens and supported the request to form a religiously affiliated student group. The Court made this decision based on the assumption that high school students can appreciate that just because a group is allowed to meet on school property does not necessarily mean that the school supports or endorses the opinion of the group.

### ***Summary of First Amendment Decisions***

The Supreme Court has given school authorities a great deal of discretion with regard to determining acceptable and appropriate student free speech behavior. In particular, schools are allowed to curtail student engagement if the speech has the potential to cause “serious disruption,” or if the content of the speech is reasonably perceived to be inconsistent with the school mission, is openly lewd and lascivious, or promotes unlawful activity. Schools that allow for the organization of voluntary, noncurriculum student groups may not, however, prevent the organization of a specific group on the basis of religion. And student expression may not be prohibited if it is not disruptive or harmful. These decisions, as a whole, represent a fundamental premise that children, as compared to adults, are vulnerable and immature, requiring in loco parentis protection while under a public school’s care.

In none of these cases did the Supreme Court make an argument with regard to developmental science. The decision to restrict minors’ free speech rights was based on the court’s assessment of the unique mission of public schools, the perceived immaturity of school children, and the need to act in ways that promoted the socialization and positive development of children. Since school is compulsory, schools are expected to safeguard the students from harmful influences, including disruptive or harmful speech by other students. It is unclear how the court will respond to schools’ attempts to regulate students’ online behavior. Such cases have appeared in lower courts (*Doninger v. Niehoff*, 2008; *Kowalski v. Berkeley County Schools*, 2011; *Wisniewski v. Board of Education of Weedsport Central School District*, 2007) but, as of this writing, have not been considered by the Supreme Court.

### **Fourteenth Amendment Rights in Public Schools (Due Process)**

Just as the Supreme Court has attempted to balance free speech rights with the need to protect students from harmful or disruptive speech, the court has also weighed in on the balance between the need for effective discipline and the right to due process when accused of wrongdoing.

#### ***Goss v. Lopez (1975)***

*Goss v. Lopez* (1975) concerned a group of junior high and high school students in Ohio who were suspended from school for 10 days without a hearing. One student in particular, Dwight Lopez, was suspected of causing disruption and property damage in the school cafeteria but maintained that he was innocent. Lopez challenged the principal's decision to issue the suspensions without preliminary hearings, and, after appeals in lower courts, the case was ultimately heard in the U.S. Supreme Court.

The Supreme Court ruled that public school students who are accused of wrongdoing in school have a right to receive notice of their charges and to tell their side of the story prior to suspension. One of the issues involved in the court's decision-making process was the potentially damaging effect that severe school sanctions could have on sanctioned students' academic endeavors, psychological well-being, and reputations. The court limited the extent to which schools can act in loco parentis (as surrogate parent), noting that severe sanctions, in the absence of due process, can be harmful to the unjustly accused. This case also provided procedural safeguards for the First Amendment rights established in *Tinker v. Des Moines Independent Community School District* (1969) and it provided a vehicle by which Fourth and Eighth Amendment rights, discussed in the next and subsequent sections, could be applied to public school students.

### **Fourth Amendment Rights in Public Schools (Search and Seizure)**

The Fourth Amendment guarantees adults the right to be free from "unreasonable searches and seizures" by government agents and requires a warrant to be issued before a search is to be conducted. Of course there are exceptions to the warrant requirement (for example, when evidence or property is in plain view, when a person has been placed under arrest, and when current circumstances make obtaining a warrant impractical), however, to prevent unreasonable invasions of privacy, warrants are not to be

issued unless there is "probable cause," which is a relatively strict evidentiary standard. These protections are available for any location in which a person could have a "reasonable expectation of privacy" (*Katz v. United States*, 1967).

However, several Supreme Court cases have established that these Fourth Amendment protections are not automatically guaranteed to students in the public school system. In *New Jersey v. T.L.O.* (1985), *Safford Unified School District v. Redding* (2009), and *Mendoza v. Klein Independent School District* (2011), the Supreme Court held that warrantless searches of students in the public school system are permissible, though they should be justified and reasonable. Specifically, the court has held that school authorities are allowed to search students' persons and properties without probable cause (or warrants), including random drug testing for participants in extracurricular activities. These decisions attempt to balance the Court's primary concern for protecting the health and safety of students with the secondary concern for protecting students' rights.

#### ***New Jersey v. T.L.O. (1985)***

*New Jersey v. T.L.O.* (1985) was the first Supreme Court case to hold that the Fourth Amendment, to some extent, applies to students in the public school system. The case began when a teacher found T.L.O. (a 14-year-old high school freshman) and her friend smoking cigarettes in the school bathroom, in violation of school rules. Though T.L.O.'s companion admitted to smoking the cigarettes, T.L.O. denied the allegation and was escorted to the vice principal's office. After T.L.O. again denied smoking in the school lavatory, Vice Principal Theodore Choplick demanded T.L.O.'s purse and rummaged inside it. Choplick uncovered a package of cigarettes, which served as impetus to continue searching through the contents of the purse. After the vice principal found cigarette rolling paper, which he believed was indicative of marijuana use, he underwent a more exhaustive search of the purse. The extensive search revealed a small amount of marijuana, a pipe, empty plastic bags, approximately \$40 in small bills, a list of names of students who apparently owed T.L.O. money, and two letters suggesting that T.L.O. had sold drugs. The evidence and T.L.O., voluntarily driven by her mother, were taken to the police station, where T.L.O. confessed to selling marijuana at school. The state used the evidence and the confession to press delinquency charges and, ultimately, T.L.O. was ordered to serve 12 months on probation.

T.L.O. appealed, arguing that the search violated her Fourth Amendment rights. She sought to suppress the evidence, as well as the subsequent confession, under her

belief that the vice principal had no right to rummage through her purse. Though lower courts and the Appellate Division concluded that Vice Principal Choplick was justified in his decision to thoroughly search T.L.O.'s purse, the New Jersey Supreme Court determined that the vice principal had indeed violated the student's Fourth Amendment rights. The state of New Jersey appealed, arguing that the Fourth Amendment protections only apply to searches executed by law enforcement personnel, and the case was eventually heard in the United States Supreme Court.

The U.S. Supreme Court ruled that the Fourth Amendment applies to searches conducted by *state agents*, including public school officials, meaning that it is not permissible for school officials to conduct unjustified searches of students' property. Furthermore, the court acknowledged that T.L.O. had a reasonable expectation of privacy with respect to her purse. However, the Court determined that searches of public school students must be (a) "justified at inception" and (b) "reasonably related in scope to the circumstances which justified the interference in the first place." The court concluded that Vice Principal Choplick was justified in his decision to open the purse, given that T.L.O. had been caught smoking in the school lavatory, and that he was justified in his decision to continue the search of the purse, given that he had discovered drug paraphernalia—rolling paper—in the purse). In contrast to *probable cause*, the court asserted that the appropriate requirement for a school search was *reasonable suspicion*. The court justified the exemption from the *probable cause* and warrant requirements because of schools' inherent responsibility to prevent disruption, violence, and drug use, to respond immediately, and to maintain order. Interestingly, the Court did not give an opinion with regard to whether these same principles would apply to other types of student searches, such as a locker.

#### ***Vernonia School District 47J v. Acton (1995)***

The *Vernonia* case concerned whether a "suspicionless" drug-testing program for high school athletes violated students' Fourth Amendment rights. Vernonia School District believed that drugs were a growing concern in its schools and that student athletes were the leaders of the drug culture. The district responded to the drug problem by offering "special classes, speakers, and presentations designed to deter drug use. It even brought in a specially trained dog to detect drugs, but the drug problem persisted" (*Vernonia School District 47J v. Acton*, 1995, p. 649). Because of the failed attempts to curtail drug use, the district proposed the Student Athlete Drug Policy, a

program that introduced random drug testing to student athletes, which parents at the initial meeting unanimously approved. Under this new program, the student and his or her parents were required before each athletic season to sign a consent form that allowed the student athlete to be subjected to random urinalysis, in order to be eligible to participate in extracurricular sports. If a student failed a random test, the athlete's parents were notified and the student was given the choice of a suspension from athletics or a 6-week treatment program. A second failed drug test resulted in mandatory athletic suspension for the current season as well as the next season.

This particular case began when James Action was denied participation on a seventh-grade football team because his parents and he refused to sign the random-drug-testing consent form. His parents filed a suit and lower courts disagreed about whether suspicionless drug testing for student athletes violated the Fourth Amendment. However, the Supreme Court ruled that the school had the primary goals of protecting its students' health and safety and decreasing drug use. As such, like the prior cases *Bethel* and *Hazelwood*, the court confirmed its deference to schools' authority and upheld the Student Athlete Drug Policy, which required all high school student athletes to undergo random urinalysis. Indeed the most noteworthy contribution of this case was the court's decision to permit schools to conduct searches of students without *probable cause* or even *reasonable suspicion*. The court justified this decision based on the belief that "students within the school environment have a lesser expectation of privacy than members of the population generally" (cited in *Vernonia School District 47J v. Action*, 1995, p. 657; quote originally from *New Jersey v. T.L.O.*, 1985, p. 348) and on the observation that testing was required only as a condition for participation in a voluntary extracurricular activity.

#### ***Board of Education of Independent School District No. 92 of Pottawatomie County v. Earls (2002)***

Years after the case of *Vernonia*, the boundaries for suspicionless drug testing in public schools were expanded to include other extracurricular activities in addition to sports. In an extension of the standards set forth in *Vernonia School District 47J v. Action* (1995), the Supreme Court ruled that it is, in fact, constitutional to conduct mandatory drug tests for public school students involved in extracurricular activities (not just student athletes). As evident in these two cases, it was the court's belief that schools have a "responsibility for maintaining discipline, health, and safety," and as a result, students have "limited expectations

of privacy.” The court also agreed that schools and school districts had a strong interest in preventing drug use. Furthermore, the court determined, “Securing order in the school environment sometimes requires that students be subjected to greater controls than those appropriate for adults” (*Board of Education of Independent School District No. 92 of Pottawatomie County v. Earls*, 2002, p. 831). It is important to note that the Court only permitted the policies to affect students’ participation in *extracurricular* and *athletic* activities. Moreover, the policies were prohibited from having legal ramifications. Owing to the drug tests’ minimally intrusive nature and the limited purpose, the court justified the invasion of students’ privacy.

In contrast to the decision in *T.L.O.*, which required that authorities have reasonable suspicion before searching a student’s person or belongings, the *Vernonia* and *Earls* cases present a situation in which presumably innocent public school students are subjected to random, suspicionless tests of the content of their bodies, as a requirement for participation in voluntary school-related activities. These decisions emphasized the court’s primary concern for protecting the Nation’s youth health and safety, including the goal of preventing drug abuse.

#### ***Safford Unified School District v. Redding (2009)***

Savanna Redding was a 13-year-old middle school student who, based on an accusation from a classmate, was suspected to possess prescription strength drugs. The case originated when a fellow classmate and friend of Redding was found to be in possession of Redding’s day-planner. Various contraband, including knives and cigarettes, were found inside the day-planner. It was clear that the day-planner belonged to Redding and at no point did Redding deny ownership. The classmate also was in possession of four prescription-strength ibuprofen pills and one over-the-counter pill used for pain and inflammation (found in the classmate’s pocket)—which she claimed belonged to Redding.

Based on the classmate’s incriminating statement, Vice Principal Kerry Wilson searched Redding’s backpack (finding nothing) and sent to Redding to the nurse’s office for a thorough strip search. The school nurse, Peggy Schwallier, instructed Redding to remove her jacket, socks, shoes, T-shirt, and stretch pants, leaving her wearing nothing but her bra and underwear. Redding was then asked to pull her bra out and “shake it” and to “pull the elastic on her underpants, thus exposing her breasts and pelvic area to some degree” (*Safford Unified School District v. Redding*, 2009, p. 2638). However, the strip search yielded nothing.

Redding’s mother believed the search was unlawful and filed a suit against the Safford Unified School District, the vice principal, and the nurse. Trial and lower courts concluded that Redding’s Fourth Amendment rights were violated, however, after reconsideration, the Ninth Circuit reversed, and the case ultimately reached the U.S. Supreme Court.

The Supreme Court drew upon the standards established in *T.L.O.* and determined that the search was *reasonable at inception*. Specifically, the vice principal had reason to suspect the Redding may have had drugs in her possession, given the classmate’s accusation and given that Redding had been implicated in an alcohol-related incident at a school dance earlier in the school year. Therefore, a search of her backpack and outer clothing was warranted: “If a student is reasonably suspected of giving out contraband pills, she is reasonably suspected of carrying them on her person and in the carryall that has become an item of student uniform in most places today” (*Safford Unified School District v. Redding*, 2009, p. 2641). However, the court found that the intrusiveness of the strip search was not proportionate to the degree of suspicion. As Wilson never asked the peer *when* Redding gave her the pills or whether Redding currently had any drugs, the vice principal had no reason to believe that Redding currently had pills on her person. Furthermore, there was no reason to believe that Redding was hiding drugs in her bra or underwear, that the suspected painkillers posed imminent danger, or that she was distributing large quantities of drugs to fellow students—all of which may have justified an imminent, intrusive search of Redding’s person. As such, the court concluded that there was no justification for something as humiliating and psychologically damaging as a strip search.

Central in the court’s rhetoric was a discussion of the belief that adolescents are inherently self-conscious about their bodies and the potential long-term effects of the embarrassment and intrusiveness of a strip search. However, the Supreme Court did not believe that any previous case had clearly established the laws, standards, and limits for this type of search, and as a result, did not hold that the vice principal and nurse knowingly violated the student’s rights. Also, the court held that the motive behind the vice principal’s behavior was clear: to decrease illegal drug use and protect the students (underscoring the court’s belief that schools are responsible for protecting youth). However, the Supreme Court was clear in its decision that the strip search went too far and that Redding’s Fourth Amendment rights had indeed been violated, even if unintentionally. The most important implication of this case was that school authorities were not immune to the

regulations of the Fourth Amendment: Search and seizures of public school students must be proportionate to the available facts.

### ***Mendoza v. Klein Independent School District (2011)***

Another search that was reasonable at inception but went too far was central to the case of *Mendoza v. Klein Independent School District* (2011). In this case, Vice Principal Stephanie Langner believed that she had observed an eighth grade student, A.M., showing a group of fellow students something on A.M.'s mobile phone. When Langner approached the students, A.M. turned off the phone and placed it in her pocket. Upon questioning from Langner, A.M. denied using the phone during school hours (a school rule violation) and refused to give the phone to Langner. The vice principal continued to question A.M., and ultimately, A.M. surrendered the phone to Langner and returned to class.

Langner took the phone to her office and turned it on to see if A.M. had, in fact, been using the mobile device during school hours. She located the most recent message and found an outgoing message that had been sent during school hours. Langner then continued to scroll through the student's phone messages and discovered a nude picture of A.M. that the eighth grader had taken of herself. A.M. was called to the vice principal's office and the student admitted to sending the photo to a boy who had sent her a similar picture of himself. The student also confessed to forwarding the nude picture of the boy to another female student. Langner informed Principal Scott Crowe about the nude photo and the principal instructed Langner to call the police department. After the police investigation, Crowe informed Jennifer Mendoza, A.M.'s mother, that A.M. was being transferred to a Disciplinary Alternative Education Program (DAEP) for 30 days for "incorrigible behavior."

Mendoza, acting on behalf of her daughter, appealed the decision to the school board, but the Superintendent of School Administration upheld the punishment. After A.M. completed her time at DAEP, she returned to the middle school, but claimed that she had lost her position on the basketball team and that her reputation had been tainted. Mendoza filed a suit against the school district (for not "training" school administrators in regard to students' rights), the vice principal, and the principal on behalf of her daughter and herself (the subscriber of the cellular service).

The Texas Southern District Court determined that school personnel do not have a right to an "unfettered search" of students' cell phones without reasonable suspicion. The two-step criteria established in *T.L.O.* were used

to determine whether A.M.'s Fourth Amendment rights had been violated. The search was *justified at inception* as it was permissible for the vice principal to turn the phone on and check the date and time of the last message sent to determine whether the student had violated school rules against using the cellular phone during school hours. However, the *scope of the search was unreasonable*; it was a violation of the student's fourth amendment rights for the vice principal to continue to peruse the student's other text messages.

### ***Summary of Fourth Amendment Decisions***

Outside of school, adults and minors are equally free from unreasonable searches by government employees. At school, however, a student's privacy protections are much more limited. In contrast to the usual standard of *probable cause*, school authorities only need *reasonable suspicion* to conduct a search of a student's person or belongings. Perhaps most striking with respect to students' Fourth Amendment rights is the Court's support for schools' suspicionless drug testing for students who participate in extracurricular activities. The court has upheld a student's privacy rights when it believes the school has gone too far: for example, when the scope of the search is not proportionate to the degree of suspicion or the availability of conclusive evidence.

### ***Eighth Amendment Rights in Public Schools (Corporal Punishment)***

There are approximately 113 countries that ban corporal punishment in schools, however the United States is not one of them. Nineteen U.S. states permitted the use of corporal punishment in public schools in the 2005–2006 school year.<sup>1</sup> In fact, in 2006, there were 223,190 students who were physically disciplined in a U.S. public school, with 40% of cases occurring in Texas and Mississippi. In *Ingraham v. Wright* (1977), the Supreme Court considered whether corporal punishment in schools should be held to the Eighth Amendment standards of Cruel and Unusual punishment and also whether the due process clause of the Fourteenth Amendment applied.

### ***Ingraham v. Wright (1977)***

In *Ingraham v. Wright* (1977), a 14-year-old junior high school student, James Ingraham, disobeyed a teacher's request to exit the stage of a school auditorium. As a result, the teacher brought the defiant student to Principal Willie

---

<sup>1</sup>United States Department of Education, Office for Civil Rights.

Wright's office, where the principal used a wooden paddle to hit the student's buttocks more than 20 times. Because Ingraham resisted the paddling, the principal asked the vice principal and an assistant to restrain the student's legs and arms. Ingraham suffered extensive bruising and was required by doctors to stay home from school for 11 days.

Ingraham's parents believed the paddling was *cruel and unusual punishment* and sued for damages. The court held that the Cruel and Unusual Punishments Clause of the Eighth Amendment was designed to be used for individuals charged with and convicted of crimes, not schoolchildren in the public school system: "We adhere to this long-standing limitation and hold that the Eighth Amendment does not apply to the paddling of children as a means of maintaining discipline in public schools" (*Ingraham v. Wright*, 1977, p. 664). The court did not excuse or condone the practice of physical punishment in school, but held that corporal punishment is not a constitutional issue, and that parents remain free to press criminal charges in such cases. The court also discussed whether the due process clause of the Fourteenth Amendment (requiring prior notice and a hearing) was applicable. Ultimately, the court held that requiring the procedural safeguards established in the due process clause of the Fourteenth Amendment (which had already been established as applicable to cases involving suspension from school in *Goss v. Lopez*, 1975) would present an unduly complicated and potentially resource-heavy requirement for schools and school districts. Furthermore, the court reasoned that there are some situations that may require immediate punishment and that students are protected because schools are monitored by the members of the surrounding communities. Given these facts, the court ultimately determined that the costs associated with procedural safeguards outweighed the potential benefits to the students. As was the decision in First Amendment cases the court had heard previously (*Bethel* and *Hazelwood*) this decision once again demonstrated the court's deference to schools and the belief that teachers and principals (as opposed to federal judges) should be responsible for controlling student behavior.

### **Zero-Tolerance Policies and the School-to-Prison Pipeline**

Zero-tolerance policies were originally intended to send unequivocal messages that violence and drug use, in any amount, will not be tolerated on school property. These policies first appeared in 1989 and initially required schools to expel students suspected to be involved with on-campus

drug use (or possession), violence, or gang-related activity (Skiba & Knesting, 2001). Over the years, the policies have expanded, and now include behaviors such as smoking and other forms of school misconduct. In 1994, the Clinton administration passed the Gun-Free Schools Act, which mandates expulsion as well as law enforcement referral for any student who possesses a firearm on school property. Though the act was originally intended to apply only to firearms, recent changes now permit the possession of other weapons to be subject to the same sanctions (Skiba & Knesting, 2001). One consequence of this "get tough" approach is that schoolchildren who violate certain school rules end up with an arrest record (Casella, 2003). This is what some researchers have termed the *school-to-prison pipeline* (American Psychological Association Zero Tolerance Task Force, 2008; Wald & Losen, 2003).

Research has consistently shown that these policies are not effective deterrents for the targeted behaviors, and that African American youth are more likely than other youth to receive punitive sanctions under these policies (American Psychological Association Zero Tolerance Task Force, 2008; Skiba & Knesting, 2001). A zero-tolerance case has not yet been heard in the Supreme Court, but given the potential for zero-tolerance policies to circumvent typical due process mechanisms for disciplinary proceedings within the school, and given their inherently disproportionate response to infractions of varying severity, their validity could be subject to challenge.

### **Summary of Legal Regulation of Children at School**

Schools are tasked with educating, socializing, and protecting future generations of adult citizens. In pursuit of maintaining an orderly educational environment, the court has given schools the authority to monitor and regulate its students. The Supreme Court has held that public school students are not guaranteed adult-like standards of First, Fourth, Eighth, or Fourteenth Amendment rights. However, the Supreme Court does provide limited protections to students. Free speech rights are protected if the speech is not disruptive or harmful. Searches that violate reasonable expectations of privacy must be based on a standard of reasonable suspicion, and must be proportionate to the perceived threat to student safety. Eighth Amendment prohibitions against cruel and unusual punishment do not apply to school officials, though excessive abuse would still be subject to criminal charges. Rights to due process apply in some cases, such as suspension, but not in others, such as physical beatings, the regulation of which would

be prohibitively complicated, and which apparently would be less effective if not performed immediately, while the principal is still angry.

Nowhere in any of these cases does developmental science come into play, other than in rudimentary observations that humiliating strip searches are bad for self-esteem, especially, perhaps, among adolescent girls. The emphasis of every relevant case has been on the protection of vulnerable children (whether from their classmates, or from overreaching authority figures), which has little to do with the changes in capabilities and competencies that occur during childhood and adolescence. A consideration of such changes would not affect the rationales presented for the various rights in question, as they apply to students in public school, regardless of maturity level.

## CHILDREN AND ADOLESCENTS IN THE JUSTICE SYSTEM

As is the case with respect to other aspects of the law, two themes dominate debates about the treatment of children and youth within the juvenile and criminal justice systems. The first is whether children and adolescents have the same rights in court as adults do. Because minors' offenses are sometimes adjudicated in juvenile court and sometimes adjudicated in criminal court, the question concerning the rights of children and adolescents in the context of the justice system is more accurately rephrased as whether the rights that are protected in criminal court are also protected in juvenile court; in criminal court, juveniles have the same rights as adults, although there are some specific instances in which they cannot face the same sanctions if found guilty. In the United States, these rights include the protection against self-incrimination guaranteed by the Fifth Amendment, as well as those that are protected under the Sixth Amendment, such as the right to counsel, the right to confront witnesses, the right to a jury trial. As we shall see, some of these protections have been extended to juvenile court, but others have not.

The second theme concerns developmental differences between minors and adults, a theme that touches on many different issues, including the criteria used to determine whether a minor's offense is adjudicated in juvenile or criminal court; whether minors are competent to stand trial in criminal court; whether minors should be held to the same standards of criminal responsibility as adults (and if so, exposed to the same punishments if convicted); and whether minors should be afforded special protections when

questioned by law enforcement officers. The central issue in each of these discussions is whether minors and adults differ in their cognitive abilities and psychosocial capacities that are relevant to legal decisions and, if so, where a sensible boundary should be drawn between individuals who are deemed immature and those who are viewed as comparable in maturity to adults. Developmental science has played a role in informing the discussion of all of these issues.

No consideration of children and adolescents in the justice system can take place without locating the discussion in a cultural and historical context. Today, the United States stands apart from most of the industrialized world in its willingness to consider juvenile offenders as adults for purposes of adjudication and sanctioning. In most other countries, Age 18 is a bright-line boundary between minors and adults for purposes of criminal law, as it had been in the United States for most of the 20th century. During the last decades of the 20th century, however, a spate of "get-tough" policies grew in popularity; among the outcomes of this change in attitude is that, in the United States, many more individuals under the age of 18 are now tried as adults, outside the juvenile justice system.

We note this because many of the issues discussed in this section of the chapter, such as whether adolescents should be held to the same standards of criminal culpability as adults, or whether minors are competent to stand trial in adult court, would not have been topics of discussion in a *Handbook* chapter on children and the law as recently as 25 years ago. In some regards, then, the importance of developmental science for discussions of children and youth in the justice system is a recent development that has been necessitated by relatively new changes in policy and practice that have blurred what formerly had been clear distinctions between adolescents and adults who come into contact with the justice system. While some of these issues are also important in other countries, they affect far more individuals in the United States than abroad. For this reason, it is important to have some familiarity with the American juvenile justice system.

## A Brief History of American Juvenile Justice

Two perspectives capture the extremes of the pendulum swings that have characterized American juvenile justice policy since the beginning of the 20th century:

Why is it not just and proper to treat these juvenile offenders, as we deal with the neglected children, as a wise and merciful father handles his own child whose errors are not discovered by the authorities? (Mack, 1909, p. 7)

Juvenile offenders are criminals who happen to be young, not children who happen to be criminal. (Regnery, 1985, p. 65)

The guiding premise behind the creation of a separate system of justice for children and youth was that juveniles are different from adults in ways that should affect the way we judge and sanction them. Ben Lindsey, founder and judge of the Denver Juvenile Court in the early 20th century, for example, believed that there were “no bad kids”—only bad conditions that led to bad conduct. The purpose of his court, as he explained in a magazine article in 1927, was to save the young people who came before his bench, not to punish them.

Indeed, still today an entirely different lexicon characterizes juvenile court proceedings than those that take place in criminal court. Juveniles commit “offenses,” not crimes; they are “adjudicated delinquent” at the conclusion of a “proceeding,” rather than found guilty at the end of a trial; and they receive “dispositions” instead of sentences. In practice, juvenile and criminal court proceedings share many commonalities, but the vocabulary of juvenile court serves as a reminder that the court was founded with rehabilitative goals in mind. Because the states’ primary purpose was to rehabilitate delinquents, the reformers were emphatic that concepts such as criminal responsibility and punishment had no place in the vocabulary of juvenile justice. As Judge Lindsey declared, “Our criminal laws are as inapplicable to children as they would be to idiots” (Lindsey & O’Higgins, 1910, p. 133).

Lindsey embodied the ideals of the Progressive Era and, like the other social reformers who worked to establish the juvenile court at the turn of the 20th century, he viewed youth involved in crime first and foremost as children. He often emphasized that his court was *not* a criminal court, and that the lawbreakers who came before him were not criminals. His only goal was to provide aid and rehabilitation, which he accomplished with the help of probation officers, social workers, physicians, and psychiatrists. Judge Lindsey’s court exemplified the rehabilitative model that dominated juvenile justice policy for much of the 20th century, a model under which delinquents were dealt with as children whose welfare was of primary concern when the state intervened in response to their criminal conduct.

Prior to the establishment of the juvenile court in the United States, only young children were insulated from criminal responsibility, reflecting the presumption under English common law that individuals under the age of 7 were incapable of committing a crime, owing to their limited capacity to appreciate the wrongfulness of their

acts (known as the *infancy defense*). Under common law, children between 7 and 14 were also presumed incapable of committing crimes, but this presumption was rebuttable, and most youth of this age who committed crimes actually were tried and punished as adults. Young people older than 14 were viewed as having the same capacities as adults. This all changed with the founding of the juvenile court, which in most locales was charged with responding to offenses committed by individuals under 18.<sup>2</sup>

For much of the 20th century, the rehabilitative model shaped the operation of the juvenile court. The goal of treatment influenced the process by which delinquency was adjudicated, the type of dispositions imposed (at least in theory), and the roles of the various participants. Delinquency dispositions were open-ended and indeterminate—which made sense, given their purported rehabilitative purpose. Like treatment for an illness, rehabilitation, in theory at least, should end when the youth was “cured.” Under the rehabilitative model, the duration bore no necessary relation to the seriousness of the offense; thus, the principle of *penal proportionality* (i.e., that the degree an individual is punished for a criminal act should be in proportion to his or her responsibility for it), like criminal responsibility, had no place in delinquency proceedings. Although in practice, the seriousness of the crime usually played a role in the type and duration of dispositions, juvenile court judges were relatively free to order dispositions based on their judgment about the youth’s “needs,” without regard to the seriousness of his criminal conduct.

### *Gault and Its Repercussions*

Despite its initial success, the traditional juvenile court and the rehabilitative model on which it was built were largely a failure. By the 1960s the rehabilitative model began to crumble, and since that time, the juvenile court has been challenged from both the left and the right. The first successful assault was launched by youth advocates who claimed that adolescents charged with crimes were getting a bad deal in a system that was ostensibly designed to serve their needs. These critics argued that the juvenile system failed to provide treatment, but that it maintained the myth that rehabilitation was its purpose as the justification for denying juveniles the procedural rights given to adult criminal defendants. Juveniles had no right to legal counsel, and delinquency proceedings lacked the careful fact-finding of

<sup>2</sup>Today, 18 remains the jurisdictional dividing line between juvenile and criminal courts in most states, although some use 17 or, less commonly, 16.

an adversarial criminal trial; yet, dispositions, at least for some youth, meant confinement in correctional facilities that, from the incarcerated youth's perspective, may have been hard to distinguish from prison. This push for reform ultimately led the U.S. Supreme Court, in the landmark 1967 opinion of *In re Gault*, to extend due process protections to youth in delinquency proceedings. Along with *Roper v. Simmons*, the 2005 Supreme Court case that abolished the juvenile death penalty (discussed later in this chapter), *Gault* is the most important case in the history of American juvenile justice jurisprudence.

Gerald Gault, Age 15, was arrested for making telephone calls to his next-door neighbor that the Supreme Court later described as being "of the irritatingly offensive, adolescent, sex variety." He was brought before a juvenile court judge, but he was not given notice of the charges against him and did not have an attorney to represent him. The neighbor never appeared in court as a witness; instead, the arresting officer testified, describing what the neighbor reported. The juvenile court judge committed Gerald to the Arizona State Industrial School for up to 6 years, for a crime that would have carried at most a sentence of 2 months in jail and a \$50 fine if committed by an adult. These facts made *Gault* the perfect case to challenge the informality of the process by which guilt was determined in juvenile delinquency proceedings, an approach that was justified by the ostensibly rehabilitative purpose of the proceedings.

Gerald Gault appealed and ultimately prevailed in the Supreme Court. The court flatly rejected the state's justification for the informality of delinquency proceedings. Justice Abe Fortas, who wrote the majority opinion, described the proceeding as a "kangaroo court," noting that delinquents generally got little rehabilitation, and what they received was ineffective, as evidenced by the high recidivism rate in juvenile crime. The court concluded that youth facing adjudication in delinquency proceedings, like adult criminal defendants, faced a loss of liberty and thus were entitled to certain due process protections as mandated by the U.S. Constitution. Juveniles, like adults, had a right to notice of the charges, a right to confront witnesses against them, a privilege against self-incrimination, and, most importantly, a right to counsel. The procedural changes ordered by the court transformed delinquency proceedings into more formal adversarial hearings—unlike criminal trials.

Although *Gault* is considered the landmark case concerning due process protections in juvenile court, it actually cemented a line of reasoning about juveniles' rights which

had been first expressed 1 year earlier, in *Kent v. United States* (1966), a lesser-known case concerning the process through which a juvenile court decides whether to waive its jurisdiction and transfer a juvenile's case to criminal court, where the individual would be prosecuted as an adult. The court ruled in *Kent* that juveniles are entitled to a hearing before their case was waived to criminal court, that their attorneys are entitled to have access to the records used in making the waiver decision, and that the judge had to provide the reasons for the decision to transfer. In some regards, *Kent* is an important case not so much for its relevance to juveniles' rights (as is *Gault*), but because one of the suggested reasons for transfer to adult court that were listed in the statute that the court reviewed in this case (these reasons are referred to as the "*Kent* criteria") was "the sophistication and maturity of the juvenile." Importantly, however, considering the maturity of the offender is only a suggestion, not a requirement. As this chapter explains, discussions of whether psychological maturity matters for judgments of criminal culpability, or whether juveniles are as "mature" as adults in ways that are legally relevant, would come to be central issues in the Supreme Court's juvenile justice jurisprudence some 40 years later.

Several Supreme Court cases subsequent to *Gault* considered the constitutionality of other procedural differences that existed between juvenile and criminal court. The two most important of these are *In re Winship*, a 1970 case in which the court ruled that juvenile courts needed to follow the same evidentiary standards as criminal courts, namely, proof "beyond a reasonable doubt" (prior to *Winship*, the standard for a finding of delinquency in juvenile court was merely "a preponderance of the evidence," consistent with the view that delinquency adjudications were civil, rather than criminal, proceedings); and *McKeiver v. Pennsylvania*, a 1971 case in which the court found that individuals whose cases were heard in juvenile court did not have the right to a jury. Thus, whereas *Winship* made juvenile and criminal court proceedings more similar, *McKeiver* maintained one of their important differences. The court's majority argued, among other things, that the introduction of a jury to a delinquency procedure would make it too adversarial, and that extending all the protections of criminal court to juvenile court would ultimately eliminate the need for a separate juvenile court. In the years following *Winship* and *McKeiver*, the court continued to clarify the boundaries between juvenile and criminal court proceedings, sometimes ruling that juveniles had the same rights and protections as adults, but sometimes ruling that they did not. A passage from the

*Gault* decision sums it up best: “We do not mean . . . to indicate that the [juvenile court] hearing to be held must conform with all the requirements of a criminal trial . . . but we do hold that the hearing must measure up to the essentials of due process and fair treatment” (*In re Gault*, 1967, p. 30).

Although *Gault* gave lip service to rehabilitation as a laudable if unrealized goal of juvenile dispositions, the rehabilitative model was in disrepute, and by the 1970s it had pretty much collapsed. Violent juvenile crime rates started to climb in the late 1980s, triggering a new wave of reforms under which young criminals increasingly were either classified as adults or punished severely within the juvenile system. By the end of the 20th century, the rhetoric surrounding the treatment of children and adolescents who violate the law, at least in the United States, could not have been more different from that espoused by the founders of the juvenile court.

### ***Trying Juveniles as Adults***

In the latter decades of the 20th century, as violent youth crime rates rose, attacks on the juvenile court intensified. Critics railed at the depiction of young criminals as children, a characterization that was discordant with media images of teenage street gangs spreading fear in urban neighborhoods. By the 1990s young offenders became “super-predators” in the popular imagination, teenage criminals without moral inhibitions who were eager to kill and maim those who came in their paths. Under the mantra of “adult time for adult crime,” young offenders became subject to increasingly harsh punishments, many of them administered by adult criminal courts and sometimes carried out within correctional facilities that had been previously reserved for individuals 18 and older.

The modern reformers pursued their goal of reclassifying young offenders as adults through several legislative strategies. First, the age of judicial transfer was lowered in many states and revised in other ways to facilitate criminal prosecutions of juveniles. In a transfer hearing of the sort mandated by the *Kent* decision, a juvenile court judge makes an individualized determination of whether the young defendant should be deemed a legal adult for purposes of criminal prosecution or adjudicated as a child in juvenile court. Under the traditional system, *judicial transfer* functioned as a mechanism to exclude from the court’s jurisdiction the occasional older youth charged with a serious violent crime (usually murder) who the judge determined was not amenable to treatment as a juvenile. Today, in a majority of states, 10-year-olds charged with murder can be transferred to criminal court, and although

almost all statutes that do set a minimum age for criminal court prosecution designate Age 14 or younger, a large minority of states have no statutory minimum age of transfer. The transfer decision under many statutes need not incorporate consideration of maturity or lack of amenability to treatment; it is often based, instead, on the seriousness of the offense and the juvenile’s criminal record.

Other legislative reforms enacted during the last decades of the 20th century gave criminal courts automatic jurisdiction over certain youth (that is, without a judicial hearing on whether the juvenile’s case should be transferred to the adult system). Under some *automatic waiver* statutes, young offenders charged with designated serious crimes are defined categorically as adults, and are excluded from juvenile court jurisdiction based on their age and the offense with which they are charged. In a few states, the general age of criminal court jurisdiction is Age 16 or 17; in these states all juveniles of the jurisdictional age or older are deemed adults for purposes of criminal prosecution, even though they typically are legal minors for most other purposes, such as voting or purchasing alcohol. Under other waiver statutes, the state leaves the choice of court venue up to the prosecutor, who can decide whether to file the charges against the youth in either juvenile or criminal court, a policy referred to as *prosecutorial discretion*. Legislative waiver statutes shift discretion from judges, who are often deemed soft on crime, to prosecutors and legislators (who are not assumed to have this deficiency).

Each year in the United States, whether through automatic waiver, prosecutorial discretion, or judicial transfer, more than 200,000 individuals below the age of 18 are tried as adults. Most of these cases involve juveniles who live in states where the jurisdictional boundary between juvenile and criminal court is set at an age lower than 18, but even in states where 18 is still the dividing line, a substantial number of young people are prosecuted in adult court as a consequence of statutes that mandate the exclusion of certain crimes from the juvenile court if the accused individual is of a certain age or that permit prosecutors to file their charges in criminal court. As judicial discretion has been increasingly constrained by these statutes, judicial waiver has become extremely rare.

Until recently, only the most violent crimes (usually murder, rape, armed robbery, aggravated assault, and kidnapping) could be the basis of criminal court prosecution of juveniles in most jurisdictions, but many statutes today include a long laundry list of transferable offenses subject to automatic waiver or prosecutorial discretion. Indeed, in most states today, youth charged with drug and property

offenses can be tried and punished as adults. Some states have extended juvenile court jurisdiction into adulthood or adopted *blended sentencing* statutes, under which juveniles who are convicted of designated felonies are subject to stiff sentences in juvenile court that are completed by transfer to adult prison when the offenders become adults. Most blended sentencing statutes include either a procedure when the offender reaches the age of 18 for determining if the adult portion of the sentence will be carried out, or a provision suspending that portion of the sentence for youth who have not violated institutional regulations or probation conditions. However, in many states, juveniles can be sentenced to very long sentences, including life without the possibility of parole for juveniles convicted of homicide.

### Developmental Concerns: Culpability and Competence

The increase in the number of juveniles tried as adults (or eligible to be tried as adults) has raised two broad categories of questions about developmental differences between adolescents and adults. One set of questions concerns juveniles' *adjudicative and procedural competence*, a phrase that refers to their competence to stand trial in adult court and to make legal decisions about such matters as whether to submit to an interrogation by a law enforcement agent, testify in their own defense, or accept the terms of a plea agreement. A second set of questions concerns juveniles' *criminal culpability*, which refers to the extent to which juveniles should be held to the same standards of criminal responsibility as adults. Although both sets of questions concern differences between adolescents and adults with respect to their psychological abilities and capacities, discussions of juveniles' competence and culpability are not the same. Questions about adjudicative and procedural competence ask whether adolescents and adults differ in the abilities necessary to make an informed decision and, if so, whether these differences warrant providing juveniles with added or special protections; in this sense, questions about adjudicate competence share much in common with questions about other aspects of juveniles' competence, such as their competence to consent to a medical procedure or provide informed consent in a research setting. In contrast, questions about adolescents' criminal culpability pertain to the extent to which juveniles are responsible for their behavior, and, in light of the principle of penal proportionality discussed earlier, the extent to which they should be punished for their bad deeds.

In other words, questions about culpability concern the juvenile's mental state at the time of an offense, whereas

questions about competence concern the juvenile's ability to make legal decisions after an offense (or an alleged offense) has occurred. Some psychological capacities are relevant to both competence and culpability, but others are not. For instance, the ability to foresee the future consequences of one's actions might influence an adolescent's decision to participate in an activity that might endanger another person (and is therefore relevant to judgments about the juvenile's culpability for any harm that may have occurred as a result) and it might also influence how a juvenile responds to a police interrogation (and is therefore relevant to decisions about whether a juvenile who decided to confess to a crime was competent to understand the ramifications of this decision). On the other hand, whether a juvenile defendant who has committed a crime understands the difference between the goals of a prosecutor and a judge is relevant to his or her competence to stand trial, but has nothing to do with the adolescent's responsibility for the offense. It is possible, therefore, for an adolescent to be fully responsible for a criminal act but incompetent to serve as a defendant in a criminal proceeding or less than fully responsible for a criminal act but perfectly competent to stand trial.

### Adjudicative and Procedural Competence

It is well established that a criminal proceeding meets the constitutional requirements of due process only when the defendant is competent to stand trial, which includes capacities to assist counsel and to understand the nature of the proceeding sufficiently to participate in it and make decisions about rights afforded all defendants (*Dusky v. U.S.*, 1960; *Godinez v. Moran*, 1993). Although the conventional standard for competence to stand trial focuses on mental illness and disability, there has been growing recognition that some youth without mental illness or disability may nevertheless be incompetent due to developmental immaturity (Grisso et al., 2003).

Past analyses of the legal concept of competence have outlined the specific functional abilities about which the law is concerned in competence cases (Grisso, 2002), which are often referred to as the "*Dusky* criteria." These abilities include a basic comprehension of the purpose and nature of the trial process, the capacity to provide relevant information to counsel, the ability to reason about this information in a logical fashion, and the ability to apply information to one's own situation in a manner that is neither distorted nor irrational. In addition to defendants' basic understanding and reasoning abilities, their "decisional competence" may be significant in cases in

which defendants must make important decisions about the waiver of constitutional rights (Bonnie, 1992, 1993). Adolescents' competence to stand trial is clearly important in discussions of whether and under what circumstances juveniles might be tried as adults (since the *Dusky* criteria apply to all criminal defendants, regardless of age), but they are also important in considerations involving juvenile court proceedings in light of post-*Gault* decisions that over time have created a relatively more adversarial climate within the juvenile justice system. There is still disagreement about whether the specific competence standards in juvenile court should be identical to or less stringent than those in criminal court (Redding & Frost, 2002), but the majority of states have agreed that, given the potentially serious outcomes of a delinquency adjudication (including, perhaps, a long period of confinement in a prison-like facility), some minimum standard of competence should apply to juvenile court proceedings.

Two obvious ways in which adolescents and adults differ that might make them differentially competent are in their basic cognitive abilities (e.g., ability to recall key bits of information) and life experiences (e.g., familiarity with the roles of the various participants in a trial). A less frequently considered but potentially important difference between adolescents and adults involves aspects of psychosocial maturation that include progress toward greater future orientation, better risk perception, and less susceptibility to peer influence (Coffman & Steinberg, 2000; Scott, Reppucci, & Woolard, 1995). Several authors have hypothesized that these developmental factors could result in differences between adolescents' and adults' decision making about important rights in the adjudicative process, including whether to submit to an interrogation (and, if so, how to respond to questions); whether to provide information to one's defense counsel (and, if so, how completely and honestly to disclose important facts); whether to testify in one's defense; and whether to accept a plea agreement (Grisso et al., 2003). Although it might be assumed that adolescents who are less than fully competent can rely on the advice of adults when making these decisions, adults are not always present (e.g., when an adolescent is picked up for questioning), are not always wise about legal matters (i.e., not all adults are competent), and do not always have the same interests as those of the adolescent (e.g., a mother who is angry at her adolescent for having gotten into trouble with the law in the past may encourage the juvenile to confess to a crime that he may not have committed).

Several studies of age differences in various capacities relevant to adjudicative and procedural competence have

been conducted (for a review see Grisso, 2005). In general, these studies indicate that individuals 15 and younger may be less likely than those 16 and older to possess the skills and capacities likely to render them competent to stand trial or to make important legal decisions, including decisions that arise during interrogations (e.g., whether to waive one's Miranda rights) and trial proceedings (e.g., whether to waive one's right to a jury trial or to accept a proffered plea agreement). As several of the present authors have pointed out in other publications (e.g., Steinberg, Cauffman, et al., 2009), these age differences in various aspects of adjudicative and procedural competence parallel age differences in other domains of competence (e.g., granting informed consent) as well as age differences in basic information-processing and logical reasoning abilities. Although studies of psychosocial development indicate continued maturation in capacities such as impulse control (Steinberg et al., 2008), risk aversion (Steinberg, 2009a), resistance to peer pressure (Steinberg & Monahan, 2007), sensitivity to costs as well as rewards (Cauffman et al., 2010), and future orientation (Steinberg, Graham, et al., 2009) beyond mid-adolescence, age differences in these capacities may not result in age differences in competence to stand trial, perhaps because these social and emotional deficiencies are less likely to impair adolescents' judgment under the particular conditions in which legal decisions are made. As we have argued elsewhere, these capacities may be relevant to assessments of criminal responsibility, however (see Steinberg, Cauffman, et al., 2009).

As noted above, competence to stand trial is only one aspect of legal competence, which also includes the competence to make legal decisions outside the courtroom. The most frequently studied aspect of noncourtroom legal decision making concerns adolescents' responses to interrogations by law enforcement officials (Kassin et al., 2010). Within this area of inquiry, researchers have studied age differences in individuals' comprehension of Miranda warnings (Grisso, 1980), in individuals' decisions about whether to confess to a crime they have committed, (Grisso et al., 2003), and in individuals' susceptibility to making false confessions (Kassin, 2008; Malloy, Shulman, & Cauffman, 2013). Generally speaking, these studies show that adolescents, especially those younger than 16, are less likely to understand their rights, more likely to comply with authority, and less likely to make decisions that reflect their best interests (e.g., remaining silent rather than confessing during an interrogation, giving a false confession in order to please an interrogator). Results of these studies have prompted many advocates to call for

greater protections for juveniles during interrogations, including mandatory videotaping and/or the presence of an adult during questioning (Kassin et al., 2010).

Under American criminal law, police officers are only required to notify those being interrogated of their legal rights, including the right to remain silent, if the individual to be questioned is in custody; this notification, which is well-known to anyone who has watched a television program or film involving a police interrogation, is known as the Miranda warning. Statements made to an officer while one is in the officer's custody are inadmissible in court unless the individual has been "Mirandized." In contrast, if an individual is not in custody, no Miranda warning is required, and anything said to a police officer subsequently can be used in a legal proceeding. One aspect of decisional competence that has received special attention from the courts, therefore, concerns individuals' appraisal of whether they are in custody, because an officer may argue that a confession obtained from an individual who was not in custody was given freely and voluntarily, even though the individual had not been informed of his or her rights.

This issue was at the center of *J.D.B. v. North Carolina*, a 2011 U.S. Supreme Court case involving a 13-year-old adolescent who was pulled out of a social studies class and interrogated by two police officers in a middle school conference room, in the presence of two school administrators. The boy was suspected of having committed two home break-ins during which several items were stolen. Although he initially denied having stolen the property, after some questioning by one of the police investigators and the urging of a school administrator to "do the right thing," J.D.B. eventually admitted that he and a friend had indeed committed the robberies. The boy had not been read his Miranda warning, however, nor was he told until after he confessed that he was free to leave the conference room. Neither the officers nor the administrators provided an opportunity for the boy to speak with his grandmother before he was questioned.

At issue was whether J.D.B.'s confession was admissible. The boy's defense attorney moved that the results of the interrogation should be suppressed, on the grounds that the confession was involuntary because it was conducted in a custodial setting in which the police officers failed to notify J.D.B. of his rights. The trial court denied the motion, arguing that J.D.B. was not in custody and that his confession was therefore voluntary. Both the appellate court and the state supreme court concurred with the trial court.

The U.S. Supreme Court disagreed. In prior cases, the court had determined that in deciding whether issuing a Miranda warning is necessary, a police officer is required to take into account all of the "circumstances surrounding the interrogation" (*Stansbury v. California*, 1994, at 322), including any circumstance that "would have affected how a reasonable person" in the suspect's position "would perceive his or her freedom to leave" (*Stansbury*, 1994, at 325). In *J.D.B.* the court ruled that the officer must take into account the age of the individual being questioned: "A reasonable child subjected to police questioning will sometimes feel pressured to submit when a reasonable adult would feel free to go" (*J.D.B. v. North Carolina*, 2011, p. 8). Importantly, the court noted that the relevant variable is the age of the interrogatee, and not the officer's judgment of that person's appraisal of the situation, a criterion that had been judged inappropriate in a previous case (*Yarborough v. Alvarado*, 2004). "A child's age is far more than a chronological fact," the majority opinion noted in *J.D.B.* "It is a fact that... generates commonsense conclusions about behavior and perception. . . . Such conclusions apply broadly to children as a class. And, they are self-evident to anyone who was a child once himself, including any police officer or judge" (*J.D.B. v. North Carolina*, 2011, pp. 8–9).

### *Criminal Culpability*

The recognition that juveniles and adults are different in ways that necessitate their differential treatment under criminal law had arisen in several Supreme Court cases that preceded *J.D.B.*, but in a different context. In these earlier cases, all but one of which concerned the death penalty, the central matter concerned whether juveniles should be held to the same standards of criminal responsibility as adults and, accordingly, subject to the same punishments for comparably serious crimes. At issue in these cases has been whether a punishment that is constitutional when applied to adults violates the Eighth Amendment's prohibition against "cruel and unusual punishment." These cases revolved both around whether a specific punishment was "unusual" when applied to a juvenile (e.g., if only a very small minority of states allowed the death penalty in cases involving minors, a state's law permitting capital punishment in these instances might be viewed as "unusual") as well as whether the punishment was "cruel," in the sense that it was disproportionate to the degree of responsibility the offender had for the criminal act. Our discussion focuses on the latter question, since the former

one is mainly an actuarial one that has nothing to do with developmental differences between adolescents and adults.

The landmark case in this series was *Roper v. Simmons*, which abolished the juvenile death penalty in 2005. *Roper* had been preceded by two earlier cases, *Thompson v. Oklahoma* (1988), which banned capital punishment for individuals under the age of 16, and *Stanford v. Kentucky* (1989), which affirmed 16 as an acceptable minimum age for eligibility for capital punishment, mainly on the grounds that there existed no national consensus against this policy. *Roper* moved this line to 18, in part because by 2004 (when the case was argued) the national consensus had changed, and in part because of increasing scientific evidence that important capacities relevant to judgments of culpability continued to mature beyond age 16.

*Thompson* was not the first case in which the court acknowledged that juveniles are less mature than adults. The court's opinion in *Thompson* built on prior cases, most notably, *Eddings v. Oklahoma* (1982), a death penalty case in which the court, while not banning the juvenile death penalty outright, opined that the age of a criminal defendant should be taken into account as a potential mitigating factor during sentencing, and *Bellotti v. Baird*, a case concerning minors' access to abortion without parental consent, in which the court explicitly recognized the developmental immaturity of juveniles, and, in particular, "their inability to make critical decisions in an informed, mature manner" (*Bellotti v. Baird*, 1979, p. 2). Thus, although *Roper* abolished the juvenile death penalty, the court had already recognized that there were important developmental differences between adolescents and adults and, in particular, that adolescents were immature in ways that mitigated their criminal responsibility.

The majority opinion looked to developmental psychology for support. Writing for the majority, Justice Anthony Kennedy pointed to three differences between adolescents and adults that made it difficult to classify juveniles "among the worst of offenders": (1) their immaturity and an underdeveloped sense of responsibility, which compromised their decision-making ability (noting that this was the very reason that states limited many juveniles' rights); (2) their heightened susceptibility to external influence, including peer pressure, which gave them less control over their environment; and (3) their still-developing character. The first two differences make adolescents less responsible for their behavior than adults, and, accordingly, less culpable for their crimes. The third difference makes

adolescents better candidates for rehabilitation. Kennedy also noted that the same characteristics that make juveniles less culpable also make them less likely to be deterred by the possibility of capital punishment, thereby undercutting one of the chief claims of death penalty proponents (that it serves a deterrent purpose).

The dissenting justices in *Roper* questioned the need for a categorical exclusion of adolescents from death penalty eligibility, as opposed to case-by-case sentencing decisions that could be made by judges or juries. In some regards, this was the central and most challenging issue in *Roper*. The dissenting justices acknowledged that there could certainly be instances in which a juvenile's immaturity mitigated his criminal responsibility, but raised concerns about cases in which the crime was an especially heinous one committed by an older adolescent who demonstrated adult-like premeditation (ironically, this is an apt description of the behavior of the defendant in *Roper*). Here, the relevant developmental evidence concerned the difficulty to reliably predict the future behavior of a juvenile offender. Developmental scientists had made the argument that, even in cases of especially heinous crimes, it was impossible to distinguish between juveniles who were incorrigible and those who were not. The court's majority agreed, noting, "If trained psychiatrists with the advantage of clinical testing and observation refrain, despite diagnostic expertise, from assessing any juvenile under 18 as having antisocial personality disorder, we conclude that States should refrain from asking jurors to issue a far graver condemnation that a juvenile offender merits the death penalty" (*Roper v. Simmons*, 2005, pp. 19–20).

*Roper* was an important decision for three reasons. First, the court widened the prohibition against capital punishment to include an age range in which there are more than just a handful of juveniles who would be affected by the decision (almost no murders are committed by people younger than 16, so the ban against capital punishment established in *Thompson* was of little practical consequence). Second, developmental science showing differences between adolescents and adults was mentioned numerous times during the case's oral arguments and in the court's decision; in previous rulings on juveniles' criminal culpability, the fact that there were differences between adolescents and adults was presented mainly as a matter of common sense. Finally, research on adolescent brain development was introduced as evidence in support of the contention that adolescents were inherently less mature

than adults. Although reference to neuroscience did not appear in the court's decision, it was discussed at oral argument. Indeed, a telling exchange between one of the attorneys and Justice Breyer suggested just how influential neuroscience might have been on the court's deliberations:

Justice Breyer: Now, I thought that the—the scientific evidence simply corroborated something that every parent already knows, and if it's more than that, I would like to know what more.

Mr. Waxman: Well, it's—I think it's—it's more than that in a couple of respects. It—it explains, corroborates, and validates what we sort of intuitively know, not just as parents but in adults that—that—who live in a world filled with adolescents. And—and the very fact that science—and I'm not just talking about social science here, but the important neurobiological science that has now shown that these adolescents are—their character is not hard-wired. (U.S. Supreme Court, 2004, p. 40)

Five years after *Roper*, the court extended the logic it drew upon in abolishing the juvenile death penalty to prohibiting the use of life without parole (LWOP) for juveniles convicted of crimes other than homicide, in *Graham v. Florida* (2010). Referencing its ruling in the death penalty case, the majority explicitly stated, "No recent data provide reason to reconsider the court's observations in *Roper* about the nature of juveniles. As petitioner's *amici* point out, developments in psychology and brain science continue to show fundamental differences between juvenile and adult minds" (*Graham v. Florida*, 2010, pp. 7–8). As in *Roper*, the dissenting justices once again asked why the prohibition of LWOP for juveniles convicted of nonhomicides needed to be categorical.

Although the essential argument advanced in *Graham* was the same as that put forth in *Roper* (i.e., that juveniles' criminal culpability was diminished by their immature decision-making, susceptibility to peer pressure, and unformed character), the LWOP decision was noteworthy in at least two respects (Maroney, 2011). First, *Graham* was the first case in which findings from developmental neuroscience were explicitly referenced in the opinion, albeit in just one sentence: "For example, parts of the brain involved in behavior control continue to mature through late

adolescence" (*Graham v. Florida*, 2010, p. 17). Although developmental differences in behavior remain more important for debates about adolescent culpability than developmental differences in brain structure or function (Steinberg, 2012), the court's stated acceptance of neurobiological immaturity as a part of the more general developmental immaturity argument signaled a shift in thinking that encouraged lower courts to look to brain science in order to justify the differential treatment of adolescents.

Second, the extension of the basic reasoning used in *Roper* beyond the realm of death penalty jurisprudence opened the door for the application of the developmental immaturity argument more generally. If adolescents' relative immaturity made the use of LWOP unfair, why, then, could this argument not be applied to any sentencing decision? Historically, many of the arguments that have been employed to limit the use of the death penalty have relied on the notion that "death is different," which justifies special scrutiny of the circumstances under which capital punishment is applied: "The Court . . . has recognized that the qualitative difference of death from all other punishments requires a correspondingly greater degree of scrutiny of the capital sentencing determination" (*California v. Ramos*, 1983). In *Graham*, the court's majority argued that, as far as adolescents were concerned, LWOP was different, too, noting that a juvenile sentenced to life would spend more years and proportionality more of his life in prison than an adult who received the same sentence. This paved the way for subsequent rulings in state courts that limited the use of excessively long sentences where juveniles were concerned, even if they were not as long as life sentences. In California, for example, the state Supreme Court ruled that a sentence in which the date of parole eligibility exceeded the natural life expectancy of a juvenile violated the portion of the *Graham* ruling that requires that juveniles convicted of nonhomicides be given a meaningful opportunity to demonstrate their rehabilitation.

The *Graham* ruling applied only to instances in which an individual had been convicted of a nonhomicide offense. As such, its practical implications were limited; nearly all individuals serving LWOP sentences for crimes committed as juveniles had been convicted of homicide. In 2012, the court revisited juvenile LWOP in its ruling in two linked cases, *Miller* and *Jackson* (*Miller v. Alabama*, 2012). Each involved a 14-year-old who had been convicted of homicide and sentenced to LWOP. In contrast to *Graham*, these cases potentially affected a far greater number of individuals. At the time they were argued,

nearly 2,500 individuals were serving life sentences in American prisons for crimes they had committed as juveniles.

Just as *Graham* built on *Roper*, *Miller-Jackson* built on *Graham*, with the majority of the court once again concluding that adolescents' developmental immaturity limited their criminal culpability. The opinion noted that the science had become even stronger since *Roper* and *Graham*, pointed out that the court's conclusions in those earlier cases continued to be strengthened by neuroscience, and went into greater detail about the research findings, mentioning the immaturity in adolescence of higher-order executive functions such as impulse control (which had been highlighted in *Graham*), as well as deficiencies in planning ahead and risk avoidance. The *Miller-Jackson* ruling differed from *Roper* and *Graham* in one very significant way, however. Whereas the earlier cases had placed categorical bans on the use of the punishment in question for juveniles, *Miller-Jackson* left LWOP on the table as an option; the ruling only prohibits states from *mandating* LWOP as a sentence for juvenile murderers, on the grounds that such mandates do not permit courts to take into account the juvenile's developmental immaturity. Writing for the majority, Justice Elena Kagan noted, "given all we have said in *Roper*, *Graham*, and this decision about children's diminished culpability and heightened capacity for change, we think appropriate occasions for sentencing juveniles to this harshest possible penalty will be uncommon." It is not yet clear whether this prediction will hold true.

### Summary of Treatment of Children and Adolescents in the Justice System

The treatment of children and adolescents in the justice system has evolved considerably. Prior to the establishment of the juvenile justice system, the justice system treated adolescents older than 14 as adults. The juvenile justice system relegated cases involving minors to a separate, supposedly paternalistic, and nonadversarial process with the aim of rehabilitation. In practice, however, the juvenile justice system could result in harsh punishments without due process protections. *Gault* established the need for such due process protections, but a gradual shift in attitudes toward juvenile crime led to increasing numbers of juveniles being tried in adult courts or subject to severe penalties such as death or life without possibility of parole. Most recently, court decisions have found such sentences inappropriate.

Developmental science has proven to be directly relevant to numerous aspects of minors' treatment by police

and courts. Police may be required to Mirandize minors prior to questioning in situations for which Mirandizing of an adult would not be necessary. Various competencies related to asserting one's rights, participating in one's defense, and assessing one's best interests evolve in ways that impact the treatment of juveniles by police and by the courts. Changes in psychosocial factors such as impulsivity, resistance to peer pressure, and consideration of long-term consequences, meanwhile, are relevant to discussions of juveniles' culpability and to assessments of their amenability to change. Courts have grown increasingly willing to allow such developmental science to inform their thinking on issues of competence and culpability.

### THE LEGAL REGULATION OF MINORS' MEDICAL DECISION MAKING

During the transitional period of adolescence, youth increase in both their desire and capacity to make medical decisions for themselves. That some minors, due to their level of intellectual and emotional maturity, should be empowered to make medical decisions independently is not controversial (Veith, 1994). However, because there is no simple test for psychological maturity, and owing to a legal tradition of deference to parental authority, laws related to adolescents' medical decision making can be complicated and seemingly contradictory.

The present section reviews the philosophical and historical basis for protecting parents' decision-making authority over minors' medical decisions and, conversely, for allowing minors to make such decisions for themselves. Supreme Court decisions are examined in order to clarify the rationale for the current state of the law in this area. Finally, we explore the degree to which developmental science accords with and informs the Supreme Court's reasoning about minors' medical decision making.

For the majority of medical decisions (e.g., whether to treat a sinus infection, or put a cast on a broken bone), the desires and interests of the various stakeholders—the minor, the parent, the state—are aligned. However, when stakeholders' desires and interests come into conflict, the courts must weigh minors' rights (e.g., to liberty and privacy) against parents' rights (to rear their children as they see fit) and the interests of the state. The Supreme Court is only given the opportunity to carry out this responsibility for cases that reach the highest level of appeal, which tend to involve particularly controversial issues. For example, the Supreme Court has heard many constitutional

challenges to laws limiting access to abortion, including several involving minors' access to abortion. As a result, minors' rights with respect to medical decision making have been delineated to a disproportionate extent in abortion-related cases. Cases involving the involuntary commitment of minors to state hospitals, minors' access to contraception, and the rights of minors to refuse recommended medical care have also helped to clarify the legal rights of minors with respect to medical decision-making. In deciding these cases, the court has articulated the competing philosophies that animate the broader, ongoing debate about where parental authority ends and adolescent autonomy begins.

### Two Pillars of Parental Authority

In the area of medical decision making, American law operates on the default rule that parental consent is required before performing any nonemergency medical procedure on a minor. Thus, absent a statute allocating discretion to the minor or the state, parents hold the decision-making authority in the medical sphere. For adults, decision-making autonomy is guaranteed by the Fourteenth Amendment rights to privacy and liberty and may not be infringed upon without due process. Minors are sometimes afforded these same protections, but only after considering the rights and interests of the parent and state.

Parental authority over minor children is grounded in two broad premises. The first is that parents have the right to raise their children as they see fit. This common law principle stems from the view that parents, more than any other parties, are optimally positioned and motivated to make decisions that serve the best interests of their children (*Pierce v. Society of Sisters*, 1925; *Meyer v. Nebraska*, 1923). Consistent with this perspective, U.S. law traditionally affords parents "a substantial measure of authority over [their] children" (*Bellotti v. Baird*, 1979, p. 638). In keeping with this tradition, the Supreme Court has interpreted the Fourteenth Amendment right to privacy as applying to families and affirming parents' right to direct the raising of their children, excepting cases of abuse and neglect.

The second premise for curtailing minors' decision-making autonomy is their presumed lack of competence. This position was made explicit by the Supreme Court in *Bellotti*, a case interrogating the constitutionality of a Massachusetts statute requiring parental consent prior to an abortion being performed on an unmarried minor. Though the court struck down the statute, in its decision,

it asserted that for "important, affirmative" decisions that entail risks, states may limit the ability of minors make their own choices because "during the formative years of childhood and adolescence, minors often lack the experience, perspective, and judgment to recognize and avoid choices that could be detrimental to them" (*Bellotti*, p. 635). In essence, the court was saying that the state may require parental consent because minors lack the capacity to make decisions that serve their own best interests.

These two pillars of parental dominion in medical decision-making—parental authority rights and the presumed incompetence of minors—are apparent in the court's decision in *Parham v. J.R.* (1979, p. 603), a case dealing with the involuntary commitment of minors to state-run mental institutions:

Simply because the decision of a parent is not agreeable to a child or because it involves risks does not automatically transfer the power to make that decision from the parents to some agency or officer of the state. The same characterizations can be made for a tonsillectomy, appendectomy, or other medical procedure. Most children, even in adolescence, simply are not able to make sound judgments concerning many decisions, including their need for medical care or treatment. Parents can and must make those judgments.

What is clear from this excerpt is that under U.S. law (absent special circumstances) decision-making authority rests, by default, with the parent (the parental rights pillar); and minors—even older ones—are not considered competent to make such decisions for themselves (the incompetence pillar). The parental rights pillar is a philosophical stance combined with an observation of traditional practice. The second position, however, is a falsifiable claim and has been subjected to the scrutiny of developmental science.

### Exceptions to Parental Authority—When Minors' Rights Prevail

Despite the tradition of minors' rights to liberty and privacy being subjugated to parental authority, there are cases in which the law makes an exception and awards decision-making autonomy to minors.

#### *Emancipated Minor*

One such exception is applied to minors whose situation places them beyond the scope of parental control. As noted in the Family section previously, "emancipated minor" status is generally assigned in situations where a minor is enrolled in military service, is married, is a

parent, or is otherwise arguably independent of his or her parents. Common law permits emancipated minors to be treated like adults for many purposes, including medical decision-making (Garber, 2009; Hill, 2012; Robertson, 2008).

### *Adolescents' Privacy Rights*

Another exception to parental authority has arisen as a reaction to the concern that if adolescents must involve their parents in certain medical decisions, they will forego or postpone needed testing and treatment—especially for conditions linked to behaviors that adolescents often prefer to keep secret from their parents, such as substance use and sexual behavior (Berlan & Bravender, 2009; Cheng, Savageau, Sattler, & DeWitt, 1993; Ford, Millstein, Halpern-Felsher, & Irwin, 1997; Lehrer, Pantell, Tebb, & Shafer, 2007). In response to this problem, many states have enacted laws affording minors access to confidential care for such sensitive medical issues. For example, all 50 states and the District of Columbia permit minors to seek testing and treatment for sexually transmitted infections without parental consent (though some impose minimum age thresholds). Twenty-one states grant minors unfettered access to prescription contraception (Guttmacher Institute, 2012). In some states, minors are also given statutory access to mental health treatment (including for drug and alcohol abuse) without parental consent (Lallemont, Mastroianni, & Wickizer, 2009). Where such laws exist, the state has essentially intervened to limit parental rights on the grounds of serving the best interests of minors and society, both of which might suffer if adolescents opted not to seek needed reproductive and mental health care.

Although state laws may recognize that adolescents will refrain from seeking needed medical care if they are not guaranteed confidentiality, the Supreme Court does not view this concern as sufficient to justify invalidating parental notification laws, at least in abortion cases. In *H.L. v. Matheson* (1981, 413), an abortion case involving a 15-year-old, dependent minor, the court declared: “That the requirement of notice to parents may inhibit some minors from seeking abortions is not a valid basis to void the statute as applied to appellant. . . . The Constitution does not compel a state to fine-tune its statutes so as to encourage or facilitate abortions.” Accordingly, this is a narrow finding may not generalize to nonelective procedures.

On the other hand, in blocking a law that would have barred (among other activities) the sale of nonmedical contraceptives to minors under the age of 16 (*Carey v. Population Services*, 1977), the court recognized minors’

right to privacy in their decisions related to sexual behavior. In this case, the court bundled decisions about contraception use, which may be thought of as a form of medical decision-making, into this privacy right. The court also refrained from articulating a lower age limit for privacy rights related to sexual behavior, noting the difficulty of balancing minors’ constitutional rights against the interests of the state in regulating their conduct: “The question of the extent of state power to regulate conduct of minors not constitutionally regulable when committed by adults is a vexing one, perhaps not susceptible of precise answer. We have been reluctant to attempt to define ‘the totality of the relationship of the juvenile and the state’” (*Carey v. Population Services*, 1977, p. 692).

Furthermore, the court strongly rejected the argument that minors may be denied access to contraception (or abortion) in order to further the state’s interest in discouraging sexual behavior among the young. In condemning the idea that the state’s response to adolescent sexual behavior should be to make the behavior more hazardous, the court (quoting *Eisenstadt v. Baird*, 1972) asserted: “‘It would be plainly unreasonable to assume that [the State] has prescribed pregnancy and the birth of an unwanted child [or the physical and psychological dangers of an abortion] as punishment for fornication.’ We remain reluctant to attribute any such ‘scheme of values’ to the State” (*Carey v. Population Services*, 1977, p. 695). Also, although the court’s decision in this case was not based on rejection of the appellants’ theory that the law would decrease sexual behavior among adolescents, the court did note that the appellants lacked empirical evidence to support that claim, whereas the appellees provided ample evidence that withholding contraception does *not* deter adolescents from sexual behavior.

### *The Mature Minor Rule*

That some youth attain adult-like intellectual capacities long before they reach the age of majority is neither controversial nor a recent discovery. Long before the evolution of current developmental science, the law began carving out exceptions to parental authority based on the observed ability of many minors to exercise good judgment.

Common law dating back to the colonial period acknowledges that some minors, referred to as “mature minors,” possess sufficient faculties to be afforded decision-making autonomy. Though the specific requirements of mature minor statutes vary (with some including criteria unrelated to reasoning capacity, such as being pregnant), minors who meet the standards are empowered

to make their own decisions about medical treatment, even if they have not been granted state-sanctioned emancipated minor status (Garber, 2009; Hill, 2012).

The mature minor rule is highly relevant to the much newer legal concept of informed consent. Under current law, a patient must provide informed consent to undergo any treatment or procedure that entails risk, except in emergency situations. At its core, the requirement of informed consent is met when “all parties to [a given] transaction take part willingly in awareness of ways in which others’ proposed action will bear on them” (O’Neill, 2003, p. 4). Formal informed consent procedures are employed in many areas besides medicine, including research participation and contractual agreements. In medicine, informed consent requires, among other things, that the patient possess the capacities to understand the nature of a medical intervention and appreciate its potential short- and long-term consequences (Grisso & Appelbaum, 1998). Many minors are appraised by health care providers as possessing these capacities. Absent prohibitory laws, health care providers may invoke the mature minor rule in order to provide standard medical treatment without parental consent (Berlan & Bravender, 2009).

However, judging the capacity of a minor to provide consent is not straightforward. There is no “gold standard” method for making such a determination and the courts have provided no official guidance as to how to do so (Veith, 1994). Doctors typically bear the responsibility to make this assessment. If a doctor determines that a minor is competent to provide consent, the doctor then becomes obliged to guard the minor’s confidentiality, meaning that the doctor may not inform the parent of the adolescents’ treatment (Berlan & Bravender, 2009). Thus, in judging a minor to be competent, the doctor is also allocating decision-making authority to the minor, with all its attendant responsibilities and protections. In doing so, the doctor places him or herself at some risk of litigation; the parent may later claim that his or her parental rights were infringed upon (Robertson, 2008). The evaluation of a minor’s capacity to consent is further complicated by the dynamic nature of the threshold for this capacity. A higher degree of cognitive capacity may be required to appreciate the nature and potential consequences for some medical interventions than for others (Grisso & Appelbaum, 1998).

### Judging Maturity in Medical Contexts

In the United States, there is quite a bit of variability in the laws related to adolescents’ ability to make their own

health care decisions. Some states lack relevant legislation altogether. Among the states that do have germane laws, several make “bright line” distinctions between classes of minors, barring access for those under a certain age to confidential medical treatment. Such laws are efficient in that they make it simple for health care providers to know how to proceed in any given case and because they excuse the provider from having to evaluate the minor’s decision-making capacity (Robertson, 2008). However, these types of laws are ethically and constitutionally questionable in that they deny rights to some minors who may be competent to make their own decisions. Research suggests that these laws also have the practical drawback of discouraging some youth who would benefit from medical attention from seeking it (Berlan & Bravender, 2009; Lallemon et al., 2009; Robertson, 2008). Other states, recognizing that psychological maturity is not dictated by chronological age, have adopted laws that allow for flexible determinations of an adolescents’ capacity to consent.

The flexible, individualized approach is the one favored by the United Nations. The United Nations Convention on the Rights of the Child (signed but not ratified by the United States) calls on state entities to encourage children to be involved in decisions related to their medical care in a manner that recognizes their “evolving capacities.” In the United States, associations representing health care providers, including the American Medical Association (AMA), the American Academy of Pediatrics, the Society for Adolescent Medicine, the American Academy of Family Practice, and the American College of Obstetrics and Gynecology, have also taken positions that favor individualized assessment of an adolescent’s capacity to make his or her own medical decisions while simultaneously supporting parental involvement (Berlan & Bravender, 2009). For example, the AMA’s Code of Medical Ethics states that:

Physicians who treat minors have an ethical duty to promote the autonomy of minor patients by involving them in the medical decision-making process to a degree commensurate with their abilities.

When minors request confidential services, physicians should encourage them to involve their parents. This includes making efforts to obtain the minor’s reasons for not involving their parents and correcting misconceptions that may be motivating their objections.

Where the law does not require otherwise, physicians should permit a competent minor to consent to medical care and should not notify parents without the patient’s consent.

Depending on the seriousness of the decision, competence may be evaluated by physicians for most minors. When necessary, experts in adolescent medicine or child psychological development should be consulted. Use of the courts for competence determinations should be made only as a last resort. (AMA, 1994)

Though the Supreme Court has not explicitly endorsed any specific mature minor rule, it has repeatedly recognized, in cases related to abortion (*Akron v. Akron Center for Reproductive Health Inc.*, 1983; *Bellotti*, 1979; *Hodgson v. Minnesota*, 1990; *Planned Parenthood Association of Kansas City v. Ashcroft*, 1983; *Planned Parenthood of Southeastern Pennsylvania v. Casey*, 1992), that minors may be mature enough to make their own medical decisions. For example, it has invalidated any parental consent or notification requirement that did not also provide a judicial bypass option. Judicial bypass is a mechanism that allows a pregnant minor to access abortion without parental consent by going through the court. If a judge evaluates the minor to be mature enough to consent to the procedure or determines that the abortion would serve her best interests, then the minor may proceed with the abortion without parental consent or notification. In *Bellotti*, the court made clear that once a judge has deemed a minor to have mature decision-making faculties, the minor must, under the equal protection clause of the Fourteenth Amendment, be afforded decision-making autonomy on par with that of adults (*Bellotti*, 1979). This means that the judge cannot then veto the “mature” minor’s “informed and reasonable decision to have an abortion” (*Bellotti*, 1979, p. 630, quoting the Massachusetts’ Supreme Judicial Court’s interpretation of the statute). Furthermore, in *Akron*, the court expressly prohibited states from making “a blanket determination” that minors below a given age (15 in this case) are incapable of demonstrating sufficient maturity to make an informed decision to have an abortion. This holding clearly favors the individualized approach (promoted by the United Nations) to the assessment of maturity in minors.

### Developmental Science and Medical Decision Making

The general consensus that minors, on average, exhibit poorer decision-making than adults serves as one of the primary justifications for limiting their autonomy under the law. Simultaneously, the law, as reviewed in this section, recognizes that decision-making competence increases with age gradually across childhood and adolescence rather than “com[ing] into being magically only when one

attains the state-defined age of majority” (*Planned Parenthood of Central Mo. v. Danforth*, 1976, p. 74). Of course, the question of how and when capacities that undergird good decision-making develop is an empirical one. At present, the best research suggests that by midadolescence, the abilities of youth to understand the facts of a medical or legal decision and reason rationally about it are often on par with that of adults, at least under conditions of low time-pressure and under low emotional arousal (Steinberg, Cauffman, et al., 2009). Studies that have compared age groups in decision-making tasks designed to probe legally relevant decision-making capacities identify different ages at which adolescents’ abilities (on average) become equivalent to adults’ (e.g., Grisso et al., 2003; Weithorn & Campbell, 1982), with the line tending to fall between 14 and 16 years of age. Furthermore, the ability to make these decisions optimally appears to track improvement in basic cognitive capacity (e.g., short-term memory, verbal fluency), which reaches adult levels by about Age 16 (Steinberg, Cauffman, et al., 2009). It is important to bear in mind, however, that studies investigating decision-making competency typically do not permit adolescent subjects to consult with medical professionals or other adults, as youth often do when really faced with important decisions (Henshaw & Kost, 1992). Such consultations may lower the age at which minors’ decision-making competence becomes indistinguishable from adults’. Overall, developmental science supports the view expressed in the mature minor doctrine and in the Supreme Court’s decisions reviewed here, that many adolescents possess sufficient capacity for reasoning and understanding to provide informed consent.

Yet, developmental science has not played a major role in shaping the law surrounding adolescents’ medical decision making. Even when developmental scientists have attempted to influence the law as it relates to minors’ medical decision making, the Supreme Court’s majority holdings do not appear to have been significantly affected. For example, despite an amicus brief from the American Psychological Association (APA) presenting evidence that “with respect to the capacity to understand and reason logically, there is no qualitative or quantitative difference between minors in mid-adolescence, i.e., about 14–15 years of age, and adults” (AMA, 1994, p. 10), the court in *Hodgson v. Minnesota* (1990) upheld a state law requiring that minors obtain parental permission or judicial approval before obtaining an abortion. Even Justice Marshall’s full-throated (dissenting) argument against the constitutionality of parental consent, parental notification and judicial bypass procedures, which noted evidence of

the harmfulness of these procedures and the unreasonableness of assuming a judge is better qualified than a doctor to assess a young woman's maturity level, did not cite the developmental literature on adolescents' decision-making capacities. His objection to these impediments to minors' access to abortion were apparently based on the view that the right to privacy should have prevailed, irrespective of decision-making capacity: "An 'immature' minor has no less right to make decisions regarding her own body than a mature adult" (*Hodgson*, 1990, p. 473). The minimal impact of developmental science in this sphere is likely attributable to the fact that legal recognition of mature minors predates the relevant research. Still, the developmental evidence supports the establishment of a lower default age than 18 for the presumption of decision-making competence in the medical sphere.

In contrast, in the area of crime and punishment, developmental science has begun to have an impact on Supreme Court decisions. As described in the juvenile justice section of this chapter, the court cited neurological and behavioral evidence of minors' *immature* decision-making capacities, supplied in amicus briefs by the American Psychological Association (APA), in its 2005 decision to proscribe the death penalty for juvenile offenders (*Roper v. Simmons*) and again in its 2010 decision barring life sentences without the possibility of parole for juveniles convicted of nonhomicide crimes (*Graham v. Florida*). For its argument opposing permanent sanctions for juvenile offenders, the APA was accused by members of the court of contradicting its prior position in *Hodgson*, where it had emphasized the decision-making competence of adolescence. As explained in Steinberg, Cauffman, et al. (2009), an article authored by scholars who had contributed to the amicus briefs, the apparent discrepancy can be resolved by acknowledging the disparate circumstances surrounding medical versus criminal decision-making and how these affect adolescents' behavior. Choices about nonemergency medical treatment are typically made over the course of days and weeks, enabling reflection and information seeking by the adolescent. Such conditions allow for maximal exertion of one's reasoning capacities. On the other hand, decisions to commit crimes are often not premeditated at all—they can result from impulsive, unthinking reactions. Furthermore, these decisions may be influenced, particularly in adolescence, by emotional arousal and peer pressure. The proposed reason for adolescents' greater susceptibility to criminogenic contexts is that, although midadolescents

may have adult-like reasoning and understanding, even older adolescents and young adults differ substantially from mature adults in terms of their ability to regulate impulses and in their immediate responses to risk and reward (see Steinberg et al., 2008, for a review). Consequently, the circumstances under which many adolescent crimes are committed—under time pressure, under high arousal, in the presence of peers—tend to undermine adolescents' still-developing self-regulatory capacities and, as a result, magnify differences between adolescents' and adults' decision-making (e.g., Chein, Albert, O'Brien, Uckert, & Steinberg, 2011; Figner, Mackinlay, Wilkening, & Weber, 2009; Gardner & Steinberg, 2005). Therefore, it makes sense for judges and lawmakers to consider the context in which a decision is likely to be made when evaluating adolescents' capacities and culpability.

### Summary of Legal Regulation of Minors' Medical Decision Making

The legal arguments for and against affording minors decision-making autonomy with respect to medical care center on the tension between deference to parental authority and respect for minors' individual rights to liberty and privacy. With a few exceptions, the law tends to lean more toward the parental rights side of the scale, as was the case with legal treatment in other family-related contexts discussed earlier. Even for the extraordinarily personal decision of whether to end a pregnancy, the court permits states to compel minors to obtain parental consent or else face a judicial hearing before being allowed to make a decision not to become a parent. It does so despite the fact that, the birth of that child would, by law, automatically release the mother from the constraints of parental authority (and remove from her own parents any parental obligations to her) by qualifying her for "emancipated minor" status. At the same time, for less controversial medical treatment, many states operate on common law or explicit rules that permit doctors to provide treatment without parental notification or consent if they perceive that a minor is mature enough to make informed decisions. Thus far, developmental science has not had a major impact of the legal reasoning in this area, most likely because law has long acknowledged that some minors possess mature decision-making capacities, but also because the maturity of a nonemancipated minor does not necessarily negate rights of parental authority.

## LEGAL REGULATION OF ADOLESCENCE IN SOCIETAL CONTEXTS

Because of their increasing autonomy, adolescents (unlike younger children) often navigate social and commercial interactions without the intervention of their parents. The law that has sprung up to regulate these transactions draws heavily on three principles that are specific to minors and serve as justifications for limiting minors' First Amendment rights. These principles are the state's interest in protecting minors from (1) their own poor judgment, (2) adults who would seek to exploit them, and (3) influences that could disrupt proper moral development. Hereafter, we refer to these as the *judgment*, *exploitation*, and *morality* concerns, respectively.

In this section, we examine the ways in which these three concerns have guided legal restrictions on adolescents' societal transactions, focusing specifically on contracts, media exposure, and sexual behavior. These examples illustrate the limitations on adolescents' autonomous conduct in society and the rationales proffered by lawmakers for these restrictions. They also set the stage for understanding current efforts to legally regulate adolescents' use of interconnected digital technology (e.g., Internet-connected computers, cell phones, and other mobile devices), particularly with respect to messages with sexual content ("sexts" or "sexting"). The intersection of adolescent sexual expression with social media has demanded new legislation balancing adults' conflicting impulses to protect and to punish youth involved in sexting.

In many of the legal domains considered, the overarching protective approach applied by the courts makes developmental science largely irrelevant. The state wishes to protect the interests of minors, regardless of their developmental status. The exceptions involve cases in which minors' rights to self-determination are in question. When do adolescents have the necessary developmental attributes to warrant a right to make autonomous medical decisions? To choose whether or not to have sex, and with whom? To decide whether to submit to police questioning? To participate in their own legal defense? How does a minor's developmental status influence their culpability for antisocial behavior, and their amenability to change? Can a minor be considered incorrigible if key aspects of her identity are still developing? Developmental science provides evidence that informs such questions, and, as such evidence has accumulated, courts

have grown increasingly willing to consider such evidence in their deliberations.

### Contracts

The ability to enter into contracts is a fundamental prerequisite for autonomous functioning in modern society. For contracts to be legally valid, the parties entering into them must do so voluntarily and must be informed about all relevant details of the transaction, enabling both parties to reasonably assess its potential risks and benefits. In the section dealing with medical decision-making, we discussed the considerations that affect whether adolescents may consent to receive medical treatment. There, the question hinged largely on adolescents' judgment—that is, whether adolescents are capable of fully appreciating the risks of various medical interventions, considering that their cognitive and emotional capacities are still maturing. In other contractual transactions, the same concern informs legal regulation. Furthermore, for contracts entered into by adolescents outside of the medical arena, the courts have also considered the possibility that adults will seek to exploit adolescents' poor judgment in order to further their own self-interest. (In medical situations, it is generally assumed that the motivations of health care providers are aligned with those of their patients.)

The Tennessee Supreme Court addressed contracts between adults and minors in *Dodson v. Shrader* (1992). The case dealt with a 16-year-old who purchased a truck from an adult, opted not to repair the truck when a mechanical problem arose 9 months later, and continued to drive the truck until the engine "blew-up." The minor then attempted to return the truck to the adult and recover his full payment (\$4,900) despite the fact that the truck's value had depreciated to \$500. A lower court had "reluctantly" permitted the minor to rescind the contract and had ordered the adult to refund to the minor the full amount paid, upon the return of the truck (which had incurred further damage when struck by a hit-and-run driver). In doing so, it cited the common law "infancy doctrine," which contains language allowing minors (referred to as "infants") to void contracts that are clearly contrary to their interests, but also those that *might* be unfavorable to their interests (i.e., where it is uncertain whether the contract advantages the minor or the adult). According to the court, the infancy doctrine serves legitimate state interests with respect to judgment and exploitation; its purpose is "to protect minors

from their lack of judgment and ‘from squandering their wealth through improvident contracts with crafty adults who would take advantage of them in the marketplace’” (*Dodson*, 1992, p. 547, citing *Halbman v. Lemke*, 1980).

Still, the Tennessee Supreme Court vacated the lower court’s decision and, in doing so, invoked the morality concern. The court set forth new legal requirements to apply to cases in which the relevant contract is reasonable and the adult has entered into it “in good faith.” Specifically, the court declared, an adult vendor need only provide a partial refund to a minor consistent with the item’s depreciated value resulting from the minor’s use of it. Though the court reiterated the importance of protecting minors from unfair or coerced contracts, its decision turned on what it viewed to be the potential for minors to exploit the law:

It does not appear consistent with practice of proper moral influence upon young people, tend to encourage honesty and integrity, or lead them to a good and useful business future, if they are taught that they can make purchases with their own money, for their own benefit, and after paying for them, and using them until they are worn out and destroyed, go back and compel the vendor to return to them what they have paid upon the purchase price. Such a doctrine can only lead to the corruption of principles and encourage young people in habits of trickery and dishonesty. (*Dodson*, 1992, p. 550)

Thus, acting on the state’s interest in preventing youth from acquiring corrupt values, the court ruled that minors must be held to a higher standard of responsibility in contractual transactions than was required by the infancy doctrine.

### Media Exposure

In *Dodson*, the Tennessee Supreme Court underscored the state’s interest in facilitating the proper moral development of minors. The same principle has long served as the rationale for laws restricting minors’ access to particular forms of media and entertainment. In the landmark case of *Ginsberg v. New York* (1968), the United States Supreme Court cited the morality concern in upholding a New York obscenity law prohibiting the sale of pornography to minors. In U.S. law, the word *obscenity* has specific denotations. Following *Miller v. California* (1973, p. 24), obscene material is (somewhat vaguely) defined as that which (a) appeals, by contemporary standards, to “the prurient interest,” (b) depicts sexual conduct offensively, and (c) “lacks serious literary, artistic, political, or scientific value.” Critically, material classified as obscene

is included in the small category of speech understood as “unprotected” (i.e., exempted from First Amendment protection) for all citizens, regardless of age. As such, the obscenity label is powerful; it grants the state rare permission to substitute its judgment for that of competent adults. In *Ginsberg*, the court addressed whether a lower threshold for obscenity could be applied for minors than for adults.

The case was brought by a store owner convicted under New York law of selling pornography to a minor (aged 16). The materials in question were “girlie” magazines, which could be sold legally to those 17 and older. One of the appellant’s contentions was that, by restricting minors’ access to material deemed suitable for adults, the statute in question represented an “unconstitutional deprivation of protected liberty” (*Ginsberg*, 1968, p. 636). The Supreme Court disagreed, finding instead that the restriction was justified on morality grounds. The court concurred with the state’s assessment that media with sexual content served as “a basic factor in impairing the ethical and moral development of our youth and a clear and present danger to the people of the state” (p. 641). In its decision, the court established that different obscenity standards may be applied for minors than for adults. Furthermore, noting that it was “very doubtful” that the state’s ‘clear and present danger’ claim represented a “scientific fact,” the court emphasized that the state need not supply empirical evidence to support such assertions: “To sustain state power to exclude material defined as obscenity by [the statute] requires only that we be able to say that it was not irrational for the legislature to find that exposure to material condemned by the statute is harmful to minors” (p. 641). In effect, the very act of defining a class of speech as harmful to the moral development of youth (i.e., obscene for minors) immediately relieves the state of any requirement to support this claim.

However, U.S. law is quite particular about the type of material that may be considered harmful to minors. In a recent case, *Brown v. Entertainment Merchants Association* (2011), the Supreme Court drew a sharp distinction between media with sexual versus violent content. The case originated in a challenge to a California statute that attempted to use the *Miller* obscenity standards as justification for outlawing the sale of violent video games to minors. Noting the Western tradition of allowing minors access to all sorts of media with violent content, ranging from books, to films, to cartoons, the court determined that—contrary to its decision with respect to pornography—the state was obligated prove its claim that violent media was harmful to

minors. Furthermore, the court was not impressed with the state's evidence in support of this claim, which consisted of psychological studies linking violent video games to heightened aggression. In striking down the statute, the court noted that the empirical evidence pointed to a correlation between violent video games and aggression, but failed to "prove that violent video games *cause* minors to *act* aggressively (which would at least be a beginning)" (Miller, 2011, p. 2740). This statement seems to indicate that the court is open to amending its position in light of future evidence of harm to minors, but will apply rigorous scrutiny to such evidence and consider it only necessary, not sufficient, to justify curtailing minors' right to consume violent media.

### Sexual Behavior

Underlying the notion that depictions of sex pose a threat to minors is the traditional view that sexual behavior by unmarried minors is to be discouraged. Indeed, all states have regulations intended to delay or deter minors from engaging in sexual behavior. These laws exist in tension with minors' rights to privacy for matters related to procreation (*Carey v. Population Services*, 1977), but are nevertheless rationalized by invoking both judgment and exploitation concerns. In addition, in *Michael M. v. Superior Court of Sonoma County* (1981, p. 475) the Supreme Court validated the State's specific interest in preventing "illegitimate teenage pregnancy." Some state legislatures have cited the similarly practical state interest in reducing welfare dependency as a rationale for prohibiting adolescent sex (James, 2009). Notably, the court refrained in this case from invoking the morality concern, perhaps betraying hesitancy to assert that sex is inherently detrimental to minors' moral development.

State supreme courts, in contrast, have proved willing to refer to morality in their defense of laws regulating adolescent sexual behavior. For example, in 1964, the California Supreme Court offered as justification for a statutory rape law the presumption that an underage woman was "too innocent and naive to understand the implications and nature of her act (*People v. Hernandez*, 1964, p. 531). The court goes on to explain:

The law's concern with [an underage woman's] capacity or lack thereof to so understand is explained in part by a popular conception of the social, moral and personal values which are preserved by the abstinence from sexual indulgence on the part of a young woman. An unwise disposition of her sexual

favor is deemed to do harm both to herself and the social mores by which the community's conduct patterns are established. (p. 531)

More recently, Arizona's Supreme Court, in affirming a 16-year-old boy's parole revocation after he was found to have fondled the breasts of a 14-year-old girl, cited the morality concern as a justification for restricting minors' sexual activity, with no further analysis related to that principle: "We are persuaded that the state has a significant interest in proscribing sexual conduct between minors. The state has a strong interest in the ethical and moral development of its minors" (*Matter of Pima County*, 1990, p. 31). Thus, state lawmakers appear to rely primarily on circular moral judgments to justify infringement on minors' privacy rights in sexual matters and, for the most part, the courts uphold their reasoning.

Laws regulating adolescent sexual behavior vary from state to state. One of the few points of consensus is that adults should not be permitted to engage in sex with children. Accordingly, all 50 states have age of consent laws, which designate an age below which a minor's willing participation in sexual intercourse with an adult partner does not inoculate the latter against criminal prosecution for rape or sexual assault. However, the age of consent varies. It ranges from 16 to 18 years of age for sex with an adult partner and from 12 to 18 years of age for consent between minors. Some laws are inflexible, establishing a single age of consent and making no further accommodations, whereas others are developmentally titrated. For example, California law simply sets the age of consent at 18 years, meaning it is illegal for two 17-year-olds to have sex with one another. At the other extreme of nuance, Washington defines the general age of consent as 16, but permits minors as young as 12 to legally consent to sex with a partner up to 2 years older; the law applies a sliding scale, permitting increasingly large age discrepancies between partners as minors age (U.S. Department of Health and Human Services, 2012). Compounding the complexity of these laws are efforts to regulate nonintercourse sexual contact, which involve distinct sets of rules and age limits. Even though age of consent laws were originally intended to regulate *adults'* sexual behavior (i.e., to deter them from having sex with minors), they are also used to regulate sexual behavior among adolescents.

The inconsistency across states in age of consent laws reflects, among other issues, the limited role that social science plays in the drafting and amending of these laws. Yet, considering the varying circumstances under which

adolescent sex occurs as well as individual differences in maturation, it would be difficult for developmental science designate a discrete, uncontroversial age at which youth should be considered capable of consenting to sex. Unlike medical informed consent, decisions surrounding sex often occur spontaneously, under conditions of arousal, and without consultation with trusted adults. These are conditions under which adolescents' judgment may be most discrepant from that of adults (Steinberg, 2009b). As a result, minors who are mature enough to make medical or legal decisions that serve their best interests may fail to make sexual decisions that do so.

Due in part to trepidation about and resistance to community research on adolescent sexual behavior (Blinn-Pike, Berger, & Rea-Holloway, 2000), there is limited empirical insight into whether sex is, as the law often assumes, harmful to youth. Existing studies suggest that among adolescents who engage in sex, the vast majority experience no adverse psychological consequences (Meier, 2007; Vrangalova & Savin-Williams, 2011); those who do tend to be female adolescents who initiate sex early relative to their peers (Meier, 2007). One of the few large-scale, longitudinal studies of the topic found no indication that adolescent sex has enduring detrimental effects on psychological well-being (Spriggs & Halpern, 2008). Moreover, at least one recent study found sexual experience (versus abstinence) during adolescence to be associated with greater well-being (Vrangalova & Savin-Williams, 2011). At this point, then, it appears that adolescent sex does not inflict psychological harm on youth. Whether it inflicts moral harm, as presumed by state law, is a subjective question better suited to philosophy or theology than to science.

Although further research is needed to fully understand the effects of adolescent sex, there is no question that sexual behavior is a typical feature of adolescence. Surveys indicate that sexual intercourse is so common during adolescence as to be normative. A recent national survey of high school students found that 33% of 9th-grade students had engaged in sexual intercourse—by 11th grade, more than half had done so (53%). Sexual contact not involving intercourse, which is also frequently illegal for adolescents, is even more common (Vrangalova & Savin-Williams, 2011). The disconnect between state laws criminalizing adolescent sex acts and the actual rates of adolescent sex acts results in these laws being only rarely enforced (James, 2009; Oberman, 2000). Justice systems would be overwhelmed if even 1% of violations related to underage sexual contact were prosecuted. In noting the apparent failure of California's

statutory rape laws to deter underage sex, Supreme Court Justice Brennan observed that in 1976, despite the occurrence of about 50,000 pregnancies of underage women in the state in the prior year, only 413 males had been arrested on statutory rape charges (*Michael M. v. Superior Court*, 1981). However, there are instances when these laws are enforced, despite the sexual activity in question being consensual. When this occurs, the result can be punishment that is severely disproportionate to the gravity of the offense, such as prison sentences and permanent registration as a sex offender (James, 2009). In some cases of sex between underage partners, both adolescents are charged with sexual assault (see James, 2009, for a review), which calls into question whether the enforcement of the laws furthers their purported purpose—to protect minors.

In some cases, public outcry has led to amendments of statutory rape and assault laws. A series of events in Georgia provides an example of this path to reform. *Humphrey v. Wilson* (2007) dealt with a case in which a 17-year-old Georgia boy received an extraordinarily harsh sentence for having received oral sex from a 15-year-old girl. The boy was convicted of aggravated child molestation—a felony—and sentenced mandatorily to 10 years in prison, after which he would have to register as a sex offender. Adding to the perceived unfairness of this outcome was the fact that had the teens engaged in intercourse rather than oral sex (which was defined under state law as “sodomy”), the offense would have been a misdemeanor; the statutory rape law included an age-difference clause that was absent from the molestation law. Soon after this highly publicized conviction, Georgia revised the child molestation statute so that minors engaging in oral sex were treated similarly to those who engaged in sexual intercourse; a change which the Georgia Supreme Court later described as “represent[ing] a seismic shift in the legislature's view of the gravity of oral sex between two willing teenage participants” (*Humphrey*, 2007, p. 507). In 2007, the Georgia State Supreme court found the boy's sentence to be “cruel and unusual” due to its disproportionality and struck it down. However, despite reforms in some states, the potential for prosecution remains one of major risks attached to adolescent sex.

### Sexting

Adolescents have also become ensnared by outsized criminal charges in connection with the practice of “sexting,” defined in *Miller v. Mitchell* (2010) as “sending or posting sexually suggestive text messages and images, including

nude or seminude photographs, via cellular telephones or over the Internet.” Historically, adolescents have been early and enthusiastic adopters of new communication technologies and digital communication media (cell phones, email, texting, social networking universes) have been no exception. In light of key features of the adolescent period—for example, sexual experimentation, social competition, desire for exciting experiences, susceptibility to peer influence, poor impulse control—it is not surprising that adolescents quickly began to use digital media to transmit sexual images of themselves to their romantic interests. Sexting is now a fairly common practice with about one third of young adults admitting to sending nude photos of themselves via cell phone (Associated Press & MTV, 2009). Among youth under 18 years of age, the proportion sending naked images of themselves (via phone or Internet) appears to be lower, though the estimates, owing to different methodologies and samples, vary widely from 1% (Mitchell, Finkelhor, Jones, & Wolak, 2012) to 27% (Temple et al., 2012).

Due to U.S. states’ strong interest in preventing adults from sexually exploiting minors (e.g., *New York v. Ferber*, 1982), state and federal laws contain strict prohibitions against child pornography. Federal law makes it a felony offense to create, possess, and disseminate visual depictions of a minor engaged in “sexually explicit conduct,” meaning real or simulated sex acts or the “lascivious” display of genital regions. State child pornography laws vary and sometimes employ a lower threshold, proscribing images that are “sexually suggestive,” regardless of whether they feature nudity or a sex act. Such laws do not provide exceptions for images produced by minors of themselves or of other minors (Haynes, 2012). A child pornography conviction carries severe penalties, including mandatory prison sentences and registration as a sex offender.

The definitions of child pornography in these laws encompass many images produced in the course of adolescents’ sexting. As a result, the first decade of the 21st century saw prosecutors charging or threatening to charge minors involved in sexting with child pornography offenses; a phenomenon that ignited national and international outcry (Haynes, 2012). In the controversy that ensued, there was little dispute that the sexts themselves posed a potential threat to minors. Such images can be (and have been) used as a means of bullying. If shared, they could also negatively impact an individual’s long-term educational and employment prospects. Rather, the crux of the conflict was whether it was ethical to use laws intended to protect minors from sexual exploitation as a means to

punish minors for a behavior viewed by many as a digital form of flirtation (Eraker, 2010).

Judges faced with this question have reached contradictory conclusions. In a 2007 Florida case (*A.H. v. State*, 2007) involving the exchange between two minors of digital images of themselves having sex, the Appellate Court denied that the child pornography statute under which the defendants were charged was intended solely to protect minors from exploitation by adults. Quoting an earlier case (*State v. A.R.S.*, 1996, p. 238), the majority argued, “The statute is not limited to protecting children only from sexual exploitation by adults, nor is it intended to protect minors from engaging in sexual intercourse. The state’s purpose in this statute is to protect minors from exploitation by anyone who induces them to appear in a sexual performance and shows that performance to other people.” In addition, the court claimed the child pornography statute was also intended to protect minors from their own immature decision making, stating that “the statute was intended to protect minors like appellant and her co-defendant from their own lack of judgment . . . if these pictures are ultimately released, future damage may be done to these minors’ careers or personal lives. These children are not mature enough to make rational decisions concerning all the possible negative implications of producing these videos” (*State v. A.R.S.*, 1996, pp. 238–239). Going even further, the majority averred that the “mere production” of images portraying sexual conduct by minors (irrespective of their subsequent use or distribution) could cause “psychological trauma to the teenagers involved” (p. 239).

In this same case, one judge dissented, offering an argument in support of the appellant’s claim that her privacy rights should have prevailed. He pointed out the sexual act that was the subject of the photographs was constitutionally protected according to the court’s earlier holding in *B.B. v. State* (1995), which found that the Constitutional right to privacy extends to minors’ sexual activity. The judge further reasoned that because the images produced during the sexual act were shared only between the involved parties and were not intended for distribution, they should be treated under the law as part of the private sexual act. This dissent voiced the view, espoused by many who protested the prosecution of adolescents under child pornography laws, that it was profoundly wrong for the state to use a law “designed to protect children from abuse by others” in order to “punish a child for her own mistake” (p. 239).

In an effort to provide prosecutors with less draconian tools for discouraging adolescents from sexting, many

states have, in recent years, passed or attempted to pass new statutes tailored to this phenomenon. The drafting of targeted statutes serves not only to eliminate disproportionate punishment, but also enables lawmakers to discriminate between the different ways in which adolescents use (and misuse) digital technology. For example, Pennsylvania passed a law (House Bill 815) defining sexting (“the offense of transmission of sexually explicit images by a minor”) and establishing different charges of graded severity for the various forms of sexting (e.g., a minor taking a nude photo of him or herself is a noncriminal summary offense, whereas a minor forwarding a picture of another minor “in a state of nudity” without the subject’s knowledge or consent is a second degree misdemeanor) (National Conference of State Legislatures, 2010). In effect, this law is sensitive to the difference between sexting as a form of flirtation or self-expression and sexting as a means of bullying. In addition, some states have amended their child pornography statutes so that they exclude cases of sexting. Colorado, for example, altered its child pornography law to exclude any “actor” who is less than 4 years older than the subject of the image, provided that the subject is at least 15 years of age (National Conference of State Legislatures, 2009). Legislative efforts such as these represent attempts to produce a legal framework that more effectively furthers state interests in protecting minors with respect to digital media while avoiding criminalizing normative adolescent behavior.

### **Summary of Legal Regulation of Children in Societal Contexts**

In many ways, the law regulating adolescents’ transactions in society has, over time, granted adolescents increasing degrees of autonomy and responsibility. This is reflected in Danforth’s allocation of greater responsibility to minors in the laws regulating their contracts. Yet, adolescents’ rights, especially to privacy in matters relating to sex, are subject to far greater infringement under the law than adults’ rights. Lawmakers remain steadfast in their determination to protect minors from exploitation by adults, from moral corruption, and from their own immature judgment. Yet, there are some cases in which the law is evolving to better reflect current sensibilities (and realities) related to adolescent sexuality. Legislative efforts to reduce or remove penalties for underage sex and to craft new laws designed specifically to address sexting and digital bullying exemplify this phenomenon. For many laws, however—particularly those related to

adolescent sex—even when scientific findings and public opinion have deviated from the original rationale for the law, anachronistic statutes remain in place until a particular instance of enforcement sparks public protest and subsequent legal reform.

## **DISCUSSION**

Modern legal standards generally attempt to protect the interests of minors. In most situations, minors are assumed, by default, to lack the maturity necessary to protect their own interests. This responsibility is reserved primarily for the minor’s parents, whose right to raise their children as they see fit is viewed as sacrosanct. Exceptions to the primacy of parental rights include cases involving parental abuse or neglect, the provision of “emancipated minor” status to youth who are effectively independent, the ability of minors to obtain contraception and medical testing or treatment for sexually transmitted diseases without parental approval, and the ability of “mature minors” to be granted medical decision-making authority if judged to be suitably competent by medical personnel.

In family-related legal contexts, unemancipated minors are generally denied independent legal standing, regardless of their level of maturity. In the public school system, similarly, developmental considerations are rarely involved in decisions regarding the appropriate balance of student rights and the interests of the school or the state. In direct interactions with the state, however, the rights of minors are generally commensurate with those of adults, since constitutionally mandated protections are not age-specific. Developmental science does inform legal policy regarding the treatment of minors by the justice system, however, to ensure that such treatment is appropriate for the minor’s cognitive and psychosocial characteristics. This affords minors additional protections during interrogations, influences the age at which they are presumed to be competent to stand trial in an adversarial court setting, and informs judgments regarding their culpability and amenability to treatment. In medical contexts, “mature minor” rules have long been in place to recognize that in many situations, minors exhibit the necessary capabilities to consent to medical treatment without parental approval. Allowances for autonomous medical decisions also extend to minors seeking treatment for conditions about which they might not otherwise confide in their parents, though parental consent (or judicial waiver) requirements have been upheld for abortion. Minors entering into contracts are provided

with additional protections not afforded to adults, to protect them from exploitation, but the extent of such protections has been reduced to avoid abuse of such protections by unscrupulous minors. Minors are shielded from exposure to obscene material. Laws prohibiting sexual contact with minors, intended to prevent abuse at the hands of adults, have also been used to punish minors. Some egregious cases have led to reforms, but many such laws remain in effect. Legislatures in various states have begun to develop statutes to handle “sexting” by minors in a way that differentiates it from dissemination of child pornography.

## INTRODUCTION

In politics, *regulation* is either a dirty word or the savior of the people. In developmental science, regulation has diverse connotations across disciplines, ranging from the neuroscientist's prefrontal cortex-mediated executive control over impulsive behavior, to the social psychologist's social conformity with peers, to the developmental scientist's mother soothing an infant's emotional outbursts, to the economist's taxation of adolescent alcohol consumption. What is common across these diverse examples is the attempt to influence a child's development. Government is one of the major sources of influence on children, directly by affording opportunities (e.g., college loans) and placing constraints on access to socializing factors (e.g., laws

against entering taverns before Age 21) and indirectly by influence on parents (e.g., programs encouraging marriage), schools (e.g., accountability requirements), and other proximal socializing agents (e.g., requiring community programs not to discriminate). This chapter examines the influence that government has on children's development.

Government influences children's development in several ways. Direct funding of programs that affect children (e.g., Head Start, public schools) changes their experience. Laws that constrain or enable persons to act in specific ways (e.g., child abuse laws, school districting) change children's interactions with adults and institutions. Finally, government support for research and demonstrations leads to best practice models that affect children's experience.

Government also asserts its influence through its institutions. International influence on U.S. children is largely symbolic, although it has been crucial in bringing resources and rights to children in developing nations. Domestically, the judiciary is responsible for the protection of children's

---

The authors are grateful to Rebecca Kuss, Kimberly Howard, Madeleine George, and Tanya Bartlett for research, fact checking, and editing. The authors are responsible for any remaining errors.

rights and minimal well-being (such as freedom from physical and sexual maltreatment), although it must balance a child's rights with those of others (such as weighing a parent's right to religious exercise with a child's right to access certain medical treatments). The legislative branch is responsible for most laws that provide resources for children, including education, health care, and cash transfers. The legislature operates at federal, state, and local levels through a complicated array of resource allocations and requirements across these levels, depending on the domain. For example, about 90% of education funding comes from state and local taxation, but the federal government imposes requirements on the use of its funds in a way that influences state and local policies. About 45% of Medicaid funding (prior to the Affordable Care Act) for children in low-income families is provided by federal resources but with local options for how those resources are spent. Finally, the executive branch exerts its impact by influencing the public discourse, proposing innovative reforms, and using discretion in administration of programs. The mixture of policies, politics, and resources make up the political economy through which government exerts enormous influence over children's development.

How do academic scholars understand government's influence on children? Even though highly popular ecological models of behavior (e.g., Bronfenbrenner & Morris, 2006) emphasize influences on individual behavioral development that emanate from the society (called the macrosystem), the study of how government regulates children's behavioral development has not occupied a prominent place in the science of child development. However, as Bronfenbrenner (1974) himself noted in his SRCDD Presidential Address, "*basic science needs public policy even more than public policy needs basic science*" (Bronfenbrenner, 1979, p. 8, italics in original). Indeed, this chapter is the first time that this prestigious *Handbook of Child Psychology and Developmental Science* has devoted an entire chapter to the topic. We hope to illustrate the reciprocal relation between developmental science and public policy, in which emerging findings from the science of child development sometimes influence the formulation of policy, and scientific evaluations of government programs and policies lead to evidence-based policy making, and, in turn, the study of the effects of government regulations and policies on children's behavior leads to reformulation of basic theories of child development.

We have four goals for this chapter. First, we familiarize child development scholars with the history, scholarly study, and current status of government policies that

affect children and families. Second, we synthesize the state of knowledge about how specific public policies in domains such as health, education, and social services affect children's development. We ground this synthesis in relational developmental systems theory (Lerner, 2006), which guides this entire volume and series and asserts a bidirectional relation between a child and his or her context, in which the child is influenced by environmental factors but then has an impact on the environment and self-selects or avoids particular environments. Third, we highlight the current challenge of optimizing children's development in a context of economic uncertainty, federal deficit, and an aging population. Finally, we argue that children's development can be optimized through more systematic, evidence-based policy making that is grounded in developmental science.

## THE ROLE OF GOVERNMENT IN CHILDREN'S LIVES

Governments operate at the local, state, federal, and international levels. We devote the majority of this chapter to how government influences children in the United States but acknowledge the need for scholarly study of both international influences on U.S. children and children's policy in other countries. Some attention is given to the United Nations Convention on the Rights of the Child, but space limits constrain us from addressing important international issues and national policy in other countries, such as children in conflict (addressed by Masten, Narayan, Silverman, & Osofsky, Chapter 18, this *Handbook*, this volume). Cross-national comparisons offer important insights for domestic policy, and the study of children across the world is necessary in its own right. Related topics are also addressed in other chapters, such as children and work (Staff, Mont'Alvao, & Mortimer, Chapter 9, this *Handbook*, this volume) and children and the law (Cauffman, Shulman, Bechtold, & Steinberg, Chapter 16, this *Handbook*, this volume).

We start by asserting that governments play two important roles in regulating child behavior: optimizing outcomes for children, and protecting children, families, and society.

### Optimizing Outcomes for Children

Political differences abound regarding the virtue of using government to influence child development, with

the primary counterargument being one of parental prerogative. Nonetheless, a belief in the legitimacy of government-funded programs to support child development is growing over time, especially when scientific evaluations prove the programs achieve positive impacts on children.

### *The Goal of Population Impact*

Whereas most psychologists direct interventions to maximize impact on a specific child, the primary concern of public policy is impact on the population. The latter concern requires assessment of indirect effects of an intervention on nontargeted individuals (called spillover, which could lead to positive, synergistic effects or to adverse effects), benefit-cost ratios, and competing interests of various subgroups, and it affords interventions at the societal level, such as laws, taxes, and regulations. Consider the challenge of placing historically unruly sixth graders into regular or segregated school classrooms. The developmental scientist is concerned with impact on an individual unruly child, whereas the policy scholar, like the school superintendent, tries to maximize total population learning and development. Developmental scientists make a unique contribution in translating basic science into intervention action that affects an individual child, and they intersect with public policy when they address intervention issues such as effects on peers, immediate versus long-term impact of early investments, and how ecological interventions can affect individual children.

Historically, developmental scientists have been focused on the “proof of concept” that a discovery from basic developmental science can be translated into an intervention that is tested through an experiment under optimal conditions to see whether it operates in accord with basic theory. The tradition of scholarly involvement in intervention began in 1747 with the physician James Lind’s use of a nonrandomized control group to test the effect of citrus fruits in preventing scurvy (D. P. Thomas, 1997), was expanded with the biostatistician Fisher’s introduction of randomized trials in the 1920s (Levitt & List, 2009), and was brought to child development in the 1950s through randomized experiments to improve outcomes for poor children (e.g., Gray & Klaus, 1970). Many current government-supported interventions originated through randomized experiments (e.g., attachment-theory-based intervention for high-risk mothers and infants, Bernard et al., 2012; classroom interventions to improve children’s self-regulation, Raver, 2012). Developmental science theory and empirical findings guide intervention design, which is then subjected to

randomized experiments executed under well-controlled conditions. Although psychologists understand that this approach does not address problems in scaling up from the laboratory to the population, they often leave these concerns to other disciplines to resolve.

An important assumption of most developmental science is that the ideal direction of impact moves from basic science to intervention science to field trial to policy, in accord with the traditional role of the scientific community in contributing to government actions, a role that has been articulated by the Institute of Medicine (IOM; Mrazek & Haggerty, 1994) and endorsed by the National Institutes of Health’s (NIH) Roadmap initiative (Zerhouni, 2003). The IOM proposes a four-stage process of policy development that begins with basic scientific research on processes of child development that spark ideas for interventions that could shape a child’s development, such as better prenatal care, a tutoring strategy for learning to read, or social skills training. The second stage is an efficacy trial in which the idea is transformed into an intervention and tested through a randomized controlled trial under ideal conditions to determine whether the intervention can work as hypothesized. Once enough evidence accumulates, the third stage begins with an effectiveness trial (optimally a randomized controlled trial) in which the intervention is tested under typical community conditions. Finally, “successful” effectiveness demonstrations are translated to public policy and scaled up for widespread practice.

Very few examples can be identified in which this process operates smoothly to become widespread practice with positive impact on an entire population (Shonkoff & Bales, 2011). Failures illuminate the challenge. For example, when Brotman et al. (2011) tried to disseminate their successful ParentCorps parent-training program to prekindergarten classrooms, they found that only 31% of the population actually participated due to ineligibility based on language, declination, and other types of attrition. Stormshak et al. (2011) found that implementation of the evidence-based Family Check-Up parenting intervention in middle school settings led to positive impacts on families that elected to receive the intervention but no impact on the 58% of the population that had declined to receive the program, highlighting the problem of low uptake rate. Herrera, Grossman, Kauh, and McMaken (2011) found that when a well-known, evidence-based intervention, Big Brothers Big Sisters School-Based Mentoring, was implemented on a large scale, it had no positive effects after one-and-a-half years, most likely because of loss of fidelity to the original model when scaling up the program.

Quite common in scaling up is the finding that a program has positive impacts on some groups of children but no impact, or even adverse impact, on other groups. Reynolds, Temple, White, Ou, and Robertson (2011) reported that the Child-Parent Center early childhood program has long-term positive impacts on higher-risk families but no impacts on lower-risk families and more positive impacts on boys than girls. An evaluation of Early Head Start (Ayoub, Vallotton, & Mastergeorge, 2011) revealed positive impacts on language development at Age 24 months for girls but not boys, whereas the New Hope antipoverty program (McLoyd, Kaplan, Purtell, & Huston, 2011) was found to have positive impacts on future orientation and employment for boys but not girls. When a program helps one group but not another, policy decisions often become political battles over which group merits greater support.

Another problem in scaling up occurs when systems-level assumptions are not met, such as the problem that occurred when California mandated smaller kindergarten class sizes for all students but could not find enough qualified teachers (Bohrnstedt & Stecher, 1999). The positive benefits of smaller class size were offset by negative effects of being taught by a less-credentialed teacher; the result was that achievement gaps across ethnic and socioeconomic groups grew rather than diminished. The lesson learned is that translating basic science to community scale may yield unanticipated outcomes if systemic considerations are ignored.

The ecological model itself would forecast new challenges at each step of the process of translating basic science to intervention practice. Bronfenbrenner's bioecological theory (2004) placed children's development in a context of widening spheres of influence over development, beginning with proximal influences called the microsystem (e.g., family, classroom). Most psychological interventions are directed toward changing the microsystem to benefit a child. The theory, however, posits that a child's development is equally influenced by the mesosystem (that is, two microsystems in interaction, producing a unique new system), the exosystem (e.g., parental workplace, neighborhood, school district's priorities), and the macrosystem (e.g., culture, political context, state of the economy). A theory of behavioral development that ignores these broader spheres of influence will be inaccurate most of the time, and an intervention based solely on the microsystem may not be effective when implemented in a different system (Bronfenbrenner, 1974). As a result, most interventions cannot be engineered to scale up without

change in penetration, fidelity, and impact. Furthermore, as systems-level analysts find, scaling up an intervention for one group of children has reverberating positive or adverse impacts on other groups of children. The world is not a zero-sum game.

An alternative to the IOM model for intervention program development emerged in the 1960s from the policy world. President Johnson's War on Poverty led to implementation of several social policies and programs at the population level and, thus, evaluation of population impact. The federal Elementary and Secondary Education Act (ESEA) of 1965 included requirements that education programs funded by the federal government be implemented at population levels but also be evaluated, leading to the growth of national nonprofit policy evaluation organizations. Economists in the 1960s generated population-level proposals, such as Milton Friedman's (Friedman & Friedman, 1980) negative income tax. Mathematica Policy Research was established in 1968 to implement one of the nation's first major social research experiments, the New Jersey Negative Income Tax Experiment (Mathematica, 2013). Although the findings continue to be debated and have had mixed impact on policy, the experiment has been praised, and the era of policy evaluation experiments grew over time.

Because much of social policy affecting children has been implemented without an experimental design but in somewhat random ways that simulate random-assignment experiments, naturally-occurring variation in implementation of social policies affords evaluation as quasi-experiments (e.g., variation in drinking-age legislation across states in the 1960s and 1970s; Begun, 1980). A second wave of social policy evaluation emerged in the 1980s with welfare-to-work experiments and continued in the 1990s with the passage of The Personal Responsibility and Work Opportunity Reconciliation Act (PRWORA) and the opportunity to evaluate changes in the impact of state welfare policies on mothers and children (Blank, 1997; Haskins, 2001). A third wave is emerging now, with President Obama's call for evaluations to "help the Administration determine how to spend taxpayer dollars effectively and efficiently—investing more in what works and less in what does not" (Orszag, 2009).

### *The Goal of Population-Level Child Well-Being*

Americans endow government with the responsibility to improve outcomes for the entire population of children, usually measured as the mean on some indicator of health or well-being, as well as for the populations of subgroups

of children, such as ethnic and income groups. Whereas many interventions designed by developmental scientists are directed toward individual children, the policy interest is in improving outcomes for an entire population (or subpopulation). Well-being indices have been reported by the Child Trends Data Bank (2013), Annie E. Casey Foundation's (2012) state-by-state Kids Count series, and U. S. Census Bureau indices such as the poverty rate.

In 2011, 21.9% of U.S. children under age 18 lived in poverty, according to U.S. Census Bureau (2012b) criteria that set the rate of annual family income (for family size of 4) at less than \$23,050. Children are the poorest group in the nation: The overall poverty rate is 15%, and the poverty rate for persons over Age 65 is just 9%. An index of household food security (Coleman-Jensen, Nord, Andrews, & Carlson, 2012) indicates that 14.9% of households experienced consistent food insecurity throughout 2011 (up from 10.5% in 2000), but the proportion of children who experience food insecurity is somewhat lower, at 11.5%, due to government child nutrition programs that are designed to compensate for low income. The Great Recession had an adverse impact on children (Aber & Chaudry, 2010), further widening the income and well-being gap between children and others, but its impact was partially offset by the nation's safety net programs and the temporary additional benefits provided by the American Recovery and Reinvestment Act of 2009.

Other measures of child population well-being have been pioneered by Land (2012), who developed the Child and Youth Well-Being Index, which uses administrative data to document secular trends in each of seven dimensions of domestic U.S. child well-being: family economic well-being, health, safety/behavioral concerns, educational attainment, community connectedness (participation in schooling or work institutions), social relationships (with family and peers), and emotional/spiritual well-being. Land, Lamb, and Zheng (2011) report that overall child well-being declined sharply between 1980 and 1994, recovered to all-time highs in 2002, but has stalled over the past 10 years. Inspection across domains indicates strong improvements in the safety/behavioral domain (e.g., violent crime and smoking) and community connectedness (e.g., voting and preschool enrollment), but health (especially obesity) and social relationships (single-parent-headed households) have declined by 30% since 1975.

The task of relating secular trends and place-based differences in child well-being to government programs and policies (or other causes) has been led by microeconomists. Developmental scientists have contributed relatively little

to understanding the causes of these secular trends in child well-being, and this gap seems fertile ground for research. A major branch of public policy research is directed toward understanding causal factors in population rates of child well-being and the impact of government policies and programs on these rates.

### *The Goal of an Optimal Distribution of Child Outcomes*

Not only is the mean level of well-being for a population important, the distribution of well-being is also of concern, albeit with major political controversy. Duncan, Magnuson, and Votruba-Drzal (Chapter 14, this *Handbook*, this volume) discuss how poverty and low socioeconomic status are toxic influences on a child's development. In this chapter, we address disparities in income, and later describe programs to support children in low-income families (called means-tested programs). The most common measure of the variation in family economic well-being is the Gini index. This index measures the extent to which the distribution of family income deviates from perfect equality, on a scale of 0 (perfect equality) to 1 (perfect inequality). The Gini index varies wildly across the world, with African nations highest and Scandinavian nations lowest in inequality. According to the Central Intelligence Agency (2013), the Gini index of economic disparity for the United States has increased dramatically since 1980 and now ranks among the highest of any industrialized nation in the world (Figure 17.1). Within the United States, Texas is highest and Maine the lowest in Gini scores.

Whether income inequality has a major impact on children's development (net of absolute income levels) and whether and how governments should seek to redistribute the wealth of its population are controversial topics. Recently, Epstein (2013) asserted in a provocatively titled article, "In Praise of Income Inequality": "You cannot make the poor richer by making the rich poorer." Some economists believe that the best strategy to improve the absolute income of relatively low-income families is to improve the income of high-income families by even greater rates so that they would invest more, which in turn would stimulate the economy and job creation. However, some scholars (e.g., Pickett & Wilkinson, 2009) conclude that income disparity is as pernicious a factor in poor child development as is the absolute level of income. According to this perspective, social comparisons and intergroup conflict lead to stress, crime, and poor health for both low-income and wealthy children. Some observers argue that income disparities are caused by a government-sanctioned economic system (R. J. Gordon

**Figure 17.1** Cross-national comparisons in the Gini Index of Income Inequality.

*Note.* Figures are from the Gini Index of Income Inequality for each of the countries in the Organisation for Economic Co-operation and Development (OECD) for the most recent available year between 2005 and 2011.

*Source:* Adapted from *The World Factbook*, by the Central Intelligence Agency, 2013, <https://www.cia.gov/library/publications/the-world-factbook/index.html>

& Dew-Becker, 2008), and thus government owns the responsibility to offset its adverse consequences.

The correlation between population-level income disparity and poor health is positive and quite robust (Brodish, Massing, & Tyroler, 2000), but the possibility that unmeasured third variables account for this correlation fuels controversy about whether the focus of policy should be to reduce disparities or raise the absolute level of the lowest groups (Eberstadt & Satel, 2004).

### ***The Goal of Positive Outcomes for All Groups of Children***

Beyond the overall population-level mean and variance, group differences in child well-being indices is the third major measure of societal child well-being. Political rhetoric certainly supports the goal of reducing group differences in well-being (or at least in opportunity to reach high well-being), as indicated by efforts to “level the playing field through education for all,” “close achievement gaps,” and provide “equal opportunity” to all groups. How to attend to the needs of children from diverse groups is discussed by McBride Murry, Hill, Witherspoon, Berkel, and Bartz, Chapter 11, this *Handbook*, this volume.

Virtually all measures of child well-being indicate very large disparities across ethnic groups. Rates of poverty

in the United States in 2007 before the recession were 10% for non-Latino/a American Whites, 27% for African Americans, and 27% for Latino/a Americans. After the recession, these rates grew to 13%, 35%, and 33%, respectively, reflecting both an overall increase in poverty and an increase in income disparity (Kaiser Family Foundation, 2013).

In turn, income-group differences in other measures of child well-being are huge, even when controlling for confounding third variables. Poverty is highly associated with increased neonatal and post-neonatal mortality rates, greater risk of injuries resulting from accidents, higher risk of physical abuse and neglect, higher risk for asthma, and lower developmental and school achievement scores on many tests across childhood (Aber, Bennett, Conley, & Li, 1997). For example, only 18% of low-income fourth-grade children score at grade level, in contrast with 48% of other children (Tyrell & Fierro, 2011).

Reardon (2011) has shown that the academic achievement gap, previously thought of in racial terms, has become primarily an income gap: the disparity between Blacks and Whites in academic achievement has actually narrowed since the 1940s, while the achievement disparity between the poor and rich has steadily increased. It is likely that a similar story of declining racial gaps but growing

income gaps is emerging in other domains of health and well-being.

Progressives hold that government policy for children should reduce group disparities in well-being, whereas conservatives would focus policy on equal opportunity, not equal outcomes. Fortunately, there is usually substantial overlap between the policies government might use to achieve either goal. Because income disparities are correlated with so much of well-being outcomes, government policy is often designed to reduce income disparities or to offset the impact of income disparities on children's well-being. Means-tested programs that assume these goals can be evaluated by whether they reduce disparities and improve population-level outcomes.

### Protecting Society, Families, and Children

Even more basic than trying to improve children's long-term outcomes is government's responsibility to protect society, families, and children from harm.

#### *The Goal of Protecting Society From Juvenile Offenders*

Some children harm society through crime. The familiar age-crime curve shows sharp increases in crime across Ages 14 to 17, peaking at 18 (Snyder, 2002). Even though 14- to 17-year-olds represent only about 6% of the population, they are arrested for one fourth of all robbery crimes and 14% of all serious violent crimes. In 2010, 1,642,500 children were arrested for nontraffic crimes in the United States (Office of Juvenile Justice and Delinquency Prevention, 2012). About 30% are female, and over a quarter are under Age 15. Confidential surveys indicate that actual offending is far greater: About 70% of adolescents report engaging in some form of criminal offense (Elliott, Hagan, & McCord, 1998). Developmental scientists have identified two groups of juvenile offenders, those who are life-persistent antisocial offenders whose problem behaviors begin early in life and persist across the life span and those whose antisocial behavior is limited to the adolescent period (Moffitt, 1993; Patterson, Reid, & Dishion, 1992). Declines in crime by each group after age 18 can be attributed to continuing brain maturation and life experiences of marriage, employment, and education (Dodge, Dishion, & Lansford, 2006).

Prior to the 20th century, the popular perspective was that children were not responsible for their behavior until they reached 7 years of age, but that at Age 7 children were equally culpable as adults and were adjudicated in the

adult justice system. As scientific knowledge about children's cognitive development grew, public policy evolved to reflect this knowledge by introducing separate justice systems for juveniles. A National Academy of Sciences report on juvenile justice (National Research Council, 2013) asserts that public policy toward juvenile offenders has evolved in four stages.

In 1899, the first juvenile court opened in Chicago to manage child offenders, for whom it was understood that children's needs differed from those of adults and that the adult justice system accelerated children's criminal behavior. By the late 1920s, virtually all states had a juvenile justice system in place. The policy guiding this Progressive Era (Lindsey & O'Higgins, 1970) assumed that the best way to protect society from children's criminal behavior was to empower a juvenile court to waive a child's judicial rights to a criminal trial and due process and instead to move directly to rehabilitation for as long as necessary. Proportionality of the severity of the crime to time under supervision was not considered. Judges were given broad discretion, which they used in various ways that sometimes were racially biased (Glueck & Glueck, 1968).

Juvenile rehabilitation programs flourished, but major experiments (e.g., Cambridge-Somerville Youth Study; McCord, 1978) revealed that interventions at that time were at best ineffective and at worst iatrogenic (Dishion, McCord, & Poulin, 1999). Criticism of the system came from child advocates on the left who argued that the juvenile court violated children's rights and harmed their development, and from law-and-order critics on the right who claimed that society was not being protected from child criminals (Handler, 1965).

The 1960s brought a second wave of reform, called Due Process, as knowledge grew that children had greater cognitive abilities than had been believed previously and deserved more rights, and following a landmark Supreme Court decision. Fifteen-year-old Gerry Gault, arrested for prank calls, was brought before a juvenile court judge without an attorney or witnesses and was committed to the Arizona State Industrial School for up to 6 years for a crime that would have resulted in a fine of \$50 and a maximum jail term of 12 months if Gault had been an adult. In *In re Gault* (1967), Justice Abe Fortas stated that juveniles experienced "the worst of both worlds" of justice, referring to the capriciousness of juvenile court and the harshness of adult court. The court ruling led to an increase in procedural due process in juvenile delinquency proceedings, including the right to counsel and a privilege against self-incrimination.

The reversal in public policy came about because of a sense that the juvenile court's interventions were not effective (Martinson, 1974). Justice Fortas noted that 66% of adolescents brought before juvenile courts became recidivists. The reforms that ensued following *In re Gault* made juvenile courts more adversarial, but courts retained discretion and tried to balance society's right to protection from children and children's right to a fair hearing.

Shortly after the Gault case had given new protections to juveniles, the nation experienced a dramatic increase in youth violent crime. Crime rates rose steadily across the period 1970 to 2000 for all age groups, but the rise was particularly steep for juvenile offenders in the late 1980s, causing public outcry that an "epidemic" of youth violence was disrupting society and leading to an era of "get tough on crime." Dilulio (1995) and Fox (1996) warned of a rising generation of youthful offenders that they called "super-predators" who could wreak havoc on society if not incarcerated. They suggested that the entire juvenile justice system was obsolete and should be abolished (Feld, 1998). The fundamental concept from developmental science that adolescent offenders differed from adult offenders lost credence (Regnery, 1985), leading to unprecedented changes in federal and state public policy toward juvenile offenders that included easier transfer of juveniles to adult court, longer confinements, and rapid expansion of prison beds (Zimring, 1998). For example, 10-year-olds charged with murder could be charged in adult courts in most states (Griffin, Addie, Adams, & Firestone, 2011).

Policies in public schools also changed during this period. Federal funding for school resource officers (SROs), who are police officers placed in middle schools and high schools to control violent behavior and find guns and illegal drugs, replaced funding for social-emotional learning and related preventive interventions in the Safe and Drug-Free Schools Act. Metal detectors became common in high-risk urban schools, and zero-tolerance policies for bringing weapons on to school property became universal (Skiba, 2000).

The most common public policy in response to juvenile offending became segregation of offenders from the mainstream peer group and placement in groups of peer offenders (Dodge et al., 2006). School policies place behavior-problem children in special education, usually in separate classrooms, or alternative schools populated with offending students who have been expelled from regular school. Schools have also instituted "in-school suspension" policies in which offending students are grouped together and segregated from mainstream peers.

For offending children who have been referred to the mental health system for treatment, group therapy with other offending children is the most common mode of intervention. Children are treated in groups for social skills training, psychotherapy, and counseling (Dodge & Sherril, 2006). Residential placements in wilderness camps, therapeutic boarding schools, and residential treatment centers have proliferated. In the justice system, group placement has always been the most common form of residential setting.

A National Academy of Sciences report (National Research Council & Institute of Medicine, 2001) concluded that the "get tough" and segregation policies were not effective and can have harmful effects on children (Dodge et al., 2006). Dodge and Sherril (2006) estimate that treating antisocial children in groups leads to a one-third decrement in treatment effect size compared with a similar treatment administered individually, and treating them in groups comprised exclusively of other antisocial children leads to an additional one-third decrement in treatment effect size compared with treatment in mixed groups. Dishion et al. (1999) document numerous cases in which the effect of treating antisocial children in groups with antisocial peers leads to significantly adverse impact on the children. They suggest that the processes through which these effects of intervention occur are similar to the well-documented processes through which deviant peer groups exert influence on children in natural settings, that is, through modeling, reinforcement, and "deviancy training."

Since 2000, juvenile justice policy has evolved in a new direction, called a developmental approach, coincident with three other trends. First, the bloodbath upon society that was predicted by Dilulio, Fox, and others never occurred. Juvenile crime rates had started to decline even before "get tough" policies were fully implemented. By 2004, youth crime rates were at a two-decade low, and by 2010 these rates were at historic lows, down 55% from their peak in 1994 (see Figure 17.2; Office of Juvenile Justice and Delinquency Prevention, 2012). In 2010, only one in every 400 children between 10 and 17 years of age was arrested for a violent crime.

Second, escalating state expenditures for juvenile justice have strained state budgets, leading to declining interest in incarceration as primary policy (National Research Council, 2013) and emerging interest in preventive interventions that may prove more cost-beneficial over the long run. Prevention scientists have created and implemented programs for juvenile offenders and high-risk

**Figure 17.2** Secular trends in youth crime rates.

youth, including Multisystemic Therapy (Henggeler, Clingempeel, Brondino, & Pickrel, 2002), Functional Family Therapy (Sexton, 2010), and Fast Track (Conduct Problems Prevention Research Group, 2011), all of which have been shown to reduce arrests and re-arrests of adolescents. The Coalition for Evidence-Based Policy has touted such evidence-based programs as better public policy than programs that are based on political views or seemingly good ideas. As will be described in more detail later in the chapter, Baron and Haskins (2011) have argued that public policy more broadly, and the U.S. Congress in particular, should use cost-effectiveness as a major criterion in guiding public policy for children and families (indeed, policy for all social spending).

Finally, several recent U.S. Supreme Court decisions have indicated a resurgence of support for a developmental perspective that society is best protected when adolescent offenders are treated differently than adults. What is precedent setting about these decisions is that, in each case, the Supreme Court used developmental science findings in rendering its decisions. The first case involved Christopher Simmons, a 17-year-old boy who was convicted of murder and sentenced to death. His attorneys argued that, following from a previous Supreme Court decision that had overturned the death penalty for persons with mental retardation on the grounds that such persons were less culpable due to their disability, an adolescent has an analogous disabling condition by virtue of being an adolescent. Reflecting the growing national sentiment

that development is still in process across the adolescent period, the Supreme Court overturned the death penalty for adolescents (*Roper v. Simmons*, 2005). Justice Kennedy's opinion cited developmental science findings that adolescence is characterized by immature brain development, impulsive and reckless behavior that fails to anticipate consequences of one's actions, vulnerability to negative influences of peers, and malleability of behavior that also enables adolescents to be amenable to intervention. The court noted that the United States had failed to keep up with "evolving standards of decency" and had fallen out of line with the rest of the world, in that only seven countries had executed juveniles in the 15 years prior to the decision.

Five years later, the Supreme Court extended this decision when it struck down mandatory life sentences without parole for nonhomicide offenses by juveniles (*Graham v. Florida*, 2010) and then 2 years later, it struck down mandatory life sentences without parole for homicide offenses by juveniles (*Miller v. Alabama*, 2012). Justice Kagan wrote that the decision was consistent with the court's emerging perspective, based on developmental science, that teenage children lack sufficient brain maturity to act responsibly, are vulnerable to peer pressure, and are responsive to rehabilitation.

In sum, current federal and state policy has evolved to take into account the incomplete developmental status of adolescents who engage in criminal behavior. All but two states (New York and North Carolina) now make provisions that treat offenders under Age 17 in a separate

juvenile court. A National Academy of Sciences report (National Research Council, 2013) supports the emerging perspective that society will be protected from juvenile crime most effectively if several government systems operate in tandem. The report recommended that the education, health, and human service systems should find ways to implement cost-beneficial, evidence-based, preventive interventions across a child's life span, and the juvenile justice system should adopt a developmental approach that recognizes the adolescent's incomplete developmental status by (a) implementing rehabilitative interventions that have been found to be effective through rigorous trials; and (b) holding the offending juvenile accountable for criminal behavior in a way that supports the safety of society while teaching the adolescent responsibility and the concept that consequences are proportional to the severity of the crime.

### ***The Goal of Protecting Parents***

Part of the hesitancy of the U.S. government to intervene with child offenders grows out of a broader philosophical belief in the separation of government and family. Although similar issues are debated in European nations, the United States stands at the extreme in favor of parents' rights (Lonne, Parton, Thomson, & Harries, 2009). Unless a parent's behavior goes beyond standards for abuse or neglect, government has no oversight of parenting and goes to great lengths to protect parents' rights to "own" their child (Wald, 2013).

Government's support of parents' rights has a long history (see *Pierce, Governor of Oregon et al. v. Society of the Sisters of the Holy Names of Jesus and Mary*, 1925) and is seen in numerous laws, court rulings, and the general policy. In all these cases, parents are presumed to be best suited and most inclined to act in the best interests of the child (Buchanan & Brock, 1989). Parents have the right to determine medical care for their child, even if the practices are inconsistent with a physician's recommendations. Courts have ruled that families would not flourish without some autonomy and that the function that families serve in society would be severely diminished if government intervened too readily.

In practice, courts have wrestled with, and often failed to follow, the criterion that a parent's decision must be in the "best interests of the child" by ruling, most of the time, that parents are allowed to make their own decision for the entire family by weighing its benefits and costs using their own idiosyncratic criteria. For example, controversial medical interventions such as cleft palate repair are left up to parents because of their high costs, even though they are

obviously in the best interests of the child (Diekema, 2004). While few persons would argue that the best interests of the child would be served better by funding the child's college education rather than the parents' vacation, parents are not required to choose in favor of college. Diekema (2004) argues that the criterion that is, and should be, used in practice is one of "no harm" in which parents are allowed to act as they wish if their behavior does not exceed a minimal threshold of causing obvious harm to the child. This principal enjoys bipartisan support, and numerous court rulings show that parents are allowed to circumcise an infant, home-school a child, impose religious practice on a minor, and even abort a fetus. Limits on parents' rights have been upheld in cases of presumed obvious harm to the child, such as when the parent has been convicted of murder of a sibling or has severe mental illness.

In addition to the criterion of obvious harm to the child (noting the controversy of abortion), courts have limited parents' rights when the welfare of general society comes into question. Courts have ruled that parents must allow their child to be immunized to the extent that not doing so imposes a public health risk, but parents are allowed to make their own immunization decisions when public health outcomes are less clear.

Just as contentious as parental rights is the policy question of how actively government should support parenting as an important function for the overall welfare of society. Depending on one's perspective, policies have gone too far or not far enough to support parents. A variety of means-tested programs support parents, especially young, unmarried parents.

### ***The Goal of Protecting Family Formation***

The most dramatic secular trend in family formation over the past 50 years has been the decline of marriage and the increase in the proportion of births to single parents. The importance of this trend to public policy is that children born to single mothers, compared with children born to married parents, are at elevated risk for living in poverty, experiencing mental health problems, failing to graduate from high school, being unemployed, and receiving government assistance throughout their lives (Amato, 2005; Carlson & Corcoran, 2001; McLanahan & Sandefur, 1997; A. Thomas & Sawhill, 2005).

In spite of a 56% decline in the rate of births to teenage women (from 89 per 1,000 in 1960 to 39 per 1,000 in 2009), the percentage of births that occur outside marriage has risen from 5% in 1960 to 41% in 2009 (see Figure 17.3; National Center for Health Statistics, 2010). The sharpest

**Figure 17.3** Secular trends in births outside of marriage, by age group.

Source: Adapted from *Births to Unmarried Women* (Appendix 1), by Child Trends Data Bank, 2013, <http://www.childtrends.org/?indicators=births-to-unmarried-women>. Data from National Center for Health Statistics, National Vital Statistics System. Demographic characteristics of mother. Available at <http://205.207.175.93/VitalStats/ReportFolders/ReportFolders.aspx>

rise occurred between 2002 and 2008. For the first time, over half of all births to women under Age 30 occur outside of marriage.

Although this phenomenon is still highly related to education (e.g., 51% of births to women with no college education occur outside of marriage in contrast with 8% for college graduates), the trend is rising among all demographic groups and is particularly noticeable among non-Hispanic White women, for whom the percentage of births outside marriage has tripled from 9.6% in 1980 to 29.1% in 2010, and Hispanic women, for whom the percentage has risen from 23.6% in 1980 to 53.4% in 2010. For Black women, the percentage has risen from 57.3% in 1980 to 72.8% in 2010. At the same time, nonmarital births are increasingly likely to occur in a cohabiting parental union, up from 40% in 2002 to 58% in 2010. Children born into cohabiting circumstances are still at risk for poor outcomes, but less so than in noncohabiting circumstances (A. Thomas & Sawhill, 2005).

Across developed countries, the percentage of nonmarital births varies widely, from 2% in Japan to 66% in Iceland (and similarly high rates in most northern European countries), with the U.S. rate in the middle but having one of the sharpest increases (Organisation for Economic Co-operation and Development, 2012). A particular pattern for the United States is the increasing rate of births to women who are cohabiting. In Europe, many unmarried parents cohabit, but the stability of cohabiting in Europe is greater than in the United States (Ventura, 2009).

Single-parent, noncohabiting families have high poverty rates and, compared with children from married-couple families, their children have high rates of school failure, juvenile delinquency, and other problems (McLanahan & Sandefur, 1997). Cohabiting parents also have higher poverty rates than married parents. Many researchers and politicians argue that public policy should attempt to reduce the number of nonmarital births, which would in turn reduce the child poverty rate. Federal policy both supports single parents and aims to reduce nonmarital births. The 1996 Welfare Reform Law, for example, aimed to promote marriage, reduce out-of-marriage childbearing, and strengthen two-parent families, while simultaneously providing cash welfare and work support benefits to single parents.

Increasing marriage rates would be likely to both reduce nonmarital birth rates and reduce child poverty. A recent simulation study using data from the Current Population Survey by Sawhill and Karpilow (2013), for example, shows that if single mothers in the bottom third of the income distribution married men from the bottom third matched on race, age, and educational attainment, the average household earnings of these low-income single mothers and their children would increase by over 30%.

A major policy question about families is whether it is possible to increase marriage rates. A review of marriage education programs by the Urban Institute showed that on average they produced substantial impacts on relationship satisfaction (average effect size = .68) and couple

communication (average effect size = .26), although impacts on marriage rates were not significant. But this review was limited because it was based on only 39 studies, many of which were not fully reported, and even more importantly, because none of the studies involved low-income couples. Moreover, the studies did not report long-term impacts on marital stability or on children's development or behavior. Nonetheless, as the authors concluded, "The review . . . indicates that evaluations of marriage programs show significant positive effects on average" (Reardon-Anderson, Stagner, Macomber, & Murray, 2005, p. 23).

In 2002, the Bush administration launched a comprehensive initiative with programs designed to encourage healthy marriages (Haskins, *in press*). Here we focus on the two Bush programs with the strongest evaluations. The first program, called Building Strong Families (BSF), aimed to strengthen the relationships and parenting of young couples who had had a baby together outside marriage. It was implemented in eight sites with 5,100 couples randomly assigned to an experimental group or a control group. Parents in the experimental group were offered marriage education classes in groups using a formal curriculum as well as advice and counseling from a family-services coordinator who also provided referrals for services.

An evaluation of BSF by Mathematica Policy Research (Wood, McConnell, Moore, Clarkwest, & Hsueh, 2010) showed that at 15 months the BSF program did not affect whether the couples stayed together or got married, and there were very few effects on relationship quality or parenting in six of the eight sites. However, the Oklahoma City program produced a pattern of positive impacts, while the Baltimore program produced some negative impacts, particularly physical assault by the fathers. The positive impacts in Oklahoma included relationship happiness, support and affection, use of constructive behaviors to resolve conflicts, avoidance of destructive conflict behaviors, marital fidelity, quality of coparenting, father living with the child, and father providing substantial financial support. However, a follow-up evaluation at 36 months (Wood, Moore, Clarkwest, Killewald, & Monahan, 2012) found virtually no significant impacts across sites with two exceptions. The Florida program had negative impacts on relationship status and quality, father involvement, and family stability. Although most of the previously positive impacts of the Oklahoma programs had disappeared by 36 months, program children were about 20% more likely to be living with both their parents than controls.

The second well-evaluated Bush marriage initiative was the Supporting Healthy Marriage (SHM) program. SHM is similar to the BSF program in that it attempts to increase the relationship skills of couples, but in this case married rather than unmarried couples. It was implemented at eight sites through random assignment of couples. Couples in the program group were then provided with structured group workshops, supplemental activities to build on workshop themes, and family support services to address participation barriers, connect families with other services, and reinforce curricular themes. MDRC reported the impacts on couples after 12 months as follows: "Approximately 12 months after study entry, program group members reported higher levels of marital happiness, lower levels of marital distress, greater warmth and support, more positive communication, and fewer negative behaviors and emotions in their interactions with their spouses, relative to control group members" (Hsueh et al., 2012, pp. ES-4–ES-6).

Although these results are more positive than results produced by the BSF program, none of the sites produced significant impacts on lowering rates of marital dissolution. Both the BSF and SHM programs cost about \$10,000 per couple. When the modest impacts of the BSF program are compared with this cost, many observers conclude that the program needs to increase its impacts, reduce its cost, or both. Some researchers and policymakers have concluded that the programs should be abandoned.

In summary, the results from the Oklahoma program at 15 months are encouraging, but most effects had faded by 36 months. For SHM, the early results are more encouraging than for BSF, but there is no evidence that the program had an impact on marriages lasting longer, which along with impacts on children are the most important goals of the Bush marriage programs.

Rather than focusing on marriage, President Obama has placed a priority on reducing teen pregnancy and has initiated a program called Teen Pregnancy Prevention to provide \$100 million per year in competitive grant funds to scale up programs with rigorous evidence of success. This program joins a host of other federal programs that provide funds to promote abstinence education and birth control. The field of teen pregnancy prevention is well developed and according to the Department of Health and Human Services there are 28 well-evaluated model programs that have a significant impact on some aspect of teen sexual behavior, including at least five that found reductions in pregnancy rates ([http://www.hhs.gov/ash/oah/oah-initiatives/teen\\_pregnancy/db/tpp-searchable.html](http://www.hhs.gov/ash/oah/oah-initiatives/teen_pregnancy/db/tpp-searchable.html)). There is also evidence that increased Medicaid coverage of birth

control reduces pregnancy rates in older women and modest evidence that media campaigns that encourage use of condoms by males also reduce pregnancy rates (Kearney & Levine, 2009; A. Thomas, 2012).

A major federal attempt to help families with children was passage of the Family Medical Leave Act (FMLA) of 1993. This legislation is a landmark measure that requires employers to grant employees up to 12 weeks of job-protected unpaid leave to tend to a newborn infant (or other urgent family health matters). By 2005, approximately 10 million workers were taking advantage of this provision annually. Although it is difficult to evaluate its impact because of the lack of randomized experiments, a survey conducted by Abt Associates (Klerman, Dailey, & Pozniak, 2012) indicates that employees selectively use this provision with great satisfaction and that most employers report little negative impact on the workplace. An important limitation of FMLA is that it exempts employers with fewer than 50 employees.

### *The Goal of Protecting Children*

Beyond protecting society and parents, government policy has increasingly sought to protect children from harm. We identify three principles that guide this policy and then summarize the history of child protective services in the United States.

The limit on parental authority is the doctrine of *parens patriae* that the state may act as a surrogate parent in extreme cases when not intervening would certainly cause life-threatening harm to the child (known as the “harm principle”). Long ago, the Supreme Court ruled, “Neither religion nor rights of parenthood are beyond limitation. Acting to guard the general interest in youth’s well-being, the state as *parens patriae* may restrict the parent’s control by requiring school attendance, regulating or prohibiting the child’s labor, and in many other ways” (*Prince v. Massachusetts*, 1944).

The principle of protecting “the best interests of the child” goes beyond the harm principle by asserting that government should intervene on behalf of a child, even a child who does not face imminent harm, in order to produce outcomes that are best for the child. Determining the child’s best interests, however, is more of a subjective judgment than determining harm. Nonetheless, this principle is the basis for public policies that aim to improve children’s outcomes such as compulsory schooling and required immunization.

A third principle that guides many government programs is that of equal opportunity. Policy makers have prioritized programs that seek to compensate children who

are at disadvantage through no fault of their own, such as being born with a disability, born into poverty, or suffering from discrimination. The goal is to “level the playing field” for all children, even if everyone’s best interests cannot be served. This principle is the basis for a wide variety of government policies and programs, including child tax credits, Head Start, Temporary Assistance for Needy Families, school nutrition program, Pell Grants, and other means-tested programs.

The history of child protection began in the late 1800s with enactment of child labor laws and associated compulsory school attendance policies that ensured that children were not being subjected to work for parental gain (Myers, 2004). In 1875, the world’s first child-protection organization opened, the New York Society for the Prevention of Cruelty to Children. The field of social work grew at the same time in response to the need for professionals to protect children. The first home to care for harmed children was Toynbee Hall, established in London, England, in 1884, followed by Hull House in Chicago, founded by Jane Addams in 1889.

Juvenile courts initiated at the turn of the 20th century ensured children’s protection from the adult justice system and intervened in cases of overt physical abuse and orphaning of children, requiring the state to assume custody. The assumption was made that parents sometimes failed to keep their children from harm (for whatever reason, from the parent’s death to gross misconduct), leading children to be orphaned, abused, or delinquent, and so these children were treated in a separate court (Lindsey & Borough, 1931).

It was not until 1962 that the problem of child abuse was publicly recognized, when Henry Kempe coined the term “battered child syndrome” to refer to a child who presented at a pediatrician’s office with clinical symptoms of bruises, malnutrition, or extreme anxiety. By 1967, all states had passed laws requiring professionals to report suspicions of abuse to police and welfare offices, and by 1974, 60,000 cases were reported annually. That figure grew to 1 million in 1980, 2 million in 1990, and 3 million in 2000. The figure has dropped sharply in the past decade, although the reasons are unclear.

Estimates of the rate at which children are physically or sexually harmed or neglected vary according to the source of information. Approximately 6.2 million children (about 8% of all children) were reported to Child Protective Services (CPS) in 2011, but about half of these reports were dismissed immediately as noncredible. Of the 3.4 million reported cases that were officially investigated, 676,569 were substantiated, or 0.9% of the child population (USDHHS, 2012). The other 2.7 million were

called “unsubstantiated,” but a high portion of the unsubstantiated cases is still at risk for poor outcomes (Cross & Casanueva, 2009). About 78% of the substantiated cases (.7% of the child population) suffered neglect, 18% (.2% of the child population) suffered physical abuse, and 9% (.1% of the child population) suffered sexual abuse (sum is > 100% due to multiple counts). More than 1,500 children died from abuse in 2011, with 82% of these cases younger than 4 years of age, and 78% of the deaths caused by a parent (USDHHS, 2012).

Of course, officially reported cases do not exhaust the number of children who are actually maltreated. The National Incidence Study (NIS) is a Congress-mandated study to generate more accurate figures by soliciting information from community professionals regarding maltreatment cases that were never reported to CPS. The NIS estimates are about 50% higher than official reports. A much higher proportion of children in a cohort will be reported to a CPS agency at least once before they grow up. Putnam-Hornstein, Webster, Needell, and Magruder (2011) found that 14% of all children born in California between 1999 and 2002 were reported as maltreated (either abused or neglected), and 5% were substantiated as maltreated by Age 5. Wald (2013) extrapolates from these figures to estimate that approximately 8 to 10% of all children in California will be substantiated as maltreated by the time they reach Age 18, and at least 15% of the population of children will actually experience maltreatment. He estimates that in addition to the 15% who experience parenting that legally constitutes maltreatment, another 5% of children receive highly inadequate parenting due to poverty, parental alcoholism, or parental depression.

Children are at greatest risk for being maltreated when they are young (Child Trends Data Bank, 2012). Children from low-income families are at much higher risk: About 35% of White and African American children in low-income families will be reported to CPS at some time before reaching Age 18 (Sabol, Colton, & Polousky, 2004).

Because CPS statistics likely underrepresent actual maltreatment and are subject to biases in reporting patterns, yet another source of information about maltreatment comes from anonymous telephone interviews. Theodore et al. (2005) used computer-assisted random-digit dialing in North and South Carolina to interview 1,435 mothers of children Ages 0 to 17 anonymously to determine incidence rates for physical abuse (4.3% of the population under age 18) that were 40 times greater than official CPS substantiation rates for physical abuse (0.1%) and 15 times greater for sexual abuse (1.1% of the population under

Age 18, compared with 0.1% from CPS rates) within the past year. Straus and Stewart (1999) used parent surveys to report that physical discipline of children is normative, with peak experience at age 4: More than 90% of preschool-age children are corporally punished in the past year, compared with 34% of infants less than 12 months of age and 25% of 16-year-olds.

Child maltreatment rates vary widely worldwide, but because of varying laws and practices for estimating rates, no official statistics on global child maltreatment are available. Confidential surveys of parents indicate that more than half of children worldwide experience physical punishment. In a study of 1,400 mothers in nine countries (China, Colombia, Italy, Jordan, Kenya, Philippines, Sweden, Thailand, and the United States), Lansford et al. (2010) found that 56% of all children had experienced mild corporal punishment, and 14% had experienced severe corporal punishment, in the past month. Country differences were large, with lowest rates in Sweden (7% mildly and less than 1% severely punished) and highest in Kenya (90% mildly and 62% severely punished). U.S. rates were in the middle of the range (37% mildly and 5% severely punished in the past month). Runyan et al. (2010) found similar rates and variation in surveys conducted in multiple countries, including the United States. Straus (2010) reviewed many studies of children in 32 countries and found that, overall, 53% of adults self-reported that they had been “spanked or hit a lot” before age 12, with countries varying from a low of 17% in the Netherlands and Sweden to a high of over 70% in Taiwan and Tanzania. Straus also reported a pattern of higher use of corporal punishment in less economically-developed countries.

Legal prohibition against corporal punishment of a child varies widely across the world. Since Sweden became the first country to pass laws to protect children from all corporal punishment in 1979, 32 other countries have passed similar laws. The momentum for a worldwide ban on corporal punishment is increasing, with 17 countries passing laws since 2007.

One challenge for policy makers and the law is to develop a coherent operational definition of child maltreatment. All 50 states permit the use of “reasonable corporal punishment,” with *reasonable* being a legal term of art to indicate acceptable under the law (Coleman, Dodge, & Campbell, 2010). Definitions and practices vary wildly across states, however. Although the U.S. rate of substantiated maltreatment in 2010 was 12.4 per 1,000 population, several states (Massachusetts, Alaska, District of Columbia, and Iowa) had rates that exceeded twice

that rate, with Massachusetts having the highest rate at 31.7 per 1,000. In contrast, Pennsylvania's rate of 1.2 per 1,000 was only one tenth of the national average. These differences cannot be accounted for by ethnicity or income but must, instead, reflect differences in laws defining maltreatment, clinical practice, and culturally based norms for reporting.

Coleman (2007) observed that judges have great discretion in defining maltreatment and often use the "know it when you see it" test, similar to the test they use to define pornography. State laws themselves vary in specificity of definition, and many defer to parents' privileges of discipline under states' common law, which provides that a "parent is privileged to apply such reasonable force or to impose such reasonable confinement upon his child as he reasonably believes to be necessary for its proper control, training, or education" (Coleman et al., 2010). The intentionally vague term *reasonable* refers to normativeness for the population.

The case for excluding normative behaviors from prosecution as maltreatment has an empirical basis. Lansford et al. (2005) found that the effects of mild corporal punishment vary according to cultural normative practices. That is, in cultures in which this practice is normative, its negative impact on a child's anxiety and aggression levels was minimal, whereas this same practice when exhibited in a culture where it is less normative is interpreted by the child as hostile (according to child interviews) and indeed causes emotional harm to the child.

A problem with sole reliance on "normativeness" of parental behavior, however, is that it ignores actual harm to the child. Some historically-common punishments (e.g., shaking a baby and striking a child with an object) might inflict permanent harm to a child. Furthermore, harm might be immediate or deferred, and it might be physical injury or long-term emotional damage. Coleman et al. (2010) suggest defining child harm based on empirical studies in developmental science that establish typical effects of a parental behavior. They cite the case of shaken baby syndrome. After the once-common practice of shaking an infant to calm her was determined empirically sometimes to cause lasting brain damage, laws and judicial practice changed to incorporate shaking an infant as maltreatment. Because the long-term impact in a particular case is not known immediately, they suggest using past empirical findings as the defining criterion in a current case. They go on to propose a new definition of maltreatment that includes parental behavior that causes or risks causing "functional impairment," which means

"short- or long-term or permanent impairment of physical or emotional functioning in tasks of daily living" (Coleman et al., 2010, p. 163).

Prior to the battered child syndrome discovery, government played only a small role in child protection. The founding of the Children's Bureau in 1912 and the establishment of Social Security in 1935 provided some resources, but maltreatment was largely ignored by states and local governments. Racial biases went unchecked: as many as 25% of Native American children were removed from their parents for alleged maltreatment until the Child Welfare Act of 1978. The Child Abuse Prevention and Treatment Act (CAPTA) of 1974 authorized federal funds to respond to reported abuse cases, growing the Child Protective Services (CPS) system which now includes both a forensic function to investigate individual cases to determine whether illegal maltreatment occurred and a clinical function to provide intervention services to minimize ultimate harm to the child and/or improve family functioning if the child remains at home. The average efficacy of these services has been doubted by a recent National Academy of Sciences committee report (National Research Council, 2013).

In 1980, the federal government passed major legislation augmenting two programs in the Social Security Act (in Title IV-B and Title IV-E) to help states pay for a range of prevention, treatment, or child maintenance services for abused or neglected children. Title IV-B, which has several parts, provides states with about \$750 million in funds annually and allows them substantial flexibility in creating programs to help at risk families avoid abuse and neglect. Title IV-E provides states with nearly \$7 billion per year to support training, administration, and maintenance costs for children who need foster care or other out-of-home placements and to families that have adopted children from foster care. Funds from Title IV-E can be used only for children from low-income families (about half the children in foster care). The federal government also invests tens of millions of dollars in research on the causes of maltreatment and on testing treatments to reduce maltreatment or mitigate its effects.

Some experts argue for greater funding for CPS agencies to intervene in cases of alleged or substantiated maltreatment (e.g., Bartholet, 2012; Dwyer, 2008), whereas others argue against this view on the grounds that CPS intervention is not helpful at best and exacerbates harm at worst (e.g., Bergman, 2010; Wald, 2013). Some scholars even argue that mandatory reporting laws themselves are harmful and should be repealed to reduce reliance on the

CPS system (e.g., Drake & Jonson-Reid, 2007; Worley & Melton, 2013). The most recent reform in the CPS system is the introduction of a differential response that separates the primary functions of forensic investigation and clinical intervention (Waldfoegel, 2009). In differential response, reported cases are bifurcated into those that require a forensic investigation (and potential prosecution) and those that merit immediate provision of “voluntary” clinical services (Child Welfare Information Gateway, 2008; Conley, 2007). The focus of the clinical track is to assist families in addressing issues that impact child safety with the goal of avoiding more serious maltreatment and future interaction with CPS.

Evaluation of differential response systems has focused on child safety and outcomes. Loman and Siegal (2004a) used a matched-community design to compare 14 counties implementing Missouri’s version of differential response with 14 matched control counties. They found that the new system did not compromise child safety and enhanced service delivery, increased family cooperation and satisfaction, was viewed by social workers as a more effective approach, and lowered rates of recidivism in maltreatment. After 5 years, Loman and Siegal (2004a) found that recidivism remained lower in counties implementing the reform, although they also found that reform counties had higher rates of subsequent out-of-home placements.

Loman and Siegal (2004b) also conducted a randomized controlled trial of Minnesota’s differential response system and found that families assigned to differential response were less likely to have subsequent maltreatment reports and had fewer out-of-home placements than the control group. A cost study showed that total costs for case management activities and other services were less for differential response cases than control cases.

Shusterman, Hollinshead, Fluke, and Yuan (2005) compared 140,000 children in six states who were referred to a differential response system with 174,000 children who received traditional investigations and found that recidivism rates for differential response cases did not differ from the rates for traditional investigation cases in any state except Oklahoma, where the recidivism rate was decreased. The underlying assumption of differential response is that if CPS identifies family needs, effective community services to address these needs will be readily available (Zielewski, Macomber, Bess, & Murray, 2006). Wald (2013) concludes that this assumption is rarely met. He calls for the creation of a comprehensive system of services that ensures protection from harm and promotes healthy development.

### International Policies to Protect Children, Families, and Society

Article 37 of the United Nations Convention on the Rights of the Child was passed in September of 1990 and has since been ratified by 193 nations. The Convention requires that states act in the best interests of the child (beyond minimal protection from harm). It asserts that children have basic rights, including the right to life, the right to legal representation, the right to independent opinion and religion, and the right to privacy. It forbids all forms of corporal punishment and other degrading practices, as well as capital punishment for children. Later optional provisions were added to prohibit children from involuntarily serving in combat and the trafficking of children for labor, prostitution, or pornography.

Three countries have not ratified this UN convention. Somalia is in the process of deliberating its ratification. South Sudan, as the newest member of the United Nations, has made internal steps toward ratification. In contrast, the United States has not ratified the convention because of opposing philosophical beliefs about parental rights and resistance to external control over internal matters. Although the United States has not ratified this convention, the Supreme Court in *Roper v. Simmons* noted that the United States was in a world minority on capital punishment of children, and the court’s overturning of this practice has been viewed as an implicit endorsement of the convention. The convention has come to symbolize even broader issues: For opponents, it symbolizes the hypocrisy of nations that would sign a document but not follow it and the presumption of the United Nations to dictate to sovereign nations, whereas for child advocates it signifies the recognition of children as full human beings. The Obama administration has voiced endorsement of the convention’s ratification, but strong opposition in Congress makes it unlikely that it will be ratified by the United States in the near future.

## THE PROBLEM OF POVERTY AND INEQUALITY

Few factors exert a more enduring and far-reaching impact on children’s development than growing up in poverty. Likewise, no issue has consumed government policy toward children to a greater extent than combating poverty.

### Trends in Poverty

Figure 17.4 shows the trends in poverty between 1959 (when the U.S. Census Bureau began calculating poverty

**Figure 17.4** Secular trends in poverty for selected groups.

Source: Adapted from *Current Population Survey, Annual Social and Economic Supplements* (Table 3: Poverty Status of People by Age, Race, and Hispanic Origin: 1959 to 2011), from U.S. Census Bureau, 2012. Available at <http://www.census.gov/hhes/www/poverty/data/historical/hstpov3.xls>

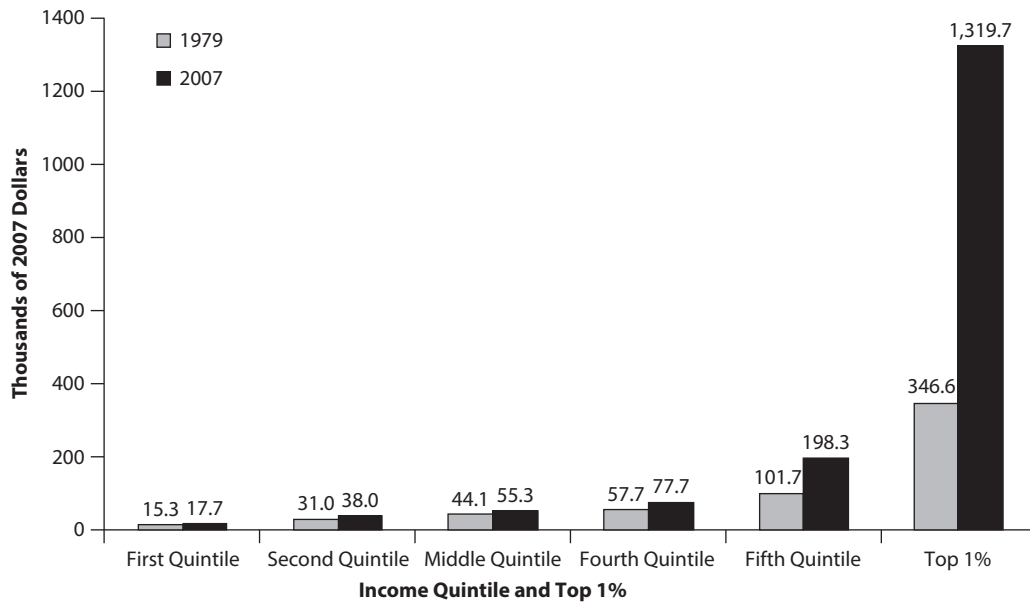

rates) and 2011 for all children, Black children, and the elderly. The poverty rates for all children and Black children declined sharply between 1959 and 1969, and then progress stalled. Poverty began to increase for both groups in the late 1970s, and then declined again in the 1990s, until starting a sustained increase beginning with the recession of 2001, and then increased dramatically after the onset of the Great Recession in 2007. By 2011, the poverty rates among all children and Black children were about where they had been four decades earlier.

The nation has had much better success in reducing poverty among the elderly. Like child poverty, elderly poverty declined substantially after 1959. However, unlike child poverty, elderly poverty has either held steady or declined in almost every year since the mid-1960s. Studies show convincingly that the major cause of this decline is Social Security (Engelhardt & Gruber, 2004). Because Social Security is unaffected by recessions, poverty among the elderly remains low even when poverty rates among working-age adults and children are increasing during recessions. The poorest demographic group in America, by far, is children.

As progress against child poverty has stalled, inequality in the United States has grown substantially, with the greatest disparities present at birth. Figure 17.5 shows the income distribution in 1979 and 2007 divided into quintiles. Income is expressed in thousands of inflation-adjusted 2007 dollars. Several points about changes in the distribution

of income are clarified by this figure, which is based on a report published by the nonpartisan Congressional Budget Office (2011). First, the disparity in income increased substantially between 1979 and 2007 and became progressively greater from the lowest to the highest income quintile. People in the bottom, middle, and top quintiles, for example, experienced income increases of 16%, 25%, and 95%, respectively. The top 1% of earners is also shown in Figure 17.5. Their income increased by more than 280% over the period. Thus, the further up the income distribution one goes, the greater the increase in income between 1979 and 2007. The obvious conclusion is that income inequality increased between the two dates, in large part because the top of the distribution separated itself from the rest.

Two questions are especially pertinent to our exploration of income, poverty, and inequality: How did the absolute income level for the poorest quintile change over this 30-year period, and what impact did government policy have on this distribution? The definition of income used in Figure 17.5 reflects the impact of both government taxes and transfer payments, which taken together tend to increase income at the bottom of the distribution and reduce it at the top. Inequality based on only market income was much greater in both 1979 and 2007 than income after government taxes and transfers. Figure 17.6 shows the importance of this distinction in understanding the growth of inequality. As in Figure 17.5, Figure 17.6

**Figure 17.5** Income change by quintiles, 1979 to 2007.

*Note.* Comprehensive household income equals cash income plus income from other sources, including in-kind benefits.

*Source:* Adapted from *Trends in the Distribution of Household Income Between 1979 and 2007: Average After-Tax Household Income*, Congressional Budget Office, 2011, Washington, DC: Government Printing Office. Available at [http://www.cbo.gov/sites/default/files/cbofiles/attachments/average\\_after-tax\\_income.pdf](http://www.cbo.gov/sites/default/files/cbofiles/attachments/average_after-tax_income.pdf)

**Figure 17.6** Income change between 1979 and 2007 under two definitions.

*Source:* Adapted from “Deconstructing Income and Income Inequality Measures: A Crosswalk from Market Income to Comprehensive Income (Table 1),” by P. Armour, R. V. Burkhauser, and J. Larimore, 2013, *American Economic Review*, 103(3), pp. 173–177.

shows changes in income between 1979 and 2007, but this time two definitions of income are used. The first bar graph in each quintile is cash market income before any government taxes or transfers are considered. Data of this type were developed by Piketty and Saez (2003), and are often cited to claim that income in the bottom quintile fell over the period. However, another picture of changes in income over time is presented by data for households,

adjusted for size, taking account of government taxes and transfers as well as income from realized capital gains (the second bar graph in each set in Figure 17.6). Based on market income, a reasonable conclusion is that tax unit data show a major decline in the bottom quintile and almost imperceptible growth in the second and middle quintiles. However, based on household data and a broader definition of income, all three of the lowest quintiles experienced

income growth of over 30% between 1979 and 2007. The most important factor in increasing income within the bottom three quintiles is the progressive government tax and transfer system, which partially reduces income inequality.

### Increasing Disparity in Income and Wealth

Figure 17.6 also shows the huge growth of household income among those in the upper reaches of the income distribution. As shown by the two bar graphs for both the top quintile and the top 5%, the growth of income using the broader income measure is huge. A recent report from the nonpartisan Congressional Research Service concludes that the major cause of the explosion of income at the top is income from capital. In addition, the more lenient treatment of capital income under the Bush tax cuts of 2001 and 2003 played an important role in the remarkable rise of income at the top (Hungerford, 2013). Some analyses show that the growth of inequality of wealth is even greater than growth of inequality of income. For example, Darity and Nicholson (2005) found that class-based disparity in capital gains and family wealth dwarfs income disparity and separates poor from nonpoor families and Black from White families in America. The top 1% of wealth holders own 60% of all the nation's assets, and the top 10% own 85% of all assets (Darity & Nicholson, 2005). Data from the Survey of Income and Program Participation indicate that the median wealth of White families in 2009 was \$113,149, compared with \$6,325 for Latino/a American families and \$5,677 for Black families (Kochhar, Fry, & Taylor, 2011). The wealth gap means that poor and minority families have fewer resources to make long-term investments in their children (from piano lessons to neighborhood school choices) that could help them escape or avoid poverty in the next generation.

Regardless of how one interprets the various definitions of income and wealth, it is notable that under every definition, income and wealth inequality increased dramatically between 1979 and 2007. There are a host of reasons that explain the increased inequality as well as the lack of progress against poverty shown previously in Figure 17.4. All of the underlying forces we review below have contributed to both the stubbornly high poverty rates and high and growing income inequality. One important factor is wages at the bottom of the income distribution. After some modest rises and declines, wages at the 10th percentile are almost exactly where they were in 1979. Over the same period, wages in the middle increased by

about 8%, while wages at the 95th percentile increased 36% (Mishel, Bivens, Gould, & Shierholz, 2012). These differential wage increases, of course, contributed to increasing inequality. The unfortunate trend in wages at the bottom of the distribution plays a major role in the difficulty the nation has encountered in reducing poverty.

A second major factor in both high poverty rates and growing income inequality is the lack of progress in increasing the educational achievement of American children whose parents are poor or near-poor. Figure 17.7 provides an overview of trends in family income during the prime earning years by level of education of the family head. Three trends are notable in the figure. First, over the nearly five-decade period between 1963 and 2011, the line graphs representing the relation between family income and education level of the household head never cross. In short, more education has consistently meant more income. Second, in recent years the gaps between the education-level groups have widened. Thus, the returns to education are even stronger than they had been previously, and education disparity contributes heavily to later family income disparity. Third, so difficult has the economic situation of those with less than a 4-year degree become that the trend of their income has been down for more than 25 years. In the United States fewer than two in five persons earn a 4-year degree (U.S. Census Bureau, 2012a).

Goldin and Katz (2008), in one of the most thorough treatments of education, technology, and income published to date, have shown by analyzing data over the past century and more that the correlation between education and earnings has been growing, in large part because of the rise of jobs in which technology plays a major role. But by any measure of educational achievement, children from low-income families are falling further behind. As we have seen, based on analysis of 19 nationally representative data sets, Reardon (2011) showed that under nearly every measure, achievement gaps between Blacks and Whites have narrowed while the gaps between children from upper-income and lower-income families have widened. If education is becoming more important in determining income, and educational achievement of children from families in the middle class or above is getting progressively higher than that for children from low-income families, the prospects for reducing poverty and income inequality and for expanding economic opportunity are dim.

A third factor contributing to the increase in both poverty and income inequality is the rise of single-parent families. Children in female-headed families have a poverty rate that is 4 or 5 times as high as children living

**Figure 17.7** Education and family income over time.

*Source:* Income figures adapted from Brookings tabulations of data from the Annual Social and Economic Supplement to the Current Population Survey, 1964–2012.

in married-couple families (U.S. Census Bureau, 2012b). It follows that the higher the share of the nation's children who live with single mothers, the higher the poverty rate is likely to be. Between 1970 and 2011, the proportion of children living with single mothers increased from 11.6% to 26.1% and is still rising (U.S. Census Bureau, 2012c). The most important factors in the increase of children in female-headed families are the rapid decline in marriage rates among those with less than a college education and the substantial increase in nonmarital births. Since 1960, the marriage rate among all women aged 40 to 44 has declined by 23%; the marriage rate among women aged 20 to 24 (a prime age range for nonmarital births) fell from 60% to 16% (Cancian & Haskins, 2013). In a trend that is undoubtedly connected to the decline in marriage, the percentage of nonmarital births population-wide has risen from around 11% in 1970 to nearly 41%, including a rate for Blacks that is over 70% (Martinez, Daniels, & Chandra, 2012).

Like growing achievement gaps, nonmarital births are correlated with the rise of inequality as well as the rise of poverty. Furthermore, there is a direct relation between education and the probability of having a nonmarital birth. The highest rate of nonmarital births is among high school dropouts, the next highest among women with only a high school degree but no college, the next highest among women with some college but not a degree, and by far the

lowest among women with a college degree (Cancian & Haskins, 2013; Martinez et al., 2012). As with the data on educational achievement, low-income families are at highest risk for behavior that reduces their child's prospects for avoiding poverty and for moving up the income scale.

A fourth factor in understanding the relation between poverty and inequality is work. As Sawhill and Karpilow (2013) point out, 60% of the households in the bottom third of income do not work or work less than full time. A major part of the explanation for low work levels is that the United States is experiencing a long-term trend in declining work levels among males. Our calculations, based on decennial census data, show that between 1970 and 2010, the percentage of employed males who were high school dropouts declined from about 88% to 67%; the decline for males with a high school degree was from 95% to 76%. The work rate among young Black males who are high school dropouts is less than 50%. With the exception of adults with large inheritances and adults who hit the lottery, it is all but impossible to avoid poverty without working. Except in rare cases, welfare alone will not bring families with children out of poverty. The impact of work—even at low wages—on poverty is well illustrated by the rapid rise in employment among never-married mothers in the mid-1990s after welfare reform and a major increase in the Earned Income Tax Credit (EITC) that provides a cash wage supplement to low-income workers. Over a 4-year

period, work by these mothers increased by 40% while the poverty rate among Black children (who are disproportionately likely to live in female-headed families), and all children in female-headed families, reached their lowest levels ever (Haskins, 2011). It is unlikely that poverty rates among children will decline very much unless work rates or hours worked by their parents increase.

Except among the elderly, the nation has made no progress against poverty since the early 1970s. To make matters worse, income inequality has increased substantially over the past three decades. Both the trends in poverty and income inequality result in large part from the underlying trends in stagnant wages at the bottom of the wage distribution, the decades long growth in the gap in educational achievement between students from low-income and high-income families, the rise of single-parent families with their very high poverty rates, and the decline of work among males, especially Black males. The two bright spots in this picture are the government tax and transfer system of progressive taxes and means-tested programs, which have slowed the growth of income inequality and allowed families in the bottom of the income distribution to increase their income and the increasing work rates among mothers at the bottom of the income distribution.

## **HISTORY OF GOVERNMENT PROGRAMS FOR CHILDREN<sup>1</sup>**

We turn now to a review of government means-tested programs, beginning with a brief review of their growth between the period before World War II and the War on Poverty in the 1960s and then a review of the most important programs as well as spending on the programs.

The history of American social policy is in large part a story of increasing government responsibility for keeping children, families, the disabled, the unemployed, and the elderly out of poverty. In addition, since roughly the mid-1980s, government has increasingly enacted policies to supplement the income of poor working families. The government's role in enhancing overall well-being is more controversial and mixed. Although local, state, and federal governments all have responsibility for raising revenue and operating programs to promote the general social and economic welfare, the federal government takes a greater role than the states and localities, both by supplying the bulk of

financing for social programs (with the exception of K–12 education) and by requiring states to meet certain requirements in order to qualify for federal funds.

These developments in the nation's social policy have coincided with powerful historical forces, perhaps the most important being the post-World War II growth of the nation's economy. The American economy has produced a volume of income and wealth, as well as goods and services, which would have staggered the imagination of anyone a century ago. Even most of the poor have goods that the middle class in previous generations did not enjoy (Rector & Sheffield, 2011). Another surprising factor in understanding the development of social policy is that government decisions about how much to spend on the poor and in what ways have hardly been influenced by the poor themselves. America lacks a tradition of either socialism or communism, which means that public debates about and legislative action on social policy have occurred primarily among elites (Mead, 1992; Teles, 1996).

A related, and unfortunate, factor in the lack of political influence by the poor was the powerful influence of conservative and racist politicians from the South. For many years before and following the world wars, Southern Democrats ran without serious competition during general elections and thus built up seniority in both houses of Congress, which, in turn, allowed them to chair important committees and thereby control legislation. It was not until one of their own, a former Senate Majority Leader from Texas, Lyndon Baines Johnson, became president and used his power to overcome his former colleagues from the South that Congress was able to pass significant civil rights legislation and initiate a War on Poverty. Before the Civil Rights Act of 1967, and in truth even for many years after 1967, Blacks in the South were largely deprived of their right to vote. Since Blacks acquired their right to vote and hold office in the South in the 1970s, federal and state spending on social programs has increased dramatically.

Another important factor has been philosophical differences between liberals and conservatives over three issues: (1) government's responsibility to rescue children from the harm of hunger and poverty (by enactment of safety net programs); (2) government's role in ensuring equal opportunity for all children, no matter what the financial circumstances of their birth; and (3) government's ability to improve outcomes for all children through social programs.

Although America led the world in spending on public education until well into the 20th century, today the United States trails many advanced democracies in spending on

---

<sup>1</sup>Parts of this section are based on Haskins (2008).

the poor and spending to equalize opportunity (Garfinkel, Rainwater, & Smeeding, 2010). Education, both K–12 and postsecondary, held out the opportunity for millions of Americans in every generation to achieve economic success. In fact, so great was the American advantage in public schooling and university education that education was perhaps the single most important factor in the nation's explosion of innovation and productivity in the years after the Civil War and the amazing growth of the nation's GDP (Lindsey, 2007).

As the nation's economy grew, it gradually became clear that many children still did not benefit from the opportunity presented by free public education. This problem was less obvious when the nation's economy generated a high proportion of service jobs and even manufacturing jobs that did not require much education. But since at least the 1970s, education and acquired skills have become an increasingly important determinant of income. Children who have lived in poverty tend to do poorly in school and, in turn, are less likely to get jobs with high pay as adults (Goldin & Katz, 2008).

### **Social Policies Before 1935**

Before the Social Security Act of 1935, state and local governments were solely responsible for public education, while families, often assisted by local organizations and especially churches, were largely responsible for the private caring of their own elderly, sick, disabled, destitute, and child members. Even so, several public policies, though modest in scope, were instituted during the period before 1935 that initiated an historic trend of greater government involvement in addressing the nation's social problems. One of the first social policies was federal and state pensions for Civil War veterans and their families (L. Gordon, 1994; Skocpol, 1991), which were generous, extensive, and expensive. But as Civil War veterans began to disappear, so did veterans' benefits. Another early policy was workers' compensation, an all but exclusive domain then and now of state government, which provides cash income and medical care to workers injured on the job (Fishback & Kantor, 2000). A third public policy was the federal Sheppard-Towner Act of 1921. The Act provided matching funds for states to establish programs to teach mothers about maternal and child hygiene. All but three states had established programs by the late 1920s, but the federal legislation was not reauthorized in 1929. The premature demise of Sheppard-Towner and its clinics did not obviate the fact that states had established a short but

lively tradition of providing public help to mothers and infants to improve their health, a capability states would soon have opportunity to use again.

Finally, and perhaps most important, nearly every state enacted mothers' pensions to provide benefits to widows—and, more grudgingly, to other single mothers—so they could stay home to rear their children. These programs, first enacted by Illinois in 1911 and then spreading to 40 states before the 1930s, allowed local jurisdictions to establish programs of cash assistance for poor single mothers (Skocpol, 1991). The characteristics of these pensions would greatly influence future social policy. First, the benefit was means-tested, providing support only for single mothers in financial need. As other industrialized nations established universal programs providing cash grants to all families with children, these means-tested American programs appear unique. Second, each state established its own program, leading to great variability rather than a single national set of requirements and benefits. Third, although the major purpose of the benefit was to allow single mothers to stay home with their children, the benefit was not given to all single mothers. At first, the benefit was given primarily to destitute widows. Subsequently, nearly every state included all single mothers. To qualify for the benefit, mothers were required to maintain homes that were consistent with community standards, thereby necessitating judgments about whether the mothers were providing an environment fit for rearing children (Bell, 1965). Thus was established the American tradition that if government paid a family benefits, government had a right to impose living arrangements that conformed to vague criteria such as "community standards."

### **Social Security Act**

The Social Security Act of 1935 initiated a process of formalizing and expanding social programs and supplementing or replacing state and local control with federal control. State and local governments remain important to this day, but the federal government, formerly a bit player, now entered the field of social policy with flags flying.

The Social Security Act featured several types of programs, which in either their original or substantially expanded forms today constitute a major portion of the nation's social policy for children. Title IV of the act established the nation's leading welfare program for mothers and children, the Aid to Dependent Children program (which has been renamed twice and is now the Temporary Assistance for Needy Families program or TANF),

offered states federal matching funds to establish programs that would give cash benefits to poor children and their mothers.

The federal-state cash welfare program lasted for more than six decades before being replaced by the TANF program enacted as part of the sweeping Welfare Reform Law of 1996. Over the years between 1935 and 1996, a host of important welfare programs—including programs to encourage or force fathers to pay child support; to provide support for abused and neglected children; to provide medical benefits to mothers, children, and the elderly; and to provide social services to needy families—were added to the Social Security Act.

The Old-Age Insurance program (called “Social Security”), established by Title II and amended many times over the years, has become the centerpiece of American social policy. Social Security made the federal government the source of security for life’s greatest vicissitude (to use Roosevelt’s term); namely, old age. Over the years, Congress helped many branches grow from this mighty oak, including survivors’ benefits in 1950, disability insurance in 1956, Medicare health insurance for the elderly in 1965, and a prescription drug benefit for the elderly in 2003. Today, about 38 million people receive Social Security retirement benefits and about 6 million families receive survivor benefits that average around \$1,050 per month; about 8 million people receive disability benefits that average over \$900 per month; and about 47 million people are enrolled in Medicare and prescription drug coverage (U.S. Social Security Administration, 2012a, 2012b). The Social Security Act, both in 1935 and today, embodies two of the major fault lines in American social policy: welfare versus insurance programs and federal versus state control. Broadly, the nation has two types of social programs that pay individuals: insurance programs and means-tested programs. Insurance programs provide benefits that are earned because they are based on tax payments over all of a person’s productive years and are mostly paid to people who are not expected by the public to work—the elderly, the disabled, and workers temporarily unemployed but looking for work. Means-tested programs, by contrast, are provided to people based in part on low income without a requirement of having paid into the financing structure.

It was Roosevelt’s intention to establish Social Security retirement and unemployment compensation as universal programs that did not require a means test. Many New Dealers lived by the motto that “poverty programs are poor programs.” Thus, Social Security old-age benefits, survivors’

benefits, disability insurance, and Medicare are all based in part on the insurance principle, although the details of the trust funds that pay the majority of these programs differ. All the insurance programs are hugely popular and are seen by the public as “earned benefits,” no matter what the facts are about financing or the relation between contributions and benefits.

In contrast, means-tested programs are not based on contributions but rather on the willingness of taxpayers to provide low-income families (especially single mothers) with cash and in-kind benefits including health care, food, housing, employment and training assistance, and social services. The perception that means-tested programs are “entitlements not based on earned benefits” leads them to be unpopular with the segment of the population that believes that these “handouts” should be stopped or at least reduced. In this context, it is not surprising that recent innovations in conditional cash transfers that involve even modest parental obligations have grown in popularity (e.g., Clinton-era welfare-to-work, Mexico’s *Progres*a, and New York City’s welfare reform).

As early as 1935, the federal government placed the insurance programs almost entirely under federal control (unemployment compensation is a partial exception) while sharing the means-tested programs with the states. Federal dominance of the insurance programs raises the second fault line in the nation’s social policy, federalism. Federal control over insurance programs almost completely cuts states out of the decision-making. Assuming a close relation between decision-making authority and support, federally operated insurance programs avoid the challenge of how to get states to comply, support, and administer programs with fidelity. On the other hand, state-controlled programs that have federal financial backing suffer from the possibility of uneven administration and fidelity with uneven impact.

### The War on Poverty

If the Social Security Act of 1935 expanded the federal role in the nation’s social policy, the War on Poverty of the mid-1960s solidified and extended the federal role, opening the door to a host of programs and policies to help poor children gain a chance at success in life. The War on Poverty itself did not represent a major initiation or expansion of big programs and spending. Rather, it committed the federal government to helping poor children and created a few modest programs to implement the commitment. Subsequently, Congress and a series of

Republican and Democratic presidents expanded the War on Poverty programs and enacted new programs to deliver on the promise of helping the poor, especially children.

The War on Poverty was developed and enacted under President Lyndon Johnson. He cajoled Sargent Shriver, a member of the Kennedy family who was already heading the immensely popular Peace Corps, into leading the effort to pass legislation that would provide the funding. Shriver developed the programs by hiring and empowering a group of intellectuals, many with Washington experience, and by enlisting many others from federal agencies, with very little consultation with Congress or the governors (Gillette, 2010). Johnson and Shriver assumed from the beginning that the programs would have to be federal because so many of the southern governors and governments were racist and could not be counted on faithfully to implement anti-poverty programs which were, after all, aimed disproportionately at helping Blacks. Although the War on Poverty created many programs and the Office of Economic Opportunity, perhaps the best known programs are directed toward children and families, including the still-active Head Start, Job Corps, VISTA, and the Community Action Program.

## CURRENT MAJOR GOVERNMENT PROGRAMS FOR CHILDREN

As it turned out, the War on Poverty opened a new chapter in American social policy. Over the next nearly half century, the nation would enact a host of means-tested programs and expand some of those created during and before the War on Poverty. By the second decade of the 21st century, the federal and state governments would be operating more than 80 major means-tested programs and spending around \$1 trillion on poor and low-income Americans.

### Spending on Means-Tested Programs

In this section, we review spending on means-tested programs in general and then spending specifically on children. We emphasize spending because we believe budgets operationalize government's values and priorities. Programs discussed in this section do not include spending on Social Security, Medicare, Disability Insurance, or Unemployment Compensation because these are insurance, not means-tested, programs. Spending on these four programs alone totaled a little over \$1.4 trillion in 2012 (Office of Management and Budget, 2013). To the extent that

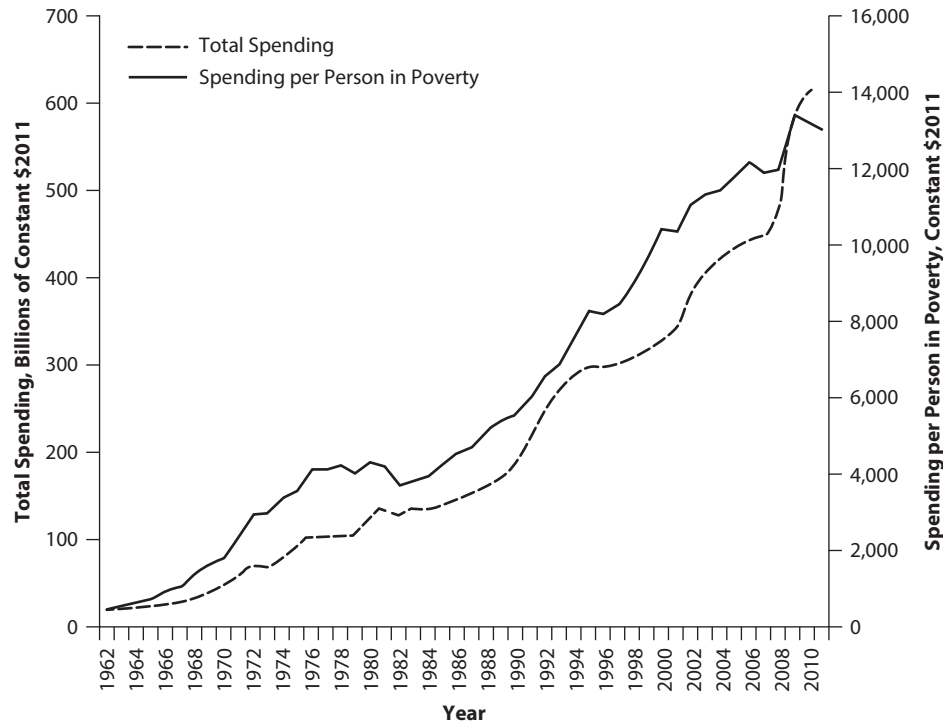

spending reflects relative importance and priority, these figures provide an account of how government leaders intend to exert influence on children's development.

The lower line in Figure 17.8, based on federal budget data published by the Office of Management and Budget, shows federal spending in dollars adjusted for inflation since 1962 on the 10 largest means-tested federal programs. In 2011, about 87% of this spending was on entitlement programs such as Medicaid, Supplemental Nutrition Assistance Program (SNAP; formerly food stamps), and Supplemental Security Income. Entitlement programs do not require an annual appropriation, meaning that anyone eligible for the benefits in a given year has a legal right to receive the benefit. By contrast, discretionary programs require an annual appropriation that is often not large enough to pay for everyone eligible for the benefit. Thus, the benefits are rationed. Childcare programs and housing programs are discretionary, and many eligible children and families do not receive the benefit.

Clearly, federal spending on poor and low-income Americans has increased enormously. Since 1980, by which time all but two of the 10 programs that spent the most money in 2011 were in place, spending has increased by about \$500 billion, from \$126 billion to \$626 billion after adjusting for inflation.

One cause of the increase in spending is that both the population and the number of poor people in the United States have increased over time. As shown by the solid line in Figure 17.8, which expresses spending on the 10 biggest federal means-tested programs on a per-person-in-poverty basis, spending has increased substantially. Over the past five decades, federal spending on major means-tested programs has increased from about \$516 to a little more than \$13,000 per person in poverty in constant dollars, although much of this money is spent on people above the poverty line. If we use the figure on spending per person in poverty in 1980, the increase is from about \$4,300 to \$13,000 per person, or more than \$3 spent in 2011 for every dollar spent in 1980. More recently, means-tested spending on the 10 biggest programs increased from about \$477 billion to \$626 billion between 2008 and 2011, an increase of about 31%. However, the recession that began in December 2007, which led to the decline in household income and the increase in poverty during and following the recession, is an important part of the explanation for recent increased means-tested spending. Most of the means-tested spending that the American Recovery and Reinvestment Act of 2009 authorized began to expire in 2010, and disappeared by 2011 or shortly thereafter.

**Figure 17.8** Secular trends in spending on 10 biggest social programs.

*Notes.* This series includes 10 spending sources: Medicaid, SNAP, EITC, CTC where credit exceeds tax liability, SSI, AFDC/TANF, Housing Assistance, Medicare Part D Low Income Subsidy, ESEA Title I Grants to Local Educational Agencies, and Federal Pell Grants. Data on the last two are available starting only in 1980 and include approximately \$27 billion in ARRA spending in 2009.

*Sources:* Most spending sources from OMB, Fiscal Year 2013 Budget, Tables 8.5, 11.3, 12.3. Title I and ESEA spending from Department of Education Budget History Table. Medicare data from CMS, 2011 Medicare Trustees Report, Table IV.B11, number for 2011 is estimated. All figures adjusted to constant dollars using OMB total deflator from historical table 10.1. Data on number of people in poverty through 2010 from U.S. Census Bureau, 2011, number estimated by Richard Bavier.

Not all means-tested spending is included in Figure 17.8. The Congressional Research Service (CRS) has reported on federal means-tested spending that includes 86 major programs in eight broad categories (CRS, 2012). The categories include health, cash, nutrition, housing, education, social services, energy assistance, and employment and training. Not surprisingly, health is by far the biggest category of spending at \$339 billion in 2011, well over twice as much as cash programs (\$145 billion), the second biggest category (CRS, 2012). Employment and training at \$6 billion and energy assistance at \$5 billion are the smallest of the eight categories.

It should be emphasized that not all means-tested spending is spent on poor people. Children in families of up to 200% of the poverty level, for example, are eligible for Medicaid or the Child Health Insurance Program (CHIP) in almost every state. Similarly, people in households with incomes up to 130% of poverty are eligible for SNAP benefits. In the case of the EITC, in 2012, a single mother with

two children could receive benefits if the mother's income was below \$41,952, about 220% of the poverty level for this family (Internal Revenue Service, 2013). Armor and Sousa (2012) used Census Bureau data and data from other sources to estimate that about half the benefits in the major poverty programs go to people and families whose income is over the poverty line at some time during the benefit year.

### Spending on Children

Isaacs, Toran, Hahn, Fortuny, and Steuerle (2012) have performed extensive analyses on changes over the past half-century in spending on children. Figure 17.9 provides an overview of federal spending on a total of 86 individual programs from which children benefit organized into 11 broad categories. In this analysis, spending on children from insurance programs such as Social Security is included (not just means-tested spending as in the analyses

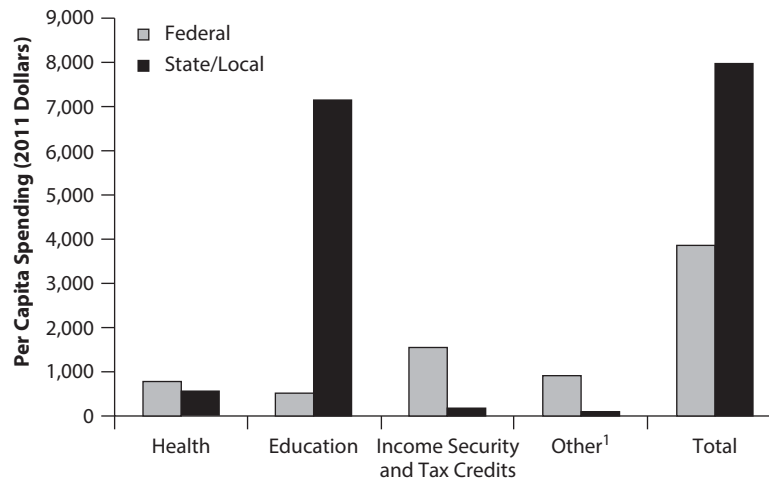

**Figure 17.9** Children's spending by category, 2011.

Source: Adapted from *Kids' Share 2012: Report on Federal Expenditures on Children through 2011* (p. 21), by J. Isaacs, K. Toran, H. Hahn, K. Fortuny, and C. E. Steuerle, 2012, Washington, DC: Urban Institute.

reported above). According to this analysis, in 2011 the federal government spent \$376.2 billion on programs that directly benefit children or provide help to households because children are part of the household. The major components of this spending are health, income security (primarily from Social Security, cash welfare, child support enforcement, and veterans' benefits), education, nutrition, early education, and various provisions in the tax code. The biggest single program is a health program (Medicaid), but the tax provisions combined are even bigger than the Medicaid benefit (\$144.1 billion compared with \$73.9 billion). Spending on children is similar to the trends for overall social spending in that there has been an increase in both the number of programs and total spending over the past half century, although future trends in spending are very much in doubt (see below). In 1960, the federal government spent about 3% of the federal budget, or \$58 billion, adjusted for inflation, on children. Both the amount of money and the percentage of the federal budget spent on children increased every decade, growing to 11% of the federal budget, or \$445 billion, in 2010. Thus, federal spending on children has more than tripled as a share of the federal budget and increased by 7.7 times in constant dollars over the past half century. This increase in spending reflects not simply a growing financial commitment to children but a broadening of the types of support provided to children. Support for abused and neglected

children and nutrition was undertaken in the early 1960s and dramatically expanded in the 1980s; health care and preschool education were added in the mid-1960s; help for the disabled and help with housing grew in the 1970s; and major expansion of programs that provide cash through the tax code occurred in the 1980s and 1990s.

The federal government is not the only source of support for children. In fact, unlike the pattern with all means-tested spending and all social spending, the majority of spending on children is paid for by local and state government (Figure 17.10), primarily because state and local governments pay for about 93% of public education. Because of Medicaid, with costs split between the states and federal government, states also spend a great deal on health, \$549 per child or about 40% of the total spending on children's health. Income security and tax credits, by contrast, are paid for primarily by the federal government, about 90% of the total. The federal government also spends more than 8 times as much as states on child nutrition, early education, social services, housing, and training (see "Other" in Figure 17.10). Given the importance of education at the preschool, K–12, and postsecondary levels, states arguably represent the single most vital part of the nation's social policy for children. As such, state and local governments are of great importance to the nation's struggle to address growing gaps in income inequality, wealth, educational attainment, health, and life success.

**Figure 17.10** Federal and state/local spending on children, by domain.

<sup>1</sup>Includes nutrition, early education and care, social services, housing, and training.

*Note.* Tax expenditures are not included in this figure. The population of children (those < Age 19) was used to calculate per capita amounts.

*Source:* Adapted from *Kids' Share 2012: Report on Federal Expenditures on Children through 2011* (p. 26), by J. Isaacs, K. Toran, H. Hahn, K. Fortuny, and C. E. Steuerle, 2012, Washington, DC: Urban Institute.

The growth in both the number of programs aimed at helping children and the level of spending on these programs indicates a rising commitment to the well-being of children by the federal government and the states. However, two additional issues provide some perspective on the nature of the nation's commitment to children. First, in 2011, for one of the few times in the past half century, federal spending on children actually declined in constant dollars. According to Isaacs and colleagues, total federal spending on children fell from \$450.1 billion in 2010 to \$444.8 billion in 2011. The decline in spending on children is accounted for primarily by the end of spending from the American Recovery and Reinvestment Act of 2009. The second issue is the comparative commitment to children versus the elderly. Isaacs and colleagues show that in 2008, the federal government spent \$3,882 per child as compared with \$25,455 per elderly person. Furthermore, 10-year projections from the Congressional Budget Office show that spending on children is expected to grow by only \$6 billion over the next decade while spending on Social Security, Medicare, and Medicaid will grow by \$876 billion (Isaacs et al., 2012). The clear message here is that spending on entitlement programs that benefit primarily the elderly is squeezing out spending on programs for children. Congress has never taken a direct vote on its view of the relative importance of spending on children versus spending on the elderly, but the budget decisions Congress has made in the past greatly favor the elderly. It seems likely that if the current trajectories of increase in spending on the elderly for

Social Security and Medicare continues, every other part of the budget, including children's programs, will be reduced.

### Specific Programs for Children

The review above traces the evolution of spending on programs, but to understand the scope and goals of federal policy for children we must examine the specific programs that provide benefits and services to prevent or ameliorate destitution or to promote the growth, development, employment, and medical treatment of children, especially those from disadvantaged families. The federal government conducts thousands of domestic programs; the *Catalog of Federal Domestic Assistance* contains about 2,200 programs (General Services Administration, 2013). Many of these programs have a direct or indirect impact on children. A more refined list of programs that influence children, which includes only major programs, is published by the Congressional Research Service (CRS, 2012). The CRS report includes detailed descriptions of 86 means-tested programs divided into eight categories. Here we review major programs, defined as programs that spend the most money or have the most participants, selected from the 2012 CRS report and various other reports from government agencies.

### Health

The federal government spends more money on means-tested medical care and related programs than on any other category of means-tested spending. In 2011, total

spending on the 10 most important means-tested health programs totaled nearly \$340 billion (CRS, 2012). By any measure, the most important health program for children is Medicaid. Although the United States trails other advanced nations in the share of its citizens who are guaranteed health care, Medicaid coverage of children has expanded greatly since its inception in 1965 until today when virtually every child in families under 200% of poverty is covered. After full implementation of the Affordable Care Act (the Obama health care law, enacted in 2009), all children should be covered by Medicaid or private health insurance. Medicaid now covers 16 million low-income adults and 15 million people who are elderly or disabled, but it also covers 31 million children, some of whom are disabled (Kaiser Commission on Medicaid & the Uninsured, 2013). Despite the huge number of children covered by Medicaid, only 20% of Medicaid's expenditures of \$414 billion in 2011 were on children. The disabled consumed 42% of Medicaid expenditures, the elderly 23%, and adults the remaining 14%.

Medicaid is funded through a partnership between the states and the federal government. The federal government pays at least 50% of the cost in every state, but above 50% in states with low per capita income. The specific percentage for each state, called the federal medical assistance percentage or FMAP, can go as high as 73% in states with very low per capita income. One exception to the FMAP formula is that family planning services, including contraception methods and supplies, are funded with a 90% federal match (Kaiser Commission on Medicaid & the Uninsured, 2013).

Eligibility for Medicaid is exceedingly complex and varies greatly from state to state. Generally, the groups qualified for Medicaid include low-income families with children in which one parent is absent, incapacitated, or unemployed; people with low income and a disability; and the low-income elderly. All children in foster care or adoption whose caregiver receives coverage under the federal foster care and adoption program are also covered. In addition, children from families with income as high as 200% of poverty, certain pregnant women, some women with breast or cervical cancer, and certain people with tuberculosis are qualified for coverage. Arguably the most important Medicaid expansion in recent years was making children from families with higher income eligible regardless of whether they were on AFDC or SSI, an expansion that solved one of the thorniest work incentive problems under the old system of limiting coverage to children on SSI or AFDC. If working families increase their earnings above the state's threshold eligibility level and lose

Medicaid, they are given a 6- to 12-month transition period of extended coverage.

Medicaid coverage will expand greatly as the Affordable Care Act (ACA) is implemented beginning in 2014. It will be recalled that states pay on average about 45% of the cost of Medicaid—a cost that imposes a huge burden on the budget of every state. Although the federal government will pay nearly all the costs of the ACA Medicaid expansions in the early years of ACA, many states with Republican governors are threatening not to accept the additional coverage and not to run the health care exchanges that are a vital part of the ACA health care expansion strategy. How these issues are resolved will have an important impact on how much Medicaid expands under ACA. Current estimates, by the Kaiser Family Foundation and others, are that ACA will cause Medicaid costs to expand by around 16% (Kaiser Commission on Medicaid & the Uninsured, 2013). In addition to ACA, the retirement of the baby boom generation will substantially boost Medicaid costs because so many of them will require long-term care which is covered under Medicaid for most of the low-income elderly.

There are many additional programs that provide medical services to low income children and adults, including the Indian Health Services, a program for low-income veterans with service-connected disabilities, family planning services, and the Maternal and Child Health Services Block Grant. Although all are much less expensive and cover fewer children than Medicaid, they represent an important part of the nation's commitment to paying for or providing health care to disadvantaged children and families.

### *Cash Transfers*

Some economists argue that cash is the best benefit because it allows recipients to buy what they most need or want and thereby maximize their utility. Thus, it is entirely appropriate that the second highest category of means-tested federal spending is on programs that provide recipients with cash. The federal government began the practice of providing cash transfers to the destitute in 1935 when the Aid to Dependent Children program was created as part of the Social Security Act. Since that time, the federal government has enacted three major cash transfer programs that provide funds to low-income individuals and families: Supplemental Security Income (SSI), the Earned Income Tax Credit (EITC), and the Additional Child Tax Credit. Taken together, TANF (AFDC's replacement program) and these three cash programs now place around \$145 billion in cash in the hands of poor and low-income families, individuals, and children each year (CRS, 2012).

Since it began implementation in 1974, the SSI program has provided benefits to people who were poor and were also either elderly or disabled. The program provided cash benefits worth \$60 billion to the poor disabled or elderly in 2011. Nearly 8 million people receive the benefit, about 16% of them disabled children (U.S. Social Security Administration, 2012b). SSI enrollment, like enrollment in the Social Security Disability Insurance (SSDI) program, has increased in recent years, leading many analysts to express concern about both the costs of the program and the effects on children's development of being placed in disability programs (Burkhauser & Daly, 2011; Duggan & Imberman, 2008). Similarly, the Office of Management and Budget has examined possible reforms to SSDI that might help more people with borderline disabilities (especially muscular/skeletal and mental impairments) remain in the labor force, at least on a part-time basis, thereby slowing the increase in enrollment (Liebman & Smalligan, 2013). Under current assumptions, the trust fund that supports the SSDI program is scheduled to run out of cash in 2016, adding a sense of urgency to discussions about rising enrollment projections. Because 1.7 million children receive benefits from SSDI, its financing is an important issue for the well-being of children (Social Security Administration, 2012a).

The two tax credit programs are in many ways ideal policy for low-income families. With the modest exception of a small benefit for childless workers (with a maximum payment of about \$500 per year), the EITC and the Additional Child Tax Credit go only to families with children, only families with earnings, and only families with low-income. Although both programs are means-tested, it seems misleading to call them welfare programs because only adults who work are eligible for the benefit. The benefit is larger for families with two children and larger still for families with three or more children. Using families with one child as an example, the EITC benefit is equal to 34% of earnings up to \$9,320. The maximum benefit of around \$3,000 stays flat for earnings between \$9,320 and \$17,090. The benefit then phases out at the rate of 16% of earnings above \$17,090 and reaches zero at earnings of \$36,920. The phase-in and phase-out rates are different for families with additional children; the maximum benefits for families with two and three or more children are \$5,200 and \$5,900 respectively. A provision enacted by Congress as part of the 2009 Recovery Act reduced the penalty in their EITC payment that some couples would experience by getting married. In 2010, around 27 million working families and individuals

received the EITC (Center on Budget and Policy Priorities [CBPP], 2013b).

The Additional Child Tax Credit is similar in many ways to the EITC. The credit is based on work, targeted on families with children, and given only to low-income families. Like any tax credit, poor and very low-income families cannot benefit from the regular Child Tax Credit, which had been enacted in 1997, because they have no income tax liability against which to take the credit. Thus, the EITC and a few other credits have been made refundable by Congress, meaning that if a family met the terms of the credit, the IRS would send them a check. In 2011, 2.9 million people, including 1.5 million children, were prevented from falling into poverty by the Child Tax Credit (including the Additional Child Tax Credit) (CBPP, 2013a). The total value of the credit to working families in 2011 was a little less than \$23 billion (CRS, 2012).

### *Nutrition*

The federal government, sometimes in cooperation with the states, conducts 12 major nutrition programs, all but one of which provide direct or indirect benefits to children. Taken together, these programs provided poor and low-income individuals, families, and children with more than \$101 billion in benefits in 2011. The biggest program by far is the Supplemental Nutrition Assistance Program (SNAP; formerly called food stamps). SNAP has grown rapidly since 2000, mostly because of the weak U.S. economy, which has had the effect of reducing the income of millions of families, making many of them eligible for SNAP. In 2011, when the program cost \$78 billion, 45 million people received SNAP benefits in an average month as compared with only about 20 million recipients in 1990. About half the 18.4 million households that received SNAP in 2010 had children (Congressional Budget Office, 2012).

SNAP stands out from other means-tested programs in that almost everyone who meets the standard of low income is eligible to receive the benefit. Most of the nation's other means-tested programs require recipients to meet conditions in addition to low-income, such as having a disability, being a single parent, or working. SNAP is a guaranteed income paid in electronic cards that can be used only for food purchases, although the program has a work requirement for some recipients that is usually not enforced by states.

In addition to SNAP, other programs provide children with nutritious foods. Taken together, these programs cost about \$23 billion in 2011 (CRS, 2012). The most expensive programs are the National School Lunch Program

(\$9.8 billion), the Special Supplemental Nutrition program for Women, Infants, and Children (called WIC; \$7.3 billion), the school breakfast program (\$3.0 billion), and a program that subsidizes snacks and meals in childcare facilities (\$2.5 billion). The goals of all these programs are to “improve children’s nutrition, increase lower-income children’s access to nutritious meals and snacks, and help support the agricultural economy” (Richardson, 2009, p. ii). This goal statement for child nutrition programs, taken from a CRS document, nicely illustrates an important political fact about nutrition programs, including both the child nutrition programs and SNAP; namely, that the support from the large and powerful agriculture lobby (including the lobby for grocery stores) for all nutrition programs is one of the reasons these programs are so strong and have grown so much in recent years. Although funding levels might decline modestly over the next decade, nutrition programs are all but politically invulnerable. The child nutrition programs operate in all 50 states, Washington, D.C., and most of the territories. They are administered mostly by states, although the Department of Agriculture has rules and regulations as well as a reputation for thorough administration. School Lunch and School Breakfast programs have been shown to provide 28% of the daily consumption of food by participating children (Potamites & Gordon, 2010).

### ***K–12 Education***

Crosnoe and Benner (Chapter 7, this *Handbook*, this volume) discuss how school influences children, and so the emphasis here is on spending and policies. Although public education in the United States has its roots in colonial New England, it gained support in the mid-19th century when waves of immigrants posed a challenge to the democracy (Coleman, 2002). Immigrants needed to be educated to fill emerging factory jobs, but even more importantly, they needed to become competent to participate in the new democracy. Education was the proposed solution with the realization that a successful democracy required a populace that participated peacefully and competently, endorsed values of equality of voice, and understood issues sufficiently to vote responsibly (Lagemann, 2000). Controversy arose over whether public education should be offered to every child or just the poor. Universal education won out. Following Massachusetts’ education law of 1882, 34 states passed compulsory schooling laws by the end of the 19th century, most requiring attendance from Age 7 through Age 14 or higher. By 1918, every state required children to attend elementary school (National Center for Education Statistics,

2004). The blot on this history, though, was the prohibition against any kind of schooling for enslaved Blacks, followed by separate and poorly funded systems for Blacks in the south.

The structure of public schooling was shaped by scientific knowledge and political and economic realities of the mid 1800s, and these features have not changed much since, in spite of scientific discoveries and changes in the political economy. As secretary of education for Massachusetts in the mid-1800s, Horace Mann created a system that mimicked assembly lines in emerging factories: For the first time, children were placed in same-age grades and were taught the same curriculum in every school (called the “common school” movement), even if their skill levels varied wildly. Professional teachers were trained in colleges that were called “normal schools.” Booker T. Washington led the development of a separate education training system for Blacks at Tuskegee Normal and Industrial Institute.

The age requirement reflected contemporary scientific understanding that children younger than Age 7 (the “age of reason”) could not be taught and there was little that most children needed to learn past Age 14 (later, 16), when they were assumed to be ready for work. The emerging school schedule acquiesced to the demands of farmers who needed children at home in the summer, to the great majority of families that had a mother at home full time to greet children in the afternoon, and to organized religion that honored the weekend Sabbath. This schedule largely continues today, even though few children farm in the summer and a minority of mothers await children at home in the afternoon. Twenty-four states have lowered the age of compulsory school attendance to Age 6, and eight states to Age 5, in recognition of emerging scientific evidence that much brain development occurs in the younger years. Eleven states now require children to stay in school until Age 17, and 20 states require attendance to Age 18.

The goals, effectiveness, and conditions of public education have been sharply debated throughout history, especially since World War II. Public education received a double jolt in the 1950s when the Russian Sputnik passed over American skies, frightening policymakers into increasing the emphasis on reading, mathematics, and science to combat the Soviet threat, and when the Supreme Court ruled in 1954 in *Brown v. Board of Education* that racially separate public education was not equal education. The Coleman Report (Coleman et al., 1966) provided strong empirical evidence that family income and separation of school districts by race were more important

determinants of student achievement than school financial resources and that Black students had higher achievement when they attended integrated than segregated schools. The next decade saw massive forced busing to integrate public schools across the South.

Access to education for all children with disabilities received a major boost with the 1975 passage of the Education for All Handicapped Children Act, its extension in 1986 to young children, and passage of the Individuals with Disabilities Education Act (IDEA) of 1990.

In 1983, a report titled *A Nation at Risk*, issued by the U.S. National Commission on Excellence in Education (1983), further exposed the inadequacies of the public education system and cajoled educators into finding ways to focus education on training future scientists and engineers. The 1989 National Governors' Association conference paved the way for efforts to increase accountability in education, culminating in the bipartisan No Child Left Behind Act (NCLB) in 2002 that made high-stakes, end-of-grade testing the most important measure of education success. This movement asserted federal control over some important aspects of education in spite of its modest financial contribution to the overall public schools budget. States were required to report student progress annually and to punish schools that did not achieve adequate student progress on standardized tests. By 2012, however, half of the states were granted waivers from the requirements of NCLB because they had failed to meet standards of proficiency, and the reform has been deemed in need of major revision. Other reforms, such as independent charter schools, have been funded as alternatives to regular public

education. These schools rely on open markets to provide high-quality education and to force public schools to improve. Because charter schools take funding away from regular public schools, however, critics argue that they harm education for public school students.

In spite of accountability reforms, the high school graduation rate has stagnated since the 1960s at around 75% (see Figure 17.11). President Obama shifted the nation's goal away from improving test scores toward increasing the graduation rate to 90% by 2020. Obama also placed an emphasis on college and career readiness and preparing the work force for jobs in STEM (science, technology, engineering, and mathematics) areas.

What follows is a selective review of studies of major education policies.

Perhaps the most consequential government policy in education is the assignment of a student to a particular group of peers. Public schools assign students to different schools to achieve racial balance. They track students according to achievement levels, retain students in grade, and assign students to self-contained special education classrooms. Given the enormous influence of peers on student behavior, these practices have a strong effect on student outcomes.

Tracking students by academic ability is common policy in American schools, implemented mostly to improve outcomes for high-achieving students who can accelerate progress and take more advanced curricula (Oakes, 2005). Low-track classrooms suffer, however, from low-level content, low expectations, and behavior problems (Lucas, 1999). As a result, many schools in the 1990s "detracked"

**Figure 17.11** High school completion rates over time.

Source: Adapted from *Digest of Education Statistics*, 2010 (Table 110), by T. D. Snyder and S. A. Dillow, Washington, DC: National Center for Education Statistics, Institute of Education Sciences, U.S. Department of Education. Available at <http://nes.ed.gov/pubs2011/2011015.pdf>

students back to heterogeneous classrooms. However, Argys, Rees, and Brewer (1996) found that when moved out of high-ability tracks, achievement of high-ability students declined, and in Massachusetts detracking led to declines in the rates of students performing at “proficient” and “advanced” levels on state tests (Loveless, 1999). Permanent tracking is common in European schools during the middle school years of Grades 4 through 8 when students are set on vocational trajectories. Hanushek and Woessman (2006) found that countries implementing early tracking systems are characterized by relatively high educational inequality and low average performance. Nonetheless, tracking has resurged in the United States in an effort to improve performance at the high end. Whether the benefits of tracking for high-achieving students offset the harm to low-achieving students, and how to optimize outcomes for all groups, are still matters of debate and research.

Grade retention is one of the most important levers in shaping a child’s education trajectory. Although numerous studies address the impact of grade retention on student success, almost none of these studies involve random assignment. Jacob and Lefgren (2009) used a regression discontinuity design to compare students who fell just short of the test criterion for passing with students who fell just beyond the criterion. He found that grade retention adversely affected students’ later outcomes of test performance and high school graduation.

Musckin, Beck, and Glennie (2013) realized that grade retention policies could affect the assignment of older, more deviant (and low-performing) peers to classrooms with younger, more vulnerable students. Adolescence is the period of maximal peer influences, and so the effect of grade retention policy might be strongest in middle school. They found that students in schools that had policies of higher proportions of grade retention (and thus many peers who are “old-for-grade”) had the lowest test scores and highest rates of suspensions for drug use.

Next we consider summer school. Most students fall back in academic achievement levels during summer break, but low-income students lose about three months of grade equivalency whereas middle-income students lose only about one month, thus widening the achievement gap (Cooper, Nye, Charlton, Lindsay, & Greathouse, 1996). Summer school has become popular as a remedy, especially for marginally-performing low-income students. Kim and Guryan (2010) found significant gains in reading for low-income Latino/a American children in a voluntary summer program, thereby narrowing the achievement gap.

Next, it has been hypothesized that children’s learning is maximized with smaller student-teacher ratios. The largest test of this hypothesis is the Tennessee STAR experiment, in which about 11,000 children were randomly assigned to kindergarten and first-grade classrooms that varied between 16 and 24 students. Standardized tests revealed that children assigned to smaller classrooms exhibited performance that was about a quarter of a standard deviation higher than that of children assigned to larger classrooms (Finn & Achilles, 1990). Long-term follow-ups indicated that small classroom children had higher high school SAT scores and college matriculation (Krueger & Whitmore, 2000).

The success of the Tennessee experiment led California to adopt small kindergarten classrooms as statewide policy. Unfortunately, this implementation suffered from a failure to realize the assumptions inherent in the smaller Tennessee experiment, namely, that teacher quality would remain constant. In order to fill the increased number of classrooms, the state had to employ a large number of less-qualified teachers. The reduced average teacher quality led to lower student performance, which more than offset any gain that might have been due to smaller classroom size and led to a net reduction in student learning (Stecher, Bohrnstedt, Kirst, McRobbie, & Williams, 2001). Nonetheless, if other factors can be kept at high quality during implementation of smaller class size, gains in student achievement are likely.

The value of high teacher quality has been further popularized by a recent study of the long-term follow-up of the students in the Tennessee STAR experiment. Chetty et al. (2011) matched school records of kindergarteners with their adult income records obtained from the Internal Revenue Service (IRS) and found that having a kindergarten teacher with more than 10 years of experience (in contrast with less than 10 years) improves a student’s earnings at Age 27 by 7%, which translates to returns of hundreds of thousands of dollars across the life span.

State policy makers who are faced with budget shortfalls today have inferred from this experience that lower class size might not offset the adverse impact of a low-quality teacher. To balance budgets while retaining high-quality teachers, they have cut support for teacher aides. It is not yet clear how to increase the average quality of teachers. Increased salaries, better training, and different incentive plans are possible strategies to increase teacher quality.

Social-emotional learning (SEL) curricula have received increasing support. Teaching children to become socially competent to participate in a democracy was the original primary goal of public education, but this goal has

been attacked by religious groups as being more properly the domain of families and by critics as “soft.” Furthermore, several early character education curricula such as D.A.R.E. (Drug Abuse Resistance Education) were found to be ineffective (Ringwalt, Ennett, & Holt, 1991). Since then, however, newer curricula based on empirically-supported models of social competence have yielded positive impacts, and long-term analyses of early childhood interventions have indicated that their positive impact is mediated through enhancement of social competence (Heckman, Moon, Pinto, Savelyev, & Yavitz, 2010). Several states have enacted legislation to require social-emotional learning (SEL) curricula.

A meta-analysis of 130 school-based SEL programs evaluated through randomized trials (Durlak, Weissberg, Dymnicki, Taylor, & Schellinger, 2011) revealed net positive impact on students’ social-cognitive skills and antisocial behavior and indirect impact in the form of an 11-percentile-point gain in academic achievement. Curricula that target skills of problem-solving and self-regulation, and those that incorporate interactive role-playing and extensions to students’ real-life peer conflicts, are most effective.

### *Early Child Care and Education*

Since the War on Poverty, federal programs to support the early child care and education of children from low-income families, specifically Head Start and more recently Early Head Start, have been the primary early childhood education policy of the federal government. Over the past two decades, states have increasingly supplemented this effort with funds for programs to reach a larger proportion of the population of young children, although this funding has declined since the Great Recession. In 2013, President Obama proposed significant increases in this investment through federal-state collaboration for universal pre-kindergarten programs. Because these issues are addressed in detail elsewhere (Burchinal, Magnuson, Powell, & Soliday Hong, Chapter 6, this *Handbook*, this volume), our treatment of this topic is brief.

Contemporary early child care and education policy addresses four issues. First, the majority of the achievement gap in education performance is present before children enter kindergarten (National Center for Education Statistics, 2004). Public education in kindergarten and beyond is remedial, at best, in closing this gap. More promising efforts at closing the gap begin earlier in life. Second, the science of child development indicates rapid synaptic growth and neural development in the first 3 years of life

(Shonkoff & Phillips, 2000). Infants are born with brains that are only 25% of full adult size, but by Age 3, their brains have grown to 80% of eventual size. Enhancing growth and learning during this period might bring an opportunity for maximal return on investment if programs could be effective (Heckman et al., 2010). By Age 5, 85% of brain development is complete, although only 14% of public education dollars are spent on children before Age 5. Third, rigorous evaluations of several preschool programs reveal positive impact, suggesting that returns on investment might well be realized (Barnett, 2011). Finally, economic realities dictate that most households with young children must deploy every available adult to work outside the home in order to make ends meet; thus, out-of-home child care is a necessity and many parents are faced with a decision of how, rather than whether, to obtain the best-available care and education.

Head Start began as part of President Johnson’s Great Society campaign. The Office of Economic Opportunity initiated Project Head Start as an 8-week summer program in 1965 that was touted as a sound economic investment to reduce poverty. It was quickly realized that 8 weeks was not nearly enough to erase several years of economic and cognitive disadvantage for low-income children. A committee chaired by Robert Cooke, a pediatrician, created year-round Head Start as a comprehensive child development program. Head Start later began funding the television show *Sesame Street*. In 1970, Edward Zigler, a psychologist, was named by President Nixon to become the first Director of the Office of Child Development and Chief of the U.S. Children’s Bureau, which became responsible for administering the nation’s Head Start program. Head Start programs are administered locally by school systems and nonprofit organizations. Its administration outside the Department of Education signals a fundamental policy controversy between Head Start’s mission as early education or early child development. The 2012 federal budget for Head Start was \$8.0 billion. In addition, local grantees must provide a 20% cash or in-kind match.

Some nonexperimental studies of the effectiveness of the Head Start program show remarkable gains by participants in cognitive and social development. Garces, Thomas, and Currie (2002) examined 4,000 participants in the Panel Study of Income Dynamics followed from childhood into adulthood. Among White adults, those who had attended Head Start were significantly more likely to complete high school, attend college, and obtain higher earnings in their early twenties than their siblings who did not attend Head Start. Black adults who had attended

Head Start were significantly more likely to graduate from high school and less likely to be arrested than were their nonparticipant siblings. Deming (2009) used National Longitudinal Survey of Youth data to find that those individuals who had attended Head Start showed stronger academic performance than their nonparticipant siblings, and were also less likely to be diagnosed as learning disabled, less likely to commit crime, more likely to graduate high school and attend college, and less likely to suffer from poor health as an adult.

One problem with these studies is that they did not involve random assignment of children. The reputation of Head Start took a blow from a report (U.S. Department of Health and Human Services, 2010) of a large trial in which nearly 5,000 3- and 4-year-old children were randomly assigned to either Head Start or a control group that did not have initial access to Head Start, but could enroll in other early childhood programs or non-Head Start services selected by their parents. It turned out that 60% of the control group children participated in other child care or early education programs during the first year of the study, and about 15% enrolled in Head Start on their own in the second year. Thus, the counterfactual group to Head Start has become, at least in part, some other form of early care and education rather than no care at all. Nonetheless, the findings indicated that access to Head Start had an initial positive but modest impact on children's school readiness (in language and literacy, vocabulary, letter-word identification, pre-academic skills, letter naming, phonological processing, parent-reported emergent literacy, perceptual motor skills, hyperactive behavior, withdrawn behavior, dental care, health status, parent spanking, parent reading to child, and family cultural enrichment activities), but the cognitive gains fade out during kindergarten, disappear by the end of first grade, and do not reemerge in third grade. Preventing fade out remains a major policy challenge.

In fiscal year 1994, the Early Head Start (EHS) program was established to serve low-income children from birth to 3 years of age. Although its mission is similar, its reach is not nearly as great as that of Head Start: It served 147,000 children in 2011, with roughly a third in home-based care, a third in center-based care, and a third in combined care.

A randomized experiment with about 3,000 children at 17 EHS sites evaluated impact on children over time (Love, 2010). Children were assigned to EHS or were prohibited from EHS but could seek other services in the community and many did so. Children randomly assigned to EHS demonstrated more favorable outcomes in cognitive, language, and social-emotional development

(reduced aggression and attention problems) at Ages 2 and 3. At Age 5, impacts on reduced aggression and attention problems persisted, but impacts on cognition and language dissipated. Impacts did persist for children who moved from EHS to Head Start at Ages 3 to 5.

Follow-up at fifth grade revealed that overall positive impacts did not persist, but were evident for some subgroups, notably Black children (Vogel, Xue, Moidubbin, Kisker, & Carlson, 2010). Positive impact on reading and math was found for the subgroup that experienced EHS, Head Start, and then an elementary school that enrolled a relatively low proportion of children receiving free and reduced-price lunch. This finding, albeit not from random assignment to these follow-up experiences but rather self-selection, suggests that in order for the benefits of EHS to be sustained, a child must continue to experience an enriching educational environment.

### *Pre-Kindergarten*

In his State of the Union address in early 2013, President Obama took the unprecedented step of proposing expansion of high-quality preschool experiences to all children. He cited scientific studies of preschool programs in arguing that the sooner a child begins learning, the stronger the impact over time, and he pointed out that low-income families spend a large proportion of their income on care for their children under Age 5. The Center for American Progress estimates that the plan would cost about \$98 billion over 10 years.

Although the Obama proposal is not likely to be enacted as proposed, it has sparked debate about government support for universal education at younger ages, with at least five considerations. First, emerging findings in developmental neuroscience highlight the rapid growth of synapses in the first several years of life, suggesting the critical nature of beginning intervention early. Less clear is how early, that is, whether formal education should begin at Age 4, or earlier. Second, a growing body of research highlights components of programs that are most effective for children's cognitive and social development, and these components should drive the kind of program offered. Third, the plan must account for the fact that the majority of mothers in both single-parent and two-parent families must work outside the home if the family is to avoid poverty, and any universal preschool plan will need to support the family work schedules if it is to be sustained. Although President Obama's goal is to support children's educational development, preschool is a core part of most families' child care plans. Fourth, the "home" for universal

pre-K programs is being battled over by departments of education and health and human services, at least at the state and local levels. This decision is not only a political one; it also will alter the nature of early care as primarily educational versus child care. The former home would likely emphasize certification of teachers and curricula that look like kindergarten, whereas the latter home would likely emphasize more holistic, family-friendly care. No studies have examined which home agency leads to better outcomes.

### ***Higher Education***

The higher education system in the United States has been heralded as the best in the world (Universitas 21, 2012). At the turn of the 20th century, fewer than 1,000 colleges enrolling 160,000 students existed in the United States, but rapid growth ensued in large part due to philanthropists who endowed private institutions and federal funding from the Morrill Land-Grant Colleges Acts of 1862 and 1890, which created aptly named “land grant colleges” that specialized in agriculture and engineering. The 1890 act created all-Black land grant colleges dedicated to teacher training. States and religious bodies also funded teacher training colleges, called “normal schools,” which evolved into state colleges with a broad curriculum after 1945.

Higher education received another major boost in 1944 when Congress passed a program of aid to veterans who had served in wartime. The GI Bill supported millions of students by paying tuition and living expenses. It also fostered the belief that college education is necessary for life success, thus further increasing the number who attended college beyond veterans. This program biased enrollments toward men, given that few women had served in the military. However, by 2000, women began surpassing men in rates of college attendance and graduation.

As part of President Johnson’s Great Society programs, Congress passed the Higher Education Act of 1965, which created federal scholarships and low-interest loans for college students, and subsidized colleges directly. Separate education bills enacted that same year provided similar assistance to dental and medical schools.

Government policy in higher education today consists primarily of federal loans for college tuition, Pell grants which provide up to \$5,550 for tuition, and state support for 4-year and community colleges. The continued heavy federal and state subsidy of colleges has been associated with continued increases in college matriculation. Enrollment in college increased by 11% between 1990 and 2000 and another 37% between 2000 and 2010, to 21.0 million

students. The proportion of the population graduating from a 4-year college has not risen, however, and remains about 40% of the adult population, placing it outside of the top ranks worldwide. President Obama has stated a goal of regaining the top rank in the world by the year 2020. As the cost of a 4-year college education increases more rapidly than the cost of living, many citizens have begun to question whether a college education is worth the expense. Furthermore, the laser focus of state legislatures on balancing their budgets has led to questions about whether government support should emphasize the liberal arts versus job skills training and how the value of a college education should be measured.

### ***Housing***

Like so many other areas of federal social policy, the federal government first entered the housing field during the Great Depression. Legislation in 1934 created the Federal Housing Administration and, among other provisions, provided funds for housing construction loans. Then in 1937, legislation brought the federal government directly into low-rent housing by requiring states to establish local public housing authorities (PHAs) to administer federal funds intended for low-rent housing. The most pertinent legislation for understanding current housing policy was the Housing Act of 1974 that created Section 8, a program that provided rental subsidies for the poor to obtain housing in the private sector. The federal government now plays a modest role in providing subsidies for construction of housing for the poor, more or less following the philosophy that if low-income people have money to rent, the market will provide enough units at the right price. However, units built under previous federal housing programs and operated by PHAs or private companies continue to provide some affordable housing.

Although Section 8 dominates federal housing policy today, as is typical of other types of federal means-tested policy, housing programs have proliferated over the years and now include 17 separate programs that attempt to develop local communities, help house individual groups such as Native Americans and the elderly, provide assistance to the homeless, help meet the housing needs of people with AIDS, and subsidize water and waste disposal in poor communities. Despite the existence of so many housing programs, of the \$46.3 billion spent by the federal government on housing in 2011, 55% is spent on Section 8 programs and public housing. Around 4.9 million low-income households received federal housing assistance in 2011 (Center on Budget and Policy Priorities, 2012).

A remarkable feature of federal housing programs is that they show impressive evidence of how government can learn from its mistakes and improve the effectiveness and efficiency of its programs. A good example of this achievement of federal policy is furnished by the movement away from government investments in construction of low-income housing to boost supply and investing instead in subsidizing low-income individuals and allowing them to find their own housing. Nearly half of federal spending on housing programs now takes the form of vouchers or voucher-like mechanisms to subsidize the cost of rental housing in the private market, provided that the housing meets moderate quality standards. It is widely believed that use of vouchers is the most efficient use of federal housing dollars (Olsen, 2008). A second example of federal learning is provided by the destruction of high-rise public housing in favor of small and dispersed housing units, often supported by individual vouchers. Experiences with the high crime and danger that seemed endemic to high-rise housing convinced federal officials that placing hundreds or thousands of the poor in concentrated spaces was bad policy, especially given the large number of adolescent males who live apart from their fathers with little supervision. As a result, many high rise units have literally been subjected to treatment by dynamite. Changes in federal housing policy, especially Section 8 rental housing, now result in the poor being spread out rather than concentrated in contagion-inducing mega-unit housing. Even so, housing units receiving federal support, both through public housing and vouchers, are still too concentrated in high-poverty neighborhoods in inner cities (Turner & Kingsley, 2008).

### ***Social Services***

Social services include a broad array of programs that range from child care to homeless grants, to legal services, to emergency food and shelters, to care for children in foster care and adoption. Of the nine programs classified as social services by the Congressional Research Service (CRS), three are especially important for children and two programs not classified as social service by CRS deserve mention. Two of these programs subsidize child care for children in low-income families. The Child Care and Development Block Grant, created by the welfare reform law of 1996, was intended to give states more money and more flexibility in how the money is used to purchase child care for low-income parents. In order to obtain their funds, states must enact minimum child care standards, give parents a choice of using the type of child care they prefer,

and allow only low-income parents to receive the subsidies. Congress has expanded the Block Grant on several occasions by adding more money. The Block Grant now provides states with about \$5.2 billion per year to pay for child care although 4% of the annual funds must be used by states to improve the quality of care in the state. In addition to the block grant, the second source of federal funding for child care is money from the TANF program that federal rules allow to be spent on programs that help low-income parents work, including payments for childcare. It is estimated that states used about \$5.5 billion to purchase child care with TANF funds in 2011 (Schott, Pavetti, & Finch, 2012), bringing total federal funds from these two sources for child care to nearly \$11 billion. Despite these funds, states have only enough funding to help perhaps 20% of income-eligible parents with their childcare bill. Research shows that poor and low-income parents who do not receive government subsidies to purchase care while they work use up to 20% of their income for childcare, thereby creating a major inequity in federal funding of childcare (Forry, 2009).

A third service program that provides help to children is the Social Services Block Grant, which provides states with \$1.7 billion to use at their discretion on a range of social services that include child care, child protective services, case management, housing, foster care, and many others. One or more states use these funds on nearly all the permissible services, but the most frequent use of the Social Services Block Grant funds is to pay for child care.

Another social service that plays a vital role in the nation's social policy for children is a complex series of programs that subsidize state systems that deal with child abuse and neglect. As this chapter has shown, each year there are 6 million reports of possible child abuse or neglect made to child welfare agencies. Around 3.6 million of these reports are judged to be credible enough to investigate and about 1.1 million of the children and families reported wind up receiving some child welfare services (Stoltzfus, 2012). The services range from a very light touch such as a meeting with a social worker to government removing children from their home and placing them in foster care. On any given day, there are about 425,000 children in foster care, many of whom have been there for a year or more and there is a great deal of turnover in children entering and leaving foster care (Stoltzfus, 2012). Many of these cases are tragic and many of the children involved are in situations that are threatening to their mental and often physical health. More than 1,500 children died from maltreatment in 2011, usually at the hands

of their parents (U.S. Department of Health and Human Services, 2012).

### *Employment and Training*

Over the years, the federal government has greatly reduced both the number of employment and training programs for the poor and spending on the programs. In the 3 years from 1978 to 1980, the average federal spending on training and employment programs was \$56.8 billion per year in 2011 dollars (Domestic Social Policy Division, 2006). By contrast, spending in 2011 was a mere \$6.5 billion. Employment and training is one of the few areas of the federal budget in which federal spending has declined substantially. Despite the decline in spending, the major purpose of federal employment and training programs has been more or less constant over the years; namely, to help the disadvantaged improve their skills, increase their work experience, and find employment and thereby promote earnings and self-sufficiency (CRS, 2012; Spar, 2006).

The Congressional Research Service counts eight major employment and training programs today, but only three of these spend even a billion dollars a year. These three programs are the TANF program, the Job Corps, and the Youth Service Activities program in the Workforce Investment Act (WIA). The TANF program is actually a block grant that provides states with \$16.5 billion per year to spend to help the poor achieve self-sufficiency. States can spend block grant funds for any purpose reasonably construed to promote self-sufficiency including cash or in-kind welfare, employment and training, work, nonmarital birth reduction, and marriage-promotion or education. In 2010, states reported spending \$3.9 billion on work-related activities (Schott et al., 2012) in their attempt to help adults, primarily mothers, leave or stay off the TANF cash program by working. States use most of the TANF funds they spend on employment and training to help recipients find jobs rather than on programs that provide them with training.

At \$1.7 billion, the second most well-funded program is the Job Corps, an original War on Poverty program. Low-income youth between the ages of 16 and 24 who are school dropouts, runaways, foster children, or deficient in reading, math, or computer skills are eligible for the program. The Job Corps is an expensive program because it places youth in residential facilities to provide basic education, vocational skills training, counseling, work experience, and health services. Young people who enroll in the Job Corps can stay in the program for up

to two years, but the average stay is 7 months. The Job Corps was subjected to a randomized controlled trial that followed participants for 4 years after assignment to the program. The original evaluation was encouraging because it showed about a 12% increase in earnings for the treated group. A benefit-cost analysis, based on the assumption that the earnings increases would continue, found that the cost to taxpayers was only \$3,000 per participant but the gain to participants was \$20,000 over their lifetime (Mathematica, 2001). Unfortunately, a follow-up evaluation based on earnings data 3 years later found that earnings gains had deeply eroded and the program costs exceeded program benefits (Schochet, McConnell, & Burghardt, 2003).

The third biggest program, with a budget of about \$1 billion, is the youth activities program of the Workforce Investment Act. A national evaluation of a predecessor program (the Job Training Partnership Act) found modest effects in helping disadvantaged youth obtain a high school diploma or GED, but no effect on earnings (U.S. General Accountability Office, 1996).

There is widespread recognition of the fact that, due in large part to the growing role of technology and international competition in the American economy, an increasing share of jobs require education beyond high school (Goldin & Katz, 2008). Many in the scholarly world and even some policymakers are calling for more government spending on apprenticeship programs and programs that prepare young people for jobs available in local economies because they might be able to boost the employment and earnings of disadvantaged youth (Lerman, 2013). Recent experimental programs that provided short-term training to disadvantaged youth for available jobs that require skill and training have shown positive and substantial impacts on employment and earnings (Maguire, Freely, Clymer, Conway, & Schwartz, 2010). Perhaps taking heart from these and similar findings, the Obama administration has launched two evidence-based programs that attempt to work with community colleges and the nation's workforce system to find more effective ways to use existing programs to boost the skills and job preparation of disadvantaged youth. These initiatives, which are being thoroughly evaluated, should begin to produce findings by 2014 or 2015. The era of making minimal government investments in the tier of education and training programs between high school and 4-year colleges is under challenge. Given the pressures on the federal budget, whether these programs can win additional funding seems doubtful.

## THE SCHOLARLY STUDY OF GOVERNMENT POLICIES FOR CHILDREN

Decision making about the programs described above is influenced by many factors that include values and politics but also, to some extent, developmental science and related scientific inquiry. In the 1960s, scientific research played a role in buttressing the case that social programs could provide a way for poor children to become successful. Federal support for social programs brought with it funding for rigorous evaluation of impact and, thus, the creation of nonprofit research agencies such as Westat in 1963, Mathematica in 1968, and MDRC in 1974.

The major child program in the War on Poverty was Head Start, which was shaped by Sargent Shriver's visit to the Early Training Project (Gray & Klaus, 1970) at Peabody College in Nashville, Tennessee. This intervention included both home visits and classroom curricula and was evaluated through a randomized controlled trial to demonstrate its positive impact. Related early childhood interventions for children living in poverty that were evaluated by randomized trials included the Abecedarian Project at the University of North Carolina (F. A. Campbell, Ramey, Pungello, Sparling, & Miller-Johnson, 2002) and Michigan's Perry Preschool Project (Schweinhart, Barnes, & Weikart, 1993). Although Head Start was based in developmental science, it was not subject to a randomized trial in its first 30 years, and uneven implementation across sites probably led to uneven impact.

A second factor stimulating the growth of the scholarly study of government policies for children was the initiation of population-based cross-sectional and longitudinal surveys. National survey data allow policy makers and scholars to know basic demographic facts about the U.S. population, population trends, and specialized facts about social status such as drug use, school dropout, teen pregnancy, use of child care, and a host of others topics. The Panel Study of Income Dynamics (PSID) was initially funded by the Office of Economic Opportunity in 1968 (and now by the National Science Foundation) to survey a nationally representative sample of over 18,000 individuals living in 5,000 families in the United States. Repeated PSID surveys have collected data on employment, income, wealth, expenditures, health, marriage, childbearing, child development, and education, and more than 3,000 journal articles, dissertations, and book chapters have been published using PSID data. The National Longitudinal Survey of Youth has followed a sample of over 12,000 individuals

born in the 1950s and 1960s, and their offspring, initially to understand labor market activities but now to understand other aspects of child development. Monitoring the Future provides both annual cross-sectional surveys of adolescent health-risk behavior and longitudinal investigation of cohorts of adolescents followed into adulthood. Many other longitudinal samples have been funded by other federal agencies, including the three samples in the Early Childhood Longitudinal Study (ECLS), the American Community Survey, the Current Population Survey, the Survey of Income and Program Participation, the National Health Interview Survey, and the National Longitudinal Survey of Adolescent Health (Add Health). These surveys and the growth of administrative data sources have enabled annual reports about the well-being of children, such as the Annie E. Casey Foundation's Kids Count state-by-state tracking of child well-being and the Foundation for Child Development's Child Well-Being Index.

A third factor in growing child and family policy research was the creation of policy research centers and large contracts with federal and foundation funding sources as well as university support. These centers differ from basic science centers in their mission of evaluating policy and their accountability to policy agencies in the government. The Assistant Secretary for Planning and Evaluation of the U.S. Department of Health and Human Services has funded grants to support research and evaluation of important social policy issues associated with the nature, causes, correlates, and effects of income dynamics, poverty, individual and family functioning, and child well-being. Other centers have been funded by the Department of Housing and Urban Development, the National Institutes of Health, and the U.S. Department of Education.

These efforts pale in comparison to research and development (R&D) support in other sectors such as health and energy. Although the United States historically spends about 2% to 3% of its gross domestic product for research and development, this figure varies greatly across sectors. Within the health, transportation, and energy sectors, expenditures for research exceed 2% of all expenditures, whereas less than 0.3% of educational expenditures and less than 0.3% of expenditures for children go to research (Grissmer, 2003). The reasons for this disparity include the (false) popular belief that policy for children is adequately based in common sense, the (falsely) perceived low quality (and less relevance) of research in this domain, the lack of a private market for the education and child policy sector, and the dispersed network of

service providers and funding for education and children (Grissmer, 2003).

### Data Sources

In contrast to a focus on the individual child, the goal of policy scholarship is to measure, understand, and manipulate the population score on important outcomes in child well-being.

#### *Use of Administrative Data in Research*

One hope for improvement in the child policy research infrastructure is the growth of administrative data bases on children, such as electronic birth records, Medicaid health insurance and other government service utilization documents, education records, criminal records, military records, and income tax files. Although these data bases were not funded primarily for research purposes, ethical and legal challenges are being surmounted so that they can be shared with researchers. Concatenating records into longitudinal databases and linking records across sources afford opportunities for longitudinal studies of the impact of public policies on child development at a fraction of the cost of collecting new data.

One domain in which such data bases are proving important is education. In North Carolina, for example, scholars have collaborated with education officials to extract population data bases on children's progression through schools to build individual-level longitudinal files to understand the impact of educational programs and policies on students' outcomes. Although these data are confidential, FERPA laws (Family Educational Rights and Privacy Act, 20 U.S.C. § 1232g; 34 CFR Part 99) allow the release of identified data to "organizations conducting certain studies for the school" (34 CFR § 99.31). Important findings have emerged from the North Carolina studies, such as the discovery that starting middle school in sixth (rather than seventh) grade is associated with students' later substance use by exposing children at an early age to a high proportion of older, deviant peers (Cook, MacCoun, Muschkin, & Vigdor, 2008), and the finding that school accountability policies that focus on school achievement status rather than growth reduce the reading achievement of higher performing students (Ladd & Lauen, 2010). Similar collaborations between scholars and K–12 education agencies have been forged in Florida, Chicago, and New York.

Even greater leverage is achieved when these educational data files are linked with individual-level data files

from other sources, such as birth records, arrest records, and adult outcome records; when they are linked to community records, such as exposure to environmental shocks including natural disasters or community job loss; and when they are used to evaluate impact of interventions and policies. Miranda, Kim, Reiter, Overstreet Galeano, and Maxson (2009) found that indicators of lead exposure in the paint in apartment buildings predict children's standardized test scores and that this factor accounts for part of the achievement gap between high and low income families. Ananat, Gassman-Pines, and Gibson-Davis (2011) found that the rate of job losses in a community is adversely related to children's subsequent reading and math scores, not only for children whose families lose jobs but also for the entire community. This kind of indirect relation to a child's development would not likely have been discovered by studies of small numbers of families.

Research groups are now building the infrastructure for longitudinal research on the impact of policies on children's development in numerous states and communities, including the Center for Analysis of Longitudinal Data in Education Research (CALDER), the Chicago Consortium on School Research, and an NSF-funded network of scholars and state education policy leaders (Figlio & Dodge, 2012).

#### *Longitudinal Studies*

Complementing the breadth of population-wide administrative data sets is a group of government-supported population-representative longitudinal studies of the same children over time or repeated cross-sectional surveys that provide depth of information about the impact of early policy and program experiences on child development. These studies include the Panel Study of Income Dynamics (PSID), the Current Population Survey, the American Community Survey, the Survey of Income and Program Participation, the National Health Interview Survey, the National Longitudinal Survey of Adolescent Health (Add Health), the National Longitudinal Survey of Youth (NLSY), the Early Childhood Longitudinal Surveys (ECLS–Birth, and ECLS–Kindergarten), and the National Institute of Child Health and Human Development's (NICHD's) Study of Early Child Care and Youth Development and Monitoring the Future. The representativeness of the samples in these studies affords generalization to populations in a way that small laboratory studies cannot.

#### *Laboratory Studies in Policy*

Policy research on children is also conducted through empirical studies in the investigator's laboratory. Because

policy development depends on decisions by key stakeholders, the study of how these decisions are made is important. One strand of research has been devoted to the impact of how concepts in child development and programs in child policy are framed to decision makers (Shonkoff & Bales, 2011). The Frameworks Institute has collaborated with the Center for the Developing Child to produce studies on topics of how concepts such as genetic effects and executive function are most effectively communicated, and which metaphors for child growth and development have the strongest impact on listener understanding and support.

Our understanding of public support for child policies is enhanced through contingent-valuation studies, which assess the public's "willingness to pay" (WTP) for a program. WTP is the maximum amount a person is willing to pay in taxes or other means to receive a good (such as improving the community's high school graduation rate) or avoid some outcome (such as crime). For example, Ludwig and Cook (2001) found that the public's WTP to reduce a gun assault is about \$1.2 million per injury. This approach informs policy making and can be used to test the receptivity the public has for innovative interventions and policies for children.

### Methods of Data Analysis

The study of public policy has championed innovative methods for the analysis of complex data that cross ecological levels. Randomized controlled trials of intervention efficacy and effectiveness remain the gold standard, but of particular importance in policy research are methods to test causality and utility for public interventions and policies that are implemented with large populations in the absence of a randomized experiment. Random assignment is not always plausible in policy implementation, but rigorous evaluation of impact is needed nonetheless. The application of typical regression models falls short because of the likelihood that omitted variables influence both the independent variable (the policy) and the dependent variable (the child's outcome), rendering a correlation as spurious. Several partial solutions have been applied in policy studies (Duncan & Gibson-Davis, 2006).

#### *Regression Discontinuity*

A regression discontinuity design is often used to test the impact of a policy when that policy is applied to a portion of a population based on a pre-treatment threshold or cut-off score, such as a student's past academic performance or family income. The impact of an intervention is tested

by examining cases that fall closely on either side of the cutoff. It was first applied by Thistlewaite and Campbell (1960) to test the impact of scholarship programs on student outcomes. A more recent example by Jacob and Lefgren (2009) compared students who fell on either side of the threshold for grade retention to determine whether the policy of grade retention has adverse impact on the probability that a student will graduate from high school.

#### *Propensity Score Matching*

This method is used to test the causal effects of a policy that is applied in nonrandomized ways to members of a population by creating a comparison group that is similar to the treated group utilizing preintervention characteristics. A regression analysis of preintervention variables is performed to predict which members of a sample participate in a policy or program. Those regression weights are then used to select a separate group that is similar to the treated group except for the treatment itself. Hill, Waldfogel, and Brooks-Gunn (2003) estimated the impact of different types of child care on children's outcomes in the Infant Health and Development Program using this method. Because families self-selected into care, the authors modeled families' child care decisions and then used those regression weights to identify comparison groups of families that were similar in all measured ways except for the child care decision. They found that center-based care led to the best child outcomes that last several years into elementary school.

#### *Fixed Effects Analysis*

Another way to control for confounding factors in testing causal impact is through fixed effects analysis. One example is the sibling design, alternatively called family fixed effects. This approach takes advantage of the variation within a family in the experience of a program such as Head Start. Each sibling's scores on all variables are subtracted from the average scores of all family members before testing the impact of the policy, so that the effect of any unmeasured factor that is common to all members of a family is removed. Currie and Thomas (1995) used family fixed effects with data from the Panel Study of Income Dynamics and the National Longitudinal Study of Youth to determine that Head Start has positive impact on children's developmental outcomes. This method is superior to one of comparing Head Start participants from one family to matched nonparticipants from another family because of the always-present possibility that omitted variables confound these groups. If the important omitted variables

apply to all members of a family, then the family fixed effects design solves this confound. However, this design is still vulnerable to the possibility that within-family differences in program participation are not random and are related to a child's outcomes. Fixed effects analysis can control for differences due to age cohorts, communities, schools, classrooms, and other units that might influence both program receipt and outcomes.

### ***Instrumental Variables (IV) Analysis***

This approach tests the impact of a program by identifying another variable (called the instrument) that is correlated with program participation and is also correlated with a child's outcome but entirely indirectly through program participation. At the first stage of analysis, the effect of the instrument on program participation is modeled. At the second stage, the predicted value of program participation is regressed on the child's outcome. An example comes from a study by Hotz, McElroy, and Sanders (2005) of the impact of teenage child-bearing on life outcomes. The problem with correlational studies of this question is that factors that might lead a teenage girl to become pregnant might also adversely affect later life outcomes such as total years of education or employment, calling into question whether the experience of giving birth to a child during teenage years has any causal impact by itself. Hotz and his colleagues employed miscarriage as a "natural experiment" and instrument that predicted teen child-bearing but could not (presumably) affect life outcomes except through its impact on child-bearing. They found that many of the life outcomes that had supposedly been attributed to having a child as a teenager disappeared in this analysis.

### ***Cost-Benefit (CBA) and Cost-Effectiveness (CEA) Analyses***

Government programs should be evaluated not only by their impact on child outcomes but also by the soundness of their investment and in comparison to other possible investments. In these analyses, the cost of a program is measured for each participant, and the totality of impacts of the program on outcomes is measured, in monetary terms for CBA and qualitative terms for CEA, so that a ratio of costs to outcomes can be computed. Outcomes are considered not only for the dependent variable of primary interest (such as educational success) but also for other outcomes that might be affected both for the participant and for others (such as siblings or other community members). Because the costs of a program are borne immediately but

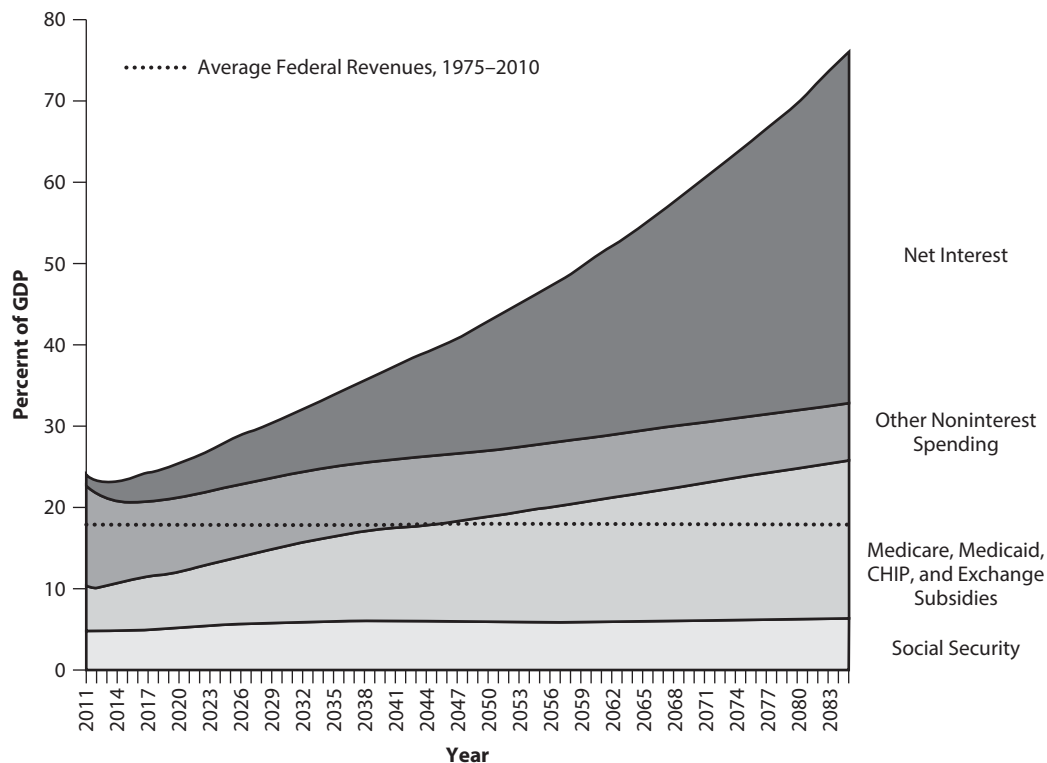

the benefits typically accrue later in time, time discounting is typically applied by a common formula.

The Washington State Institute for Public Policy, led by Steve Aos, is often given credit for popularizing cost-benefit calculations in child policy decision-making. For example, Aos and Pennucci (2013) analyzed 53 evaluations of the impact of classroom size on education outcomes and concluded that reduction in classroom size has a positive cost-benefit ratio for early grade levels but not later grade levels.

## **THE CURRENT DILEMMA OF ECONOMIC AND BUDGET CONSTRAINTS**

The federal budget is seriously out of balance. There is widespread agreement among economists and even most politicians that in the long run the deficit is unsustainable (National Research Council, 2010). Figure 17.12, based on estimates by the nonpartisan Congressional Budget Office (CBO), shows why. Consider three points made clear by the figure. First, as a percentage of the gross domestic product (GDP), under tax and spending policies in place in 2011, federal spending would grow from around 24% of GDP to about 50% of GDP in 2060 and 75% of GDP by 2085. In other words, government spending would equal about half the total value of goods and services produced by the U.S. economy by 2060 and would continue growing rapidly thereafter. Few analysts or politicians doubt that spending could never reach this level because government policies would change long before spending got to 50% of GDP. Second, most of the increase in spending as a percent of GDP has two related causes—the growth of health care spending and the growth of interest spending. The growth of interest spending, in turn, is caused primarily by the fact that the nation's rapidly rising expenditures for health care cause the federal government to borrow unprecedented amounts of money. The borrowing, of course, comes at a price; namely, interest payments. And even under CBO's modest assumptions about future interest rates, interest payments explode, rising rapidly after about 2015 and then even more rapidly later as both health care costs increase and interest payments expand, necessitating more borrowing to pay the interest, creating still higher interest payments, and so on until spending and revenues come closer to balance or a crisis occurs.

Although long-term budget predictions are no more than approximations, the story of expanding deficits and interest payments that are unsustainable under current policies is a

**Figure 17.12** The unsustainable fiscal path, 2011 to 2085.

*Notes.* This series includes 10 spending sources: Medicaid, SNAP, EITC, CTC where credit exceeds tax liability, SSI, AFDC/TANF, Housing Assistance, Medicare Part D Low Income Subsidy, ESEA Title I Grants to Local Educational Agencies, and Federal Pell Grants. Data on the last two are available starting only in 1980 and include approximately \$27 billion in ARRA spending in 2009.

*Sources:* Most spending sources from OMB, Fiscal Year 2013 Budget, Tables 8.5, 11.3, 12.3. Title I and ESEA spending from Department of Education Budget History Table. Medicare data from CMS, 2011 Medicare Trustees Report, Table IV.B11; the number for 2011 is estimated. All figures adjusted to constant dollars using OMB total deflator from historical table 10.1. Data on number of people in poverty through 2010 from U.S. Census Bureau, 2011, number estimated by Richard Bavier.

very high probability. At some point in the deficit and debt spiral, federal spending will have to decline and federal revenues will have to rise. How the nation will be extracted from the deficit spiral remains an open question. There are at least three reasons Americans should be worried about the deficit. The first is that a financial crisis will be precipitated if the federal government reaches the point that it can no longer repay its creditors. As shown in detail by a review of 800 years of economic crises in 66 nations by Reinhart and Rogoff (2009), two virtually certain impacts of a federal default would be a severe and abrupt reduction in government spending, during which many social programs (perhaps especially children's programs) would experience sharp reductions, and a decline in the nation's economic growth that would probably last a decade. No one doubts that a financial crisis precipitated by federal debt is to be fervently avoided. As Winston Churchill said: "Americans can always be counted on to do the right thing—after they

have exhausted all other possibilities." Federal policymakers are still in the process of exhausting alternative possibilities, although they have made some progress in reducing the debt.

A second problem is that as long as the federal government keeps borrowing, interest costs will rise at some point in the future. These first two consequences should be of great concern to the nation, but a third consequence of the deficit is perhaps the most alarming. Consider the process by which Social Security and Medicare are funded. Both are entitlements and are permanently authorized by Congress. Unlike most other federal spending, the budgets for Social Security and Medicare are not even reviewed on a regular basis and Congress does not vote to authorize spending for the benefits on an annual, semiannual, 5-year, or any other regular basis. According to CBO, spending on Medicare will grow from \$551 billion to \$1,079 billion, almost doubling over the next 10 years and this growth will

occur without any action by Congress. In fact, Congress would have to take an action to stop or alter the growth.

Whatever else might be said about the nation's deficit, it seems likely that future spending on programs for children will not enjoy the kind of growth shown in Figure 17.1. In fact, the agreements reached so far on reducing the deficit have already resulted in cuts for Head Start, childcare, housing, and a number of other programs that support children. There are certain to be more cuts in the future unless more progress is made to reduce the long-term deficit.

## TOWARD EVIDENCE-BASED POLICY MAKING

One component of a comprehensive solution to the dual problems of the budget crisis and the dire futures for children in low-income families would be a shift toward evidence-based policy-making that incorporates the best methods and most robust findings of developmental science and policy scholarship. President Obama has vowed to steer program priorities and budget decisions to protect or even provide increased funding for programs that work and decrease funding for or even terminate programs that do not work. If implemented more fully, we believe this approach could improve outcomes for low-income children while increasing the benefit to cost ratios for government use of taxpayer dollars.

The recent case story of home-visiting legislation provides a good example of a shift toward evidence-based policy making for children and families (Haskins, Paxson, & Brooks-Gunn, 2009). Home visiting as a practice to support families with a newborn infant has been around for over a century and is implemented universally in several countries (e.g., New Zealand, Switzerland, Great Britain) and selectively for low-income families in all U.S. states. Home visiting aims to connect parents with a home visitor and other community resources in order to improve parenting and prevent child maltreatment so that child development and well-being improve. Home-visiting programs come in many forms, differing in credentials of the home visitors, curricula implemented, timing across the infant's life span, and target population. Its impact has been touted by advocates but doubted by critics.

Debate about federal funding for home visiting in 2009, like that for many children's programs, was filled with personal anecdotes and political rhetoric by congressional leaders, but especially persuasive was the scientific evidence for one program, the Nurse Family Partnership

(NFP), which was a specialized program limited to low-income, first-time mothers who agreed during the second trimester of pregnancy to participate in a 30-month series of home visits (Olds, Henderson, Tatelbaum, & Chamberlin, 1986). Infants randomly assigned to NFP were less likely than controls to be maltreated and less likely to become juvenile delinquents years later (Olds et al., 1998). Economic analyses indicate that every dollar invested in NFP yields \$2.37 in savings down the road. This argument has been played out by Heckman et al. (2010) who describe the compounding benefits of investments of this sort in early life. President Obama responded by proposing legislation to provide funding for the NFP program because of its strong evidence.

Social scientists immediately weighed in on the debate. They agreed with the empirical support for the NFP and the lack of support for programs that had been found through rigorous trials to be ineffective. But they also noted that at least 10 other programs had rigorous evidence supporting their efficacy, and the proposed legislation did not address the real needs of numerous other groups of families with newborns (such as middle-income families with low-birth-weight infants and low-income families having a second birth), nor did it allow for emergence of other programs that might eventually prove to be equally or even more effective than the NFP. President Obama revised his legislative plan in response to this debate with an \$8.8 billion three-tier proposal. The first tier provided financial support for programs that had passed muster through randomized trials. The second tier provided support for programs that had strong evidence from evaluations that had modest shortcomings. The third tier supported innovative programs that were promising but had limited evidence of effectiveness. After compromise, \$1.5 billion was authorized through 2014 to award three tiers of funding for home visiting programs. Seventy five% of the funds are spent on projects using one of 11 model home visiting programs determined by HHS to have evidence from top-tier evaluations that they produce positive impacts on one or more measures of parenting or child outcomes.

The precedent set by this legislation is enormous, in several respects. First, it indicates that the federal government will sometimes place scientific evidence at "the center of decision making" (according to Office of Management and Budget Director Peter Orszag, cited in Haskins et al., 2009) to determine the merit and funding of one program or policy over another. Thus, scientists and evidence have a place at the decision-making table. Second, it pushes the joint

scientific and policy communities to establish standards for determining whether a program has an evidence base. For example, evaluations based on a randomized controlled trial have greater value than others, and replications across multiple trials are valued more than one trial; but questions remain about determining generalizability of programs to new populations and ways of calculating benefits. Third, it endorses the government's role in providing venture capital to spawn new programs to meet the needs of different populations, and, fourth, it requires that the standards of evidence be applied rigorously to programs as a way to determine future funding. The home-visiting program joins several others promoted by the Obama administration that are models for evidence-based social policy making (Haskins & Baron, 2011).

The Coalition for Evidence-Based Policy in Washington, D.C., headed by Jon Baron, has endorsed the home-visiting evidence-based approach and has succeeded in getting Congress to make numerous other funding decisions based on an objective analysis of the scientific evidence of a program or policy's effectiveness. The Washington State Institute for Public Policy has taken this movement a step further by evaluating not only a program's impact but its cost effectiveness and cost-benefit ratio as well.

The next decade of policy making for children will be improved if it continues these evidence-based and cost-benefit approaches by implementing several elements. First, the basic science infrastructure that spawns the empirical and theoretical basis for children's programs should be preserved and enhanced. Second, the infrastructure for high-quality program evaluation by federal agencies should be expanded, including the administrative data files that enable the follow-up of children over time. Third, the entrepreneurial spirit of innovation should be rewarded through grants and support for innovative programs backed by promising research. Fourth, government at the state and federal level must be willing to engage in randomized trials of programs that show promise but are not yet fully evaluated, in the spirit of Campbell's experimenting society (Campbell, 1998). Fifth, the president and Congress should commit to following the empirical evidence, wherever it leads—including reform or termination of programs that do not work.

Following these principles will lead to more effective outcomes for children and can help in allocating scarce resources to expand successful programs for children and families. These principles are by no means a panacea, but they do represent a strong step toward the integration of

the scientific community into government decision making for children and families.

## CONCLUSION

Government's role in the lives of American children has grown exponentially over the past century, whether measured by the breadth of influence, number of programs for children, or taxpayer dollars spent on children. Although this growth has coincided with measureable improvement in children's well-being, the judgment of whether this reach is positive or negative has depended in large part on political philosophy. Likewise, policy-setting for children has been based largely on politics. We propose a transformation in the evaluation of government effectiveness toward an empirical analysis of evidence using standard rules of science, and in policy-making toward evidence-based practice. With support from scholars and advocacy organizations, President Obama has made the use of evidence a basis for policy decision making in domains such as infant home visiting, teen pregnancy prevention, education, employment and training, and community-based services for young people. Randomized controlled trials are the gold standard in program evaluation and should be used whenever possible as part of the policy-making process. We envision a golden era of scientific contribution to policy for children and families. The result will be continuing improvement in the effectiveness of policies and programs for children and families. Developmental scientists should play a central role in this process.

## INTRODUCTION

Children always have been exposed to the devastation wrought by human warfare and natural disasters, yet the systematic study of mass-trauma experiences emerged surprisingly late in the history of developmental science. World War II spurred concerns about the effects of war on children as many communities and nations responded to millions of children threatened by bombing of civilian populations, starvation, displacement, persecution, death camps, and the effects of widespread destruction and death on family life. Clinicians and researchers began to examine and describe the effects of war on children. After World

War II, research on adversity and mental health surged and a sequence of highly publicized disasters underscored concerns about the effects of mass-trauma events on child development.

Initially, reports on children in war and disaster were sparse. In the first *Manual of Child Psychology*, published shortly after World War II, war was mentioned only briefly. In his chapter titled “Emotional Development,” Jersild (1946) commented: “Findings with respect to the responses of children at various levels of maturity to acute dangers such as prevail during air raids are as yet too meager for anything but tentative generalizations” (p. 764). In the ensuing decades, research on children in war and disaster expanded and reviews emerged in influential compendiums of child psychology and psychiatry (e.g., Garnezy & Rutter, 1985). The 2006 edition of this *Handbook* included a chapter on “Children and War Trauma” (Klingman, 2006).

Since the turn of the 21st century and the World Trade Center terrorist attack on 9/11 in 2001, children and

---

This chapter is dedicated to all of the participants, investigators, and funders around the world who have made it possible to study risk and resilience in young people experiencing war and disaster. We especially want to pay tribute to the families and young people who shared their stories so that others could learn better ways to prepare for such devastating experiences and promote resilience.

families around the world have experienced terrifying mass-trauma events, including the complex trauma and upheaval wrought by destructive storms, earthquakes, terrorist attacks, war, and intense political violence. The numbers of children affected directly and indirectly by such catastrophes are staggering. The United Nations (UN) estimates that over 25 million children live in “conflict-affected poor countries” (UN, 2012) and in 2011, UNICEF (2011) estimated that disasters affect up to 175 million children every year. Recent estimates of children displaced by violent conflicts and disaster are approximately 16 to 18 million; one third of the children are international refugees or asylum-seekers and two thirds are internally displaced (Drury & Williams, 2012; Reed, Fazel, Jones, Panter-Brick, & Stein, 2012; UN High Commissioner for Refugees [UNHCR], 2010). In 2011, about 34% of 895,000 international asylum-seekers were children and 17,700 of these children were unaccompanied or separated from their caregivers (UNHCR, 2012a, 2012b). Children separated from their caregivers during conflict also can be vulnerable to forced enlistment as child soldiers. In 2012, UNICEF estimated there were 300,000 child soldiers.

This chapter is focused primarily on research of the 21st century, although we summarize key findings from 20th-century research. The chapter focuses on studies of children under 18 and their families, although we also include key studies of young people in the transition years between adolescence and adulthood (late teens to late 20s). We highlight developmental research on children experiencing the mass-trauma experiences of war, violent political conflict, terrorism, major technological accidents, and natural disasters.

Our overall conceptual framework reflects a risk-and-resilience approach, the prevailing perspective in this literature (Masten & Narayan, 2012). This approach is grounded in relational developmental systems theory (e.g., Overton, 2013; see Overton & Molenaar, Chapter 1, this *Handbook*, Volume 1) and contemporary developmental psychopathology (e.g., Cicchetti, 2013a). Human adaptation and development are presumed to arise from countless interactions across many levels of function, within the organism and between the organism and environment, from the molecular level to the level of culture, media, and the wider ecology of life. Mass-trauma experiences require consideration of many systems beyond the individual child, family, peer group, and school because these experiences often are defined by their extensive scope and breakdown across multiple systems simultaneously (Masten & Obradović, 2008). Consequently, these situations emphasize the profound

interdependence of human adaptation and development on the function of many other systems. Furthermore, the risks and the protections involved in mass-trauma experiences depend on the complex roles of large scale systems, such as national emergency response systems, weather patterns, and government systems, and the functions of proximal social microsystems in the child’s immediate life, such as family, peers, and school. The specific implications of these broad, conceptual perspectives are delineated further in the theoretical section of this chapter.

This chapter is divided into five sections. In the introduction, we highlight historically important research and describe the challenges of research on children in extreme situations of mass trauma. The following section describes major theoretical perspectives that inform and drive this literature. Then we selectively review empirical findings on mass-trauma experiences in two sections, one focused on violent political conflicts, including war, terrorism, and prolonged political conflicts, and the second focused on natural and ecologically extensive disasters, including technological accidents. These sections include promising research on assessment and intervention. In the final section of the chapter, we draw conclusions about the overall state of the evidence, gaps and limitations in the literature, and implications for future research, practice, and policy. The chapter closes with a call to action for developmental scientists to participate in global preparedness for mass trauma and recovery.

## Historical Perspectives

Before World War II ended, Anna Freud and Dorothy Burlingham (1943) published a volume titled *War and Children* that was based on their clinical observations and case studies. In what has become one of the most replicated conclusions about children in war and disaster, they noted that “traumatic shock” was rarely observed in children when they were in the care of mothers or mother surrogates. In contrast, trauma reactions often were observed when children were lost or separated from parent figures during wartime, for example during the Blitz (Garmezy, 1983; Garmezy & Rutter, 1985). Over a million children were evacuated from cities and towns in Great Britain to safer locations in a monumental effort to protect children from life-threatening bomb attacks (Foster, Davies, & Steele, 2003; Welshman, 2010). However, many children apparently showed such severe adverse reactions to the separations that they were returned to bombing zones to be reunited with their families. Some of the evacuated children

also may have been exposed to violence, maltreatment, and/or sexual abuse (see Welshman, 2010; Yule, 1994).

Anna Freud and other clinicians also were involved in interventions to help orphaned children from liberated concentration camps. Detailed observations of children from the Terezin camp were published by Freud and Dann (1951). They described dramatic improvements in the children over time, but also notable signs of lingering effects, termed “sensitization” or psychological “scarring.” This mixed picture of recovery after experiences of prolonged, severe trauma or deprivation continues to be noted in more recent studies of rescued child soldiers and children adopted from institutions providing extremely poor care, described further below.

During the last three decades of the 20th century, a series of disasters captured international attention. One of the most influential and well-documented disasters occurred in 1972 when a coal slurry impoundment dam above the mining community of Buffalo Creek in West Virginia gave way and flooded the hollow below, killing 125 people and injuring many others (Erikson, 1976; Gleser, Green, & Winget, 1981; Green et al., 1991). Documenting effects of this disaster over time on children and adults in the community was part of a litigation process, which raised concerns about bias in the findings. However, many of the critical observations from Buffalo Creek have been widely replicated, including their observations of symptom variations related to age, sex, and exposure severity. Moreover, there was an unprecedented 17-year follow-up study (Green et al., 1994; Korol, Kramer, Grace, & Green, 2002) indicating that dose effects had largely dissipated, although survivors still showed higher current and lifetime rates of posttraumatic stress disorder (PTSD; 7% current; 32% lifetime) than a comparison sample (4% current; 6% lifetime). After such a devastating tragedy that essentially destroyed the community, higher than normative rates of PTSD, especially for lifetime diagnosis, might be expected; however, it was notable that resilience and recovery was observed in the majority of the exposed individuals.

Another large scale disaster with extraordinary documentation of short- and long-term consequences is the 1983 Australian bushfire. Initially, McFarlane (1987) compared symptoms in over 800 fire-exposed children in primary schools in the fire zone with a group of 725 children recruited in 1985 from a neighboring region not directly affected by the fire. Although child symptoms were related to dose of exposure as would be expected, child symptoms were more strongly predicted by maternal separation or maternal symptoms than direct exposure.

After 20 years (McFarlane & Van Hooff, 2009), some dose effects remained but they were small in magnitude.

Children were also studied following two 20th-century commercial nuclear accidents at Three Mile Island and Chernobyl. In 1986, in the worst of these accidents, the Chernobyl nuclear plant exploded, spreading radioactive dust over an extensive area (Wroble & Baum, 2002). Initially concealed by authorities, subsequent data indicated that the radiation was 200 times greater than the radiation released by bombs at Hiroshima and Nagasaki combined. Families in the area were evacuated, relocated numerous times, and forced to live with uncertainty about the extent of the exposure, which contributed to chronic and often severe stress. It has been difficult to document effects of this disaster for many reasons, but there are reports of both psychological and physical consequences in exposed children (Bromet & Havenaar, 2007; Fushiki, 2013).

One of the clear effects on children documented after Chernobyl, consistent with studies after Hiroshima and Nagasaki, was differential timing effects of radiation exposure on health and development (Fushiki, 2013). The Chernobyl accident spread radiation in the form of radioactive iodine, resulting in high doses of radiation accumulation in the thyroids of born and unborn children. Higher rates of thyroid cancer were reported as the children grew up. One of the ways that the radiation pervaded families was through drinking milk from radiation-affected cows. Evidence indicates that fetal exposures have the greatest effect during organogenesis and early fetal development; the fetus is particularly sensitive to radiation exposure in the 8- to 25-week gestation period. Dose effects are related to timing and degree of exposure.

Chernobyl also generated a massive fear vector in neighboring countries due to uncertainties about the spread of radiation. Years later, a national study of twins in Finland was able to utilize the known timing of the Chernobyl accident to carry out a natural experiment comparing adolescent development in twins who were in gestation in 1986 during Chernobyl with twins born a year later (Huizink et al., 2008). Findings suggested lingering biological effects related to prenatal stress exposure, not attributable to radiation, and consistent with programming effects on the fetus. For example, levels of salivary cortisol, a hormone involved in stress-regulation, were significantly higher among adolescent offspring of mothers pregnant during Chernobyl. These timing effects also suggested greater vulnerability beginning in the second trimester.

The Three Mile Island and Chernobyl nuclear accidents and the poorly managed geopolitical response raised global

concerns about the perceived safety of nuclear energy and the credibility of government reports on meltdowns. Nuclear accidents can induce intense fears about invisible dangers carried through the atmosphere or groundwater, such as radiation poisoning, birth defects or delayed cancers. Additional problems include chronic stress engendered by the evacuation context and uncertainty about the accuracy of government information. These issues would surface again when the Japanese nuclear plant at Fukushima Daiichi failed following the earthquake and tsunami that struck Japan in March of 2011.

Other important studies were conducted following five disasters clustered between 1987 and 1992. The *Herald of Free Enterprise* ferry sank in 1987 with 459 passengers and 80 crew on board (193 died, including seven children), and the *Jupiter* cruise ship sank in 1988 after it was struck by a container ship, with a group of 400 British adolescents on board for a school trip (one student and one teacher died). In a series of publications in the 1990s, Yule and colleagues documented the level of posttraumatic stress symptoms and disorder in children and teenagers, ascertained by direct clinical interviews and questionnaires with survivors (Yule, Udwin, & Bolton, 2002). Yule and colleagues were among the first investigators to document systematically the extent of trauma reported by children and adolescents. To this day, investigators and clinicians report that adults often underestimate trauma symptoms and stress in children and adolescents compared to what youth report for themselves (Masten & Narayan, 2012).

Yule and colleagues also compared survivors with students from the same school who were either unable to go on the trip although they wanted to go or who had never wanted to go. They reported a dose-response gradient of highest symptoms for survivors, followed by the “near miss” group, followed by the students who never wanted to go but were in the same school, with the lowest symptom levels found in a control school uninvolved in the trip (Yule et al., 2002).

On December 7, 1988, a severe earthquake struck northern Armenia, killing over 25,000. The timing and location of the earthquake resulted in many deaths and injuries to children who were in school at the time. Many schools were destroyed in the city of Spitak, located near the epicenter, and in some schools more than one-half the children were killed. One and a half years after the earthquake, Pynoos et al. (1993) compared symptoms and rates of PTSD among 231 children (Ages 8 to 16) located in three different cities at various distances from the epicenter. This was one of the earliest natural disaster studies to both employ a child self-report measure of posttraumatic stress and diagnose

child PTSD based on a clinical interview that applied new criteria for PTSD adopted by the American Psychiatric Association (1987). Child reports of trauma symptoms were strongly related to a PTSD diagnosis. Rates of PTSD also were over 90% in high-exposure locations.

Another study by the same team (Goenjian et al., 1997) examined the effects of an intervention on a sample of young adolescents exposed to the earthquake, with pre- and postintervention assessments. A 5-year follow-up indicated sustained treatment effects compared with untreated adolescents. Although this intervention did not utilize the gold standard, a randomized controlled trial (RCT), it was an influential demonstration that intervention research was feasible in schools after major disasters.

Hurricane Hugo, which struck South Carolina in 1989, and Hurricane Andrew, which struck South Florida in 1992, are historically important in providing early evidence that severe storms lead to symptoms of PTSD in a substantial proportion of children (e.g., La Greca, Silverman, Vernberg, & Prinstein, 1996; Lonigan, Shannon, Finch, Daugherty, & Taylor, 1991; Shannon, Lonigan, Finch, & Taylor, 1994; Vernberg, La Greca, Silverman, & Prinstein, 1996). These studies found moderate symptoms of PTSD in approximately 30%–50% of youth (full diagnostic criteria were met for 5%–10%). “Reexperiencing” symptoms (e.g., intrusive thoughts or dreams about the disaster) were the most common and “avoidance” or “numbing” symptoms were the least common symptoms reported. PTSD symptoms declined over the first year for the majority of children but persisted for about one third (e.g., Shaw et al., 1995; Swenson et al., 1996). La Greca, Silverman, and Wasserstein (1998) provided rare evidence that predisaster characteristics, particularly high anxiety, predisposed children to more severe disaster reactions over time. This finding was later replicated in children exposed to Hurricane Katrina (Weems et al., 2007).

### Conclusions From Early Reviews

Numerous other prominent incidents were studied by the end of the 20th century, including the Oklahoma City bombing. Soon the growing literature produced a series of influential reviews by some of the most prominent scientists and clinicians of the time (e.g., Eth & Pynoos, 1985; Garnezy & Rutter, 1985; Jensen & Shaw, 1993; La Greca, Silverman, Vernberg, & Roberts, 2002; Norris et al., 2002; Norris, Friedman, & Watson, 2002). These reviews reached conclusions that the next generation of studies would corroborate, including the following: (a) Dose of exposure was related to perceived stress, PTSD, and other aspects of

adjustment; (b) older children often had greater exposure and more trauma symptoms; (c) more anxiety and depression symptoms were found among girls (particularly adolescents), while more aggression or disruptive behavior was observed in boys; (d) child responses were related to cumulative risks and protections; (e) loss of effective parenting posed considerable risk; (f) severe and prolonged trauma had worse and more lasting effects; and (g) trauma symptoms decreased over time, with recovery and resilience common over the long term. Although these reviews noted the paucity of intervention research, there also were hints that advance preparation and stress-inoculation strategies had value in contexts where repeated exposure to the same experience was likely (e.g., areas prone to hurricanes or conflict). Finally, numerous observers suggested that children responded well after disaster to efforts for normalization, such as resuming family routines and school.

### The Challenges of Research on War and Disaster

Over time, reviewers have recognized the challenges facing investigators in the context of massive trauma experiences, both in the midst of an unfolding catastrophe and during recovery (e.g., Bonanno, Brewin, Kaniasty, & La Greca, 2010; Masten & Narayan, 2012). There are profound issues and dilemmas involved in ethical conduct of research during times of great pain, loss and suffering, and under field conditions that may be fraught with chaos and ongoing danger for both the potential participants and researchers. Careful consideration must be given to the possibilities of harming already traumatized parents and children and traumatizing the researchers through secondary exposure. Traumatized parents also may be understandably protective of their children and reluctant to trust unfamiliar researchers.

Furthermore, there often are issues of informed consent when research is conducted in cultures or communities who are unfamiliar with research protocols and risks. Methodological and ethical concerns also arise from applying measures and theories developed in different cultures or contexts and thus may have unknown psychometrics relating to reliability, validity, and measurement equivalence. In intervention science, where an RCT is the optimal design for causal inference, there may be practical and/or ethical issues that render systematic measurement and random assignment to treatment conditions, and particularly to comparison control conditions, untenable (Masten & Narayan, 2012).

In addition, disaster and warfare frequently destroy or damage infrastructure systems for research, such as communication, safety, food supplies, medical systems, computer systems, and postal services. Oftentimes, the most impoverished areas, already lacking resources, are affected the most by disasters due to geographical vulnerabilities (Narayan & Masten, 2012).

Also, rarely do data exist on preconflict or predisaster functioning of the children or families such as the type reported by La Greca et al. (1998) and Weems et al. (2007). Without baseline data, it is difficult to know whether observations of individuals represent either preexisting behaviors or effects of exposure. Comparison groups with less exposure to the mass trauma event can be studied, although this strategy may not solve the causal inference problem. Additionally, exposure dose in war and disaster often is nonrandom, which complicates recruitment of suitable, “matched” comparison groups.

Longitudinal studies that follow war or disaster survivors, whether focused on the natural recovery course or intervention effects, are difficult to implement and remain rare, although their numbers are increasing (Masten & Narayan, 2012). The scope of these events can generate long-lasting chaos and communication problems that hinders following participants over time. The displacement, which commonly follows disasters, may compound the challenges of conducting longitudinal work (Fazel, Reed, Panter-Brick, & Stein, 2012; Reed et al., 2012). Nonetheless, it has been possible in more economically advantaged countries to track postdisaster effects by following samples of affected children for longitudinal data of traumatic events, such as 9/11 (e.g., Silver, 2011).

Finally, because it is not possible to predict situations of mass trauma events, funding may be difficult to obtain in a timely fashion. There also may be limited resources for research in remote locations, and funders may be skeptical about the ethics or feasibility of the research.

Despite all these challenges, there has been progress (e.g., Barber & Schluterman, 2009; Betancourt, Borisova, et al., 2013; Masten & Narayan, 2012). Many findings are consistent, and the quality of the literature has improved in notable ways highlighted in this chapter.

### THEORETICAL PERSPECTIVES

The study of children in mass-trauma experiences is focused on both typical patterns of response and recovery and individual differences. Over the decades, this body

**Figure 18.1** Pathways of response to mass-trauma events commonly described in the literature.

A = stress-resistance; B = disturbance with recovery; C = breakdown without (yet) recovery; and D = posttraumatic growth.

of research has become increasingly developmental in perspective. Moving beyond initial attention to age and sex differences, work in this area now considers developmental timing effects related to exposure and response. There also is concern with sensitive periods, when children may be more vulnerable to exposure and the biological embedding of experiences. Concepts from developmental psychopathology and resilience science have influenced the perspectives of investigators and practitioners who work with children exposed to war or disaster (e.g., Franks, 2011; La Greca & Silverman, 2006; Masten & Narayan, 2012). Research and practice also reflects the assumptions and concept from relational developmental systems theory, which infuses contemporary theories on risk and resilience (see Cicchetti, 2013b; Lerner, 2006; Lickliter, 2013; Masten, 2013; Sameroff, 2010; Zelazo, 2013). In this section we highlight concepts that currently play a central role in theory and research on children in war and disaster.

### Pathways

The effects of disaster or trauma are often portrayed as pathways, marked by an acute or chronic experience of extreme disturbance triggered by the traumatic exposure. These are usually abstract models illustrating different patterns of response and recovery that individuals are believed to follow in the aftermath of major life threats. These paths reflect the overall level of functioning of one

or more individuals, showing patterns of adaptive or maladaptive function over time. Disasters often have an acute onset, although the aftermath may be either short-lived or prolonged, whereas chronic experiences, such as war, often have gradual beginnings and endings. Contemporary scholars differentiate response patterns for relatively acute versus chronic situations of mass trauma (see Bonanno & Diminich, 2013; Masten & Narayan, 2012).

Figure 18.1 illustrates a set of theoretical pathways commonly described in the context of a relatively acute onset mass trauma event (Bonanno, 2004; Kronenberg et al., 2010; Masten & Narayan, 2012). Four patterns are illustrated: (1) *stress-resistance*, when the person continues to function well (in the adaptive zone) following an acute threat; (2) *disturbance with recovery*, when adaptive function is disturbed for some period and then returns to normal levels; (3) *breakdown without recovery*, when the individual is affected and has not recovered (at least not yet); and (4) *posttraumatic growth*, when adaptive function improves in response to the threat. Breakdown can occur immediately after exposure or after some time delay, as the stress load increases (from prolonged adversity) or the adaptive capacity of the person is depleted.

There is some debate about how to label some of these patterns. For example, in the case of pattern B, there is disagreement about whether to distinguish *resilience* from *recovery*, either by the level of disturbed function shown or the length of time when adaptation is disturbed

(see Bonanno & Diminich, 2013; Masten & Narayan, 2012). Bonanno (2004) argued that only short-term, mild disturbances in function should be described as *resilience*, and deeper disturbances or more prolonged disturbances in function should be described in terms of recovery. Bonanno and Diminich (2013) refined this perspective to distinguish responses in the context of chronic and prolonged exposures from those following acute and isolated exposures, introducing the terms *emergent resilience* and *minimal-impact resilience*, respectively, to differentiate resilience in these situations. Masten and colleagues (Masten & Obradović, 2008; Masten & Narayan, 2012) describe all patterns of maintaining or returning to normal or better levels of function following catastrophic levels of exposure to acute or chronic adversity as variations in a spectrum of resilience pathways, while recognizing that there are distinct differences related to acute and chronic exposure, timing, and trajectory of impairment or recovery. Terminology aside, there is strong agreement that common patterns of function (defined by symptoms or adaptive behavior) vary during acute or chronic exposures to severe adversities and their aftermath and that these patterns hold important clues to understanding outcomes and informing interventions for children or adults.

### Multiple Interdependent Systems and Levels of Analysis

Contemporary thinking about children in war and disaster also has been profoundly influenced by Urie Bronfenbrenner's ecological systems model (Bronfenbrenner, 1979; Bronfenbrenner & Morris, 2006), as well as relational developmental systems theory. In large-scale disasters, interacting systems across biological to macrosystem levels are usually disrupted, often simultaneously. As noted above, mass trauma experiences inherently underscore how dependent individual and family systems are on the many other systems in which their lives are embedded. These other systems may include basic utilities and water purification systems, emergency systems, economic systems, communications systems, transportation systems, school systems, food distribution systems, medical systems, and many other systems by which communities and governments function and also respond to emergencies. Disasters and war also highlight the role of culture, media and, increasingly, social media in both trauma exposure and human adaptation. Human life and development reflect the interaction of systems across many levels of analysis, from the molecular to the global level.

Increasingly, scientists conducting research and consulting on interventions for large scale disturbances have considered multiple levels of analysis and the importance of engaging multiple disciplines in efforts to understand, prepare and act in contexts of large scale threats (e.g., Gunderson, 2010; Masten & Obradović, 2008). In human research, there is growing interest in the processes by which trauma “gets under the skin” to influence current functioning and long-term development (Cicchetti, 2010; Gunnar & Herrera, 2013; McEwen, 2012; Pluess & Belsky, 2011; Pratchett & Yehuda, 2011). Attention to media effects is growing, especially as personalized media access and social media expand worldwide. Moreover, nations and international agencies are beginning to recognize that adequate preparation and response to large-scale humanitarian crises, whether they result from war, pandemic, industrial or natural disasters, requires expertise and coordinated action at many levels (Masten, 2011).

### Risk and Resilience Models

As noted, the literature on children in war and disaster is typically conceptualized within a risk and resilience framework. This framework emphasizes risk and promotive effects, cumulative risk and dose gradients, mediators of these influences, and vulnerability or protective influences that moderate the impact of adversity on adjustment or development. These models call attention to positive responses and adaptation in the wake of disaster and complex trauma, but they also acknowledge the impact of severe trauma exposure on children.

### Dose-Response Gradients

In the research on risk in development, investigators soon realized that risk factors tend to co-occur and that the association of cumulative risk exposure with negative outcomes tend to follow a rising gradient (Evans, Li, & Whipple, 2013; Obradović, Shaffer, & Masten, 2012). In the literature on trauma, disaster, and war, these findings and the graphs depicting the relation of rising risk to rising stress symptoms, frequency of posttraumatic stress disorder, and other problems are typically described as dose-response gradients.

Cumulative risk has been measured in various ways in the dose-response literature. These methods include life event questionnaires and interviews tailored to particular situations that assess whether particular experiences have happened and then tally them in some way. Items usually address multiple domains of potential traumatic events or

disruptions, such as exposure to violence, deprivation, loss of social support, relocation, or extent of social loss. In some situations, the proximity of the child or the caregiver to the “epicenter,” “ground zero” or path of destruction, literally or psychologically, has served as a severity index (Comer & Kendall, 2007; Goenjian et al., 2005). In cases of tornadoes, floods, earthquakes or terror attacks, literal proximity to areas of greatest destruction serves as a good index of exposure severity, with a falling gradient of exposure as the physical distance increases from the center of destruction.

In the case of other disasters and war without a single epicenter or path of destruction, exposure may be better indexed by a tally of exposure to specific traumatic experiences, such as witnessing death or torture, loss of loved ones, or rape (American Psychological Association [APA], 2010; Harder, Mutiso, Khasakhala, Burke, & Ndeti, 2012). Psychological distance also has been indexed in dose measures, because perceived threat or emotional proximity to the victims may have equal or more importance than actual threat or physical proximity for psychological impact (Dimitry, 2012; Hoven et al., 2005). In sum, multiple parameters of severity may be important to consider when gauging the “dose” of exposure for different individuals to events such as 9/11. These could include assessments of physical location during the event, extent of injury, perceived danger, relationship to victims and number of known victims affected, intensity of witnessed death and destruction, or the duration of these exposures during or after the event.

Investigators also have studied cumulative risk with respect to experiences that precede and/or follow an acute or chronic trauma experience. Research indicates that prior exposure to traumatic events, sometimes combined with additional adversities in the aftermath or recovery period, is related to worse outcomes. The combined effects are viewed as a higher dose of exposure or in terms of sensitizing effects. For example, the tsunami experience in Sri Lanka showed worse effects overall for children already living in a war zone than for children living in better pre-tsunami conditions (Catani et al., 2010). Prior childhood experiences of physical abuse had a sensitizing effect during the Second Lebanon War in Israel, such that abused adolescents had higher rates of PTSD (Schiff et al., 2012). For youth recovering after war or displacement, recovery does not go as well for those who experience ongoing or new abuse, community rejection, or other stressors during reintegration or in refugee camps (Reed et al., 2012).

Both linear and nonlinear dose effects have been observed (Klingman, 2006; Masten & Narayan, 2012). Studies of dose gradients usually test for linear effects, but curvilinear patterns relating exposure to adaptive function have been observed. Nonlinear effects could be exponential, with an accelerating increase in symptoms as risk level rises or a pattern of minimal observable effects at low exposure followed by a rapid increase at some threshold of severity (Masten & Narayan, 2012). Another kind of nonlinear pattern would be asymptotic effects, where effects of additional trauma exposure level off. This could occur when there is a threshold beyond which trauma exposure is so high that further exposure does not increase symptoms, a pattern observed in child soldiers (e.g., Klasen et al., 2010). Finally, exposure to extreme adversity may reverse the nature of responses. In a study of Palestinian children in Gaza, Qouta, Punamäki, and El Sarraj (2008) found a typical dose-response gradient from low to moderate levels of exposure, with adaptive behavior declining as dose of exposure increased; however, at extremely high exposure, functioning improved. The authors speculated that extreme political violence can inspire greater engagement or heroism, essentially motivating a growth response.

### *Unpacking Risk*

Measures of cumulative risk and corresponding dose gradients typically aggregate experiences into a single index. There are several major reasons for aggregation: (a) Measures of cumulative risk often have stronger associations with outcomes than any particular single risk factor; (b) the particular mix of risk factors often does not seem to matter as much as the overall number of factors; (c) risk factors commonly co-occur; and (d) this strategy serves the goal of data reduction (see Evans et al., 2013; Obradović et al., 2012). For certain research questions, however, “unpacking” these risk indices may make more sense (e.g., aggregated scores may obscure specific processes and interaction effects). Currently, there is growing interest in unpacking dose for situations of extreme or mass trauma to learn whether there are particularly toxic experiences that have more severe or lasting effects (Layne et al., 2010).

### *Determinants of Exposure*

Exposure is rarely completely random, and it often is related to development; both age and sex affect the odds for exposure to particular experiences during situations of extreme adversity. Age effects may occur because young children understand less of what is happening, because they are actively shielded from exposure by adults, or because
